General Diagnosis.—The diagnosis of the cause of headache depends entirely upon the patient's history and the presence or absence of certain associated symptoms. This will be readily appreciated after a review of the conditions in which headache occurs, either as a concomitant or as a pathognomonic symptom. The general health of the patient must always be carefully investigated, particularly with regard to the function of the digestive tract and the action of the kidneys. While the seat of the pain is often suggestive, too much stress must not be placed on this indication, for in all forms of headache the pain may vary in its location from time to time. In supraorbital and occipital neuralgia, the pain is more or less paroxysmal and superficial in character, being usually confined to the anatomical distribution of the nerve, and is therefore not a true cephalalgia. Continuous headache lasting many days, with nocturnal exacerbations, should always lead to the suspicion of cerebral syphilis. It is always necessary to decide whether the headache is due to a functional disturbance, or is the result of organic intracranial disease. A safe rule to follow in all cases of persistent headache is to ascertain if any signs of cerebral disease are present, such as muscular spasm; paresis or paralysis affecting the face, extremities, or cranial nerves. A constant general headache which is accompanied by optic neuritis and frequent attacks of vomiting invariably points to intracranial disease. The examination of the pupils should never be omitted. In hyperæmic forms of headache the pupils are usually contracted, while in anæmia they are found dilated. When the pupils fail to react to light, or are absolutely rigid, the vision being unaffected, it is highly suggestive of cerebral syphilis or some other form of cerebral degeneration. The ophthalmoscope often proves extremely valuable in diagnosis. Although abnormities of the cerebral circulation may exist without evidence of such disturbance in the retina, the discovery of "choked disc" or optic neuritis, or a high degree of hypermetropia or myopia, will often be the means of determining the cause of the headache. The most important use of the ophthalmoscope in cases of headache is to determine the presence or absence of optic neuritis. While its absence does not exclude organic disease, its presence is presumptive evidence of some form of intracranial disease (basal meningitis, increased brain pressure from cerebral tumor, or the vascular degeneration associated with renal disease).

Treatment.—A careful investigation of the entire organism is essential in every case, the most important element in the treatment of patients with headache being the recognition of the cause, as the pain is oftener dependent upon some underlying constitutional condition than upon organic intracranial disease. The discovery and correct interpretation of such facts should be the principal guide in the adoption of therapeutic measures. In the toxæmic form of headache, as well as in all other forms, it is absolutely necessary that the intestine be kept free from fæcal accumulation, and that the action of the digestive organs be regulated by suitable diet. Headache from constipation is rapidly relieved by a brisk cathartic. All supposedly reflex causes should be rectified, but too much stress must not be laid upon the paramount importance of such disorders, for many patients seem to possess an inherited or inherent predisposition to develop headache upon the slightest provocation. It is generally desirable and universally advocated that any existing error of refraction or eye-muscle defect be corrected. Even when such conditions are discovered and remedied, relief from the headache does not always follow, for several causes may be operative in the same individual. Therefore, before saddling a patient with spectacles for slight refractive errors, or cutting the eye muscles, or operating upon the nose for deviated septum, or replacing a slightly displaced uterus, or suturing a trifling laceration of the cervix, etc., all other probable causes of the headache should be systematically eliminated. Headache due to cerebral congestion may be relieved by the avoidance of all forms of cerebral stimulants and psychical excitement, regulation of the diet, free purgation by calomel and salines, and the administration of bromide of potassium gr. xv., and fluid extract of ergot ♏ xv., every three or four hours. Severe cases require cupping or blistering over the nucha, and local blood-letting or venesection. It would appear from the experiments of Leonard Hill and others upon dogs that the application of ice-bags to the head as a form of treatment has practically no effect upon the cerebral circulation. Hence the time-honored custom of using the ice-coil and ice-bag in cases of meningitis or cerebral congestion is without any scientific evidence as to its action. Its clinical value, however, is still an open question. When the ice-cap is used, it should always be applied to the shaven scalp. In headache from cerebral anæmia, rest in bed with the head low, and special attention to the cause (which is usually general anæmia) are of prime importance. The administration of cardiac tonics, and the use of iron and easily assimilated food, generally prove successful when organic visceral disease is absent. In every form of headache we are often forced to resort to the temporary use of local applications of dry or moist cold or heat, or some form of anodyne or counter-irritant. Antipyrin, acetanilid, phenacetin, caffeine with bromide of potassium, etc., or diffusible stimulants such as aromatic spirits of ammonia, tincture of valerianate of ammonia, etc., often prove serviceable as symptomatic remedies, but their selection must be left to the judgment of the physician. When headache accompanies the infectious or malarial fevers, the reduction of the temperature by hydriatric or other appropriate measures, or the use of quinine, usually proves efficacious. In headache due to cerebral tumor, free catharsis from time to time, the avoidance of cerebral stimulation or of causes known to produce interference with the intracranial circulation, the administration of the drugs above mentioned, or morphine if necessary, constitute the essential features in the medical treatment. The operation of trephining the skull should be resorted to if other methods fail to relieve the pain. This is often followed by decrease in the intracranial pressure and cessation of the headache. When the tumor is accessible to surgical measures, it should be removed as soon as its location is established. It is customary, before operating, to institute a thorough course of antisyphilitic treatment in order to give the patient the benefit of any doubt as to the possible gummatous character of the growth. The subsidence of headache and other general symptoms of cerebral tumor during the administration of mercury and iodide of potassium does not necessarily imply that the neoplasm is syphilitic, for the irritative symptoms of sarcomatous and other processes have been known to undergo retrogression under this plan of treatment. Headache due to syphilis (gumma, meningitis, periostitis) is rapidly relieved by mercury and iodide of potassium. In cerebral abscess, correct localization and immediate surgical operation constitute our only hope.

William M. Leszynsky.

HEAD, WOUNDS OF.*—Certain features in the anatomy of the skull are of great surgical importance when considering the nature and occurrence of wounds of its component bony parts and of injury to the brain. The periosteum of the cranium—called usually the pericranium—is not thick, but is strong and resistant. Except over the sutures and the great foramina, it can be easily stripped off, or even made to glide over the bone; though in the aged its connection with the underlying bone is more firm. It is nourished principally by vessels from the bone. The internal periosteum of the cavity of the cranium is the dura mater, which is thicker and tougher than the pericranium. Concerning the cranial bones themselves, it should be remembered that the diploë exists only during middle life, and is not to be found in the very young or very old. The amount of space which the frontal sinus may occupy should always be borne in mind.

Of great importance are the connections which the veins of the superficial soft parts enjoy with the deep sinuses and the veins of the diploë through the emissoria Santorini. The most important of these anastomoses are: (1) Among the occipital veins, which connect with the lateral sinus through the mastoid foramen; (2) along and around the interparietal suture, especially its posterior extremity, where numerous openings connect with the superior longitudinal sinus; (3) the ophthalmic veins, according to Sesemann's investigations, empty into the cavernous sinus as well as into the facial veins. It will thus be seen that the sinuses of the brain have their overflow outlets, or "waste weirs," in abundance. Nevertheless, this freedom of venous connection enhances materially the danger from pyæmic or thrombotic trouble in case of erysipelas or phlegmon of the external soft parts.

It will be well, at the very outset, to give here the greatest possible prominence to the classical dictum (so often ascribed to Sir Astley Cooper, but really clearly enunciated by Hippocrates): "*No injury to the head is too slight to be despised, nor too severe to be despaired of.*" There is a great temptation to ignore trivial scalp-wounds, to cleanse them insufficiently, or to dress them carelessly. If nothing else teaches the danger of carelessness in these cases, the experience gathered from the sword-duels of German students should be convincing, since each year several deaths are caused by comparatively trivial scalp- or face-wounds.

SUPERFICIAL WOUNDS.—Bruises and contusions need only slight attention besides rest; evaporating lotions, cold applications, or, if the patient is not seen till after swelling and ecchymosis have taken place, then hot applications constitute all that is required. Upon a superficial abrasion some antiseptic should be used. Any ordinary effusion of blood between scalp and bone will be checked, and then reabsorbed, under this treatment. The hair may be cut short or shaved if required; this should be done if the wound has been in any sense severe. If effusion be very great, and apparently unchecked after prolonged trial with simpler measures, then it would be right to make a free incision, turn out the fluid or solid blood, search for bleeding vessels, twist them or tie them with catgut, cleanse thoroughly, wait till all bleeding has stopped, and then neatly approximate the edges of the incision with fine silk or catgut, with the insertion of a few threads of horse-hair or catgut for drainage, and with a firm compress over all. Of course all this should be done under antiseptic precautions, with clean hands and instruments, etc.

Small punctured wounds need only antiseptic occlusion after their freedom from foreign matter has been secured. Small instruments and weapons sometimes make small punctures, yet wound a vessel of some size. Numerous cases of aneurism of terminal vessels have been reported from such causes. From such a wound hemorrhage would be free, while it would be easy to recognize whether an artery or a vein, or both, had been injured. If a vein, pressure would in most cases suffice; this should be made a part of the antiseptic occlusion, being maintained by an elastic bandage or by some mechanical device.

But if an artery be wounded and such pressure be insufficient, it should be included in a deep suture or occluded by acupressure. This might need to be done on either side of the cut, which should then be cleaned and occluded as before. In other cases it might be well to clip off the hair, shave the part, and enlarge the opening so that the bleeding vessel may be caught and secured.

Extensive lacerations or complicated incised wounds are often received, by which large skin flaps are torn up and the periosteum is stripped rudely off, and yet with only temporary concussion or "stunning."

In such cases the attendant should satisfy himself that the bone has received no such injury as may call for operative interference. He should first check hemorrhage, next shave the parts, and then, with sponge and forceps, address himself to removing every particle of dirt and every loose hair. Shreds of tissue whose vitality is doubtful had best be removed. It then remains only to close the wound. If periosteum have been torn and raised, it is best to readapt the torn edges with fine catgut sutures. Then the superficial wound edges are carefully approximated by silk or catgut sutures, continuous or interrupted. At each angle a stitch may be omitted for the escape of serum, or a few catgut threads may be inserted for capillary drainage.

---

* Use has been made in this article of a portion of that which appeared in the first edition of this work on "Skull, Fractures of the Base of," by Dr. Thomas H. Russell, of New Haven, Conn. The part thus used is enclosed in quotation marks.

In the dressing of such wounds, gentle compression should be so exerted as to compel approximation of raw surfaces. For small wounds collodion makes a very serviceable application, the parts being first thoroughly dried and dusted with an antiseptic powder. When a moist dressing is used about the scalp or hairy face, the writer usually prefers a glycerin dressing: *i.e.*, some antiseptic in glycerin solution or emulsion, since whatever serum exudes from the wound will be readily taken up, and the dressing cannot dry and so stick to the parts that its removal will be very unpleasant to the patient.

For all dressings about the head, the writer esteems naphthalin very highly, since it seems to be particularly prophylactic against erysipelas; the latter being more common after head injuries than after those of any other part of the body. Should there be any special reason to fear inflammation, as meningitis, an ice-bag may be applied outside the dressing.

Cases occasionally occur in which some part, or nearly the whole, of the scalp has been torn off or torn loose, as by machinery or "scalping." If the patient be seen in time an effort should be made to replace the loose portion. Astonishing successes have been reported in injuries of this nature, and the case must indeed be very severe which does not justify a trial. The general rules given above are sufficient to guide the reparative effort; perfect cleansing, proper antisepsis, accurate approximation, and judicious pressure constituting the important canons of treatment. Should the effort partially succeed or fail, if the loss of substance be not too great, a plastic operation may be attempted: otherwise the bare or raw surface must be kept clean, and healthy granulations stimulated by such dry applications as zinc oxide or boric acid, or compresses soaked in a saturated solution of potassium chlorate. The healing process may be further hastened by Thiersch skin-grafting. No case of this kind, which is not speedily and primarily fatal, need be despaired of.

The soft spots about the head and face possess great reparative and recuperative power, and pieces which have been severed may yet unite by adhesion if properly and quickly reapplied. Thus, by bites and by various accidents, portions of the nose and ears may be nearly or quite detached. Unless the circumstances be very unpropitious the attempt should be made to restore them. Careful cleansing and perfect approximation are here, as elsewhere, essential to success.

Ragged lacerations of the lips and cheeks may sometimes be cleaned and sewed up; at other times it will be best to trim or pare their edges, and then neatly close the wound, this procedure causing less scar or disfigurement.

It may happen that we are called upon to deal with parts which have already become inflamed, or, perhaps, erysipelatous. In such case we should proceed as follows: The hair or beard should be closely removed. If the appearance of the part or the general condition of the patient indicates any septic process, the wound should be opened, its interior freely exposed to examination, and a most painstaking disinfection of its entire surface made. Foul spots or suppurating surfaces should be treated with an eight-per-cent. solution of zinc chloride, new openings made for drainage at the most dependent parts, and, according to circumstances, the edges reunited or the whole left open to close by second intention, putrefying and necrotic tissue being removed with knife, scissors, or curette. Abscesses should be laid freely open and their cavities disinfected. If erysipelas have supervened, the whole scalp may be covered with antiseptic poultices, of which the best is made of common brewers' yeast, to be soon followed by the Credé silver ointment, or one containing two per cent. of guaiacol and ten per cent. of ichthyol. Few surgeons would feel justified in making ice applications in such a case unless cerebral complications were extremely severe. It will of course be remembered, in the light of the vascular connection between the scalp and deeper parts (*vide* above), that all cases of erysipelas of the head are at least serious.

With reference to later results of former injuries in the way of granulating or indolent ulcers, caries, necrosis, etc., there are no indications calling for treatment different from that generally resorted to for similar conditions elsewhere about the body. A healthy ulcer may be covered by skin grafts, or by a plastic operation; an unhealthy one should first be made healthy. All dead or dying bone should be removed with curette or chisel, and its surface allowed either to heal by granulation or to be covered by a plastic operation.

The soft parts about the head and face are, if possible, more vascular than in other parts of the body. This means, on the one hand, that life may be lost by neglect or from ignorance. Thus, within a short time, the writer has seen a drunken man so completely exsanguinated by hemorrhage from a superficial scalp wound only 2 cm. long, that it was with the greatest difficulty and care that he was recalled to life. On the other hand, by virtue of this excessive vascularity, reparative processes go on more rapidly; and, provided that proper precautions have been taken, it is the rule for most extensive solutions of continuity to heal *per primam.*

Superficial gunshot wounds should be treated on general principles. It must be remembered that a bullet may not only pursue a most tortuous track, but may carry in foreign matter. Such a wound should either receive primary antiseptic occlusion, without the slightest exploration or disturbance, or its track must be carefully cleansed and drained, being laid open for this purpose if necessary. After it has been interfered with or explored it differs in nowise from other wounds, so far as indications for treatment are concerned. There is seldom any positive indication for removal of a deeply buried bullet, save the anxiety of the patient, and this of course is a minor consideration.

DEEP WOUNDS WITH INJURIES TO THE BONES.—Like all other wounds, these call at first for hæmostasis, then for perfect cleanliness, with removal of the hair in the neighborhood. This completed, exact exploration should be made. Should it appear that underneath a small external lesion extensive damage is concealed, then by free incision the whole must be exposed to touch, if not to sight. According to the extent of these deeper lesions the superficial wound, as thus extended, should or should not be reunited.

It may happen that one or more pieces of the external table, or of the malar or other bones, may be chipped off or entirely separated from their bony basis, and held only by their connections with the periosteum and soft parts. Not forgetting that they may still be nourished by these connections, it is, on the whole, the safest plan to remove them, leaving if possible the periosteum. But should a prominent process of bone be thus detached from its seat, *e.g.*, a part of the supra-orbital ridge or margin of the orbit, or even the mastoid process (and such cases have been reported), it would only be proper to make every effort to save it. Such a fragment is to be held in place by pressure, by stitches in the periosteum, or by drilling and suturing with catgut or silver wire. Pieces of bone that lie quite loose must unhesitatingly be removed, even if dura mater or brain be thereby exposed.

Hemorrhage from a denuded bone surface, and oozing from a deep wound, may commonly be checked by ice-water or hot water and pressure. A solution of antipyrin (five per cent.) makes a most excellent styptic, while suprarenal extract or "adrenalin" furnishes almost an ideal remedy in this regard. Once checked, the bleeding is not likely to recur after the wound is protected from the air and dressed with suitable compression.

Aside from leaden projectiles, a great variety of foreign bodies may not only injure the cranial bones and those of the face, but parts of them may even become embedded or disappear from sight—as, for example, workmen's pointed tools, knife-blades, bayonet, sword or foil points, arrow-heads, hatchet or tomahawk points, pieces of glass, splinters or chips of wood, etc. The deeper they penetrate the greater the gravity of the case; the greater also the possibility of perforation or depression of the inner table of the skull. Thus fatal injury of the brain is not so rare in connection with a wound of the orbit, and the condyle of the inferior maxilla has been forced through into the cavity of the cranium. By means of a wound in the oropharynx, death, with literally no external injury, has been caused. In all these cases the indications for treatment are general, yet explicit. Obviously, removal of a foreign body is called for in almost every case, and this should be accomplished with the least possible disturbance. The only exception would probably be when it has totally disappeared within the brain substance. If simple traction be insufficient to dislodge it, enlargement of the external wound and instrumental aid must be resorted to. Strong forceps, a pointed elevatorium, the chisel and gouge, the trephine, or even the surgical engine may be called for. Thus the writer has had to resect almost the entire upper jaw to get away a piece of wood which had been deeply driven into the skull as it flew off from a circular saw. The more recent the case the better, as a rule, the results. If a pointed object have penetrated the cranium, it should be removed by traction in the direction of its line of entrance, so that further injury to the brain or its coverings may be avoided. In such a case it would, in many cases, be well to trephine at the site of its entrance into the skull, in order to remove any depressed bone, and smoothly to round off the opening; by means of the free opening thus made hemorrhage can be more easily checked. Bullets have occasionally been more easily removed by making a counter-opening. This is more easy now than a few years ago when the telephone probe and the Röntgen rays were not available.

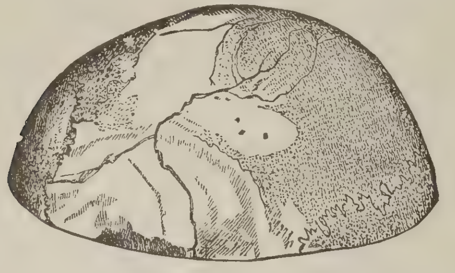

FIG. 2538.—Lines of Fracture Visible on the Outside of a Skull. (After Hewett.)

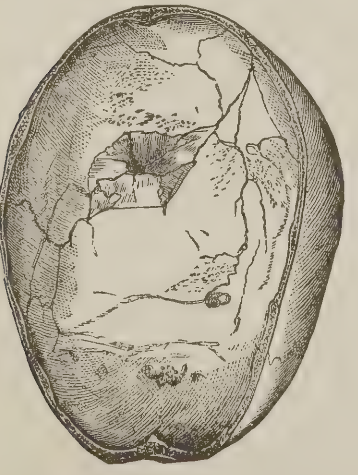

FIG. 2539.—Lines of Fracture Visible on the Inside of the Same Skull. (After Hewett.)

In every case in which solution of continuity of the external table has taken place, the attendant should bear in mind what a vantage ground the diploë offers for the lodgment of septic germs, and for the development of inflammatory and septic thrombotic processes which may greatly militate against the safety of the patient; and he should in such cases omit no precaution which may tend to avert their destructive tendency. Rigid antisepsis, or, if it can be secured, rigid asepsis, must be our motto; without it no such wound can be properly treated.

The possible remote consequences of a blow on the head should not be lost sight of. Inflammatory hypertrophy of the bone may be the result, or caries or necrosis may ensue. These latter may be limited to the part injured, or may be very widespread, affecting one table or both, and even involving the whole vertex. Extensive destruction of the inner table alone has been known, and Saviard's celebrated case proved that the entire vertex might separate, since in his patient, two years after a blow, the whole skull cap came away. Not to speak of other bone lesions, we must also remember the remote results of hemorrhage, as when a clot organizes into a cyst, etc. (*vide Brain, Tumors of*). For every reason, then, we should endeavor to diagnose at the time, if possible, the nature of the injury, and to meet the indication at once, in order that untoward after-consequences may be avoided.

FRACTURES OF THE SKULL.—*General Considerations.*—Those of the vault are usually direct, the result of the force applied, whether the head have been struck, or whether the patient have fallen upon it, and they consist at one time of a depression (in a yielding skull, akin to green-stick fracture), at another of an abrupt perforation, of a linear, a stellate, or a comminuted fracture. Fractures may here, as elsewhere, also be simple or compound. If the fracture be fissured the fissure may be short, or may pursue a long devious line, even to the base of the skull, extending through two or three bones. The comminuted fracture is usually less extensive as far as lines of cleavage are concerned. Fractures of the vertex also involve either one or both of the tables. Thus we often have fracture of the external table alone, and fracture of the inner table without visible lesion of the outer is known. Displacement may occur outward or inward. The lines of fracture visible on the outside of a given skull are seldom any index as to what may be found on its inner surface.

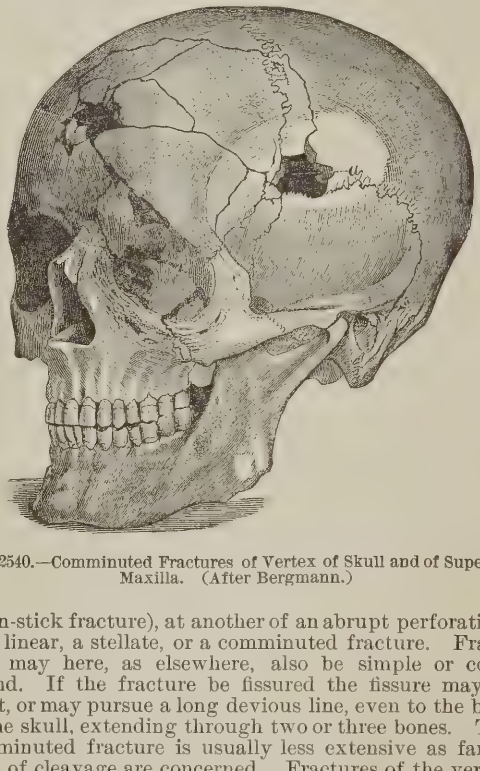

FIG. 2540.—Comminuted Fractures of Vertex of Skull and of Superior Maxilla. (After Bergmann.)

Figs. 2538 and 2539, from Hewett's monograph in Holmes' "Surgery," third edition, illustrate this fact; they represent respectively the outer and inner aspects of a vertex thus injured. A large number of similar illustrations may be found in their appropriate places in the "Surgical History of the Civil War." On the other hand, Fig. 2540, from Bergmann, will give an idea of the extent of some fractures of this kind.

There is, further, the possibility of fracture by *contre-*

coup. By this term is meant fracture by violence transmitted by the arched construction of the skull to a point more or less opposite to that injured. It is known that in cracking a cocoanut, for instance, the shell is not always broken at just the point where the hammer strikes it, but often at some other place. So a blow on the right side of the head may cause fracture of the left side, or in both places. Thus may be explained those cases in which a man sustaining injury, as by a kick of a horse, on the right side, is a little later found to have paralysis of the same side of the body; the explanation being fracture of the left side of the skull by *contre-coup*, with rupture of vessels and formation of a clot (or even rupture of vessels without lesion of the bone), with paralysis consequently on the side opposite the clot as an ordinary compression symptom. There is no limit to the peculiarities of fracture by *contre-coup*, save that it is never depressed.

Concerning the diagnosis of fractures of the vertex, it is not paradoxical to say that it is easy in proportion to the severity of the case, and most difficult when the injury is most trivial. The merest novice may recognize the ordinary compound fracture at a glance, while the expert may be at a loss in some cases of simple linear fissure.

Doubtless many cases of concussion of the brain following head injury are accompanied by some fissuring of one or both tables, yet, while we may suspect this, there is no way of proving it. Even a compound fracture is sometimes overlooked when the broken bone lies deep under the temporal muscle. Mistakes occur in the opposite direction also; thus, mere extravasation of blood has been mistaken for fracture with depression, and pre-existing abnormal depressions have been deemed to be the result of recent violence.

Fractures at the Base of the Skull.

"If we view the skull as a whole from either side, and especially from the rear, it will be noticed that while the upper and posterior surfaces have a dome-like arch the shape of which is well calculated to resist any ordinary violence, the base or under surface, especially viewed from the rear, is nearly flat. This is more strikingly apparent if we make a transverse and vertical section just back of the foramen magnum. This will show that the base of the skull at that point is almost exactly flat, and lacks the arched contour calculated to withstand blows or pressure. This will be made evident by reference to the accompanying illustration (Fig. 2541) of a transverse vertical section just back of the foramen magnum.

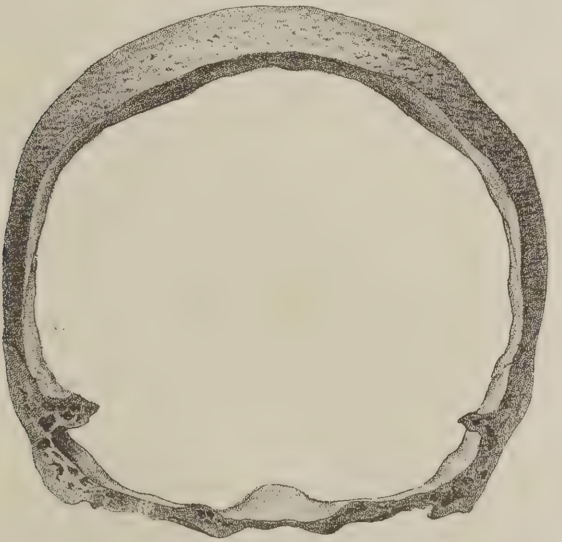

FIG. 2541.—Transverse Vertical Section of Skull through the Foramen Magnum, at Junction of its Middle and Posterior Thirds; showing thinness and flatness of the base in contrast with the thickness and convexity of the vertex. (Thomas H. Russell.)

"A glance at the under surface from without will show that it is weakened, not only by the large foramen magnum, but by the numerous foramina on either side and in front of it. If the base be viewed from within, being held between the observer and a moderately strong light, a considerable portion of the entire base will be found to be quite translucent, and some portions almost transparent, owing to their extreme thinness. The posterior fossa of a skull before me is thinner than at any other portion of its entire contour. In this specimen it is easy to distinguish through the posterior fossa small objects held on the other side of it, the bone here being as thin as the thinnest paper.

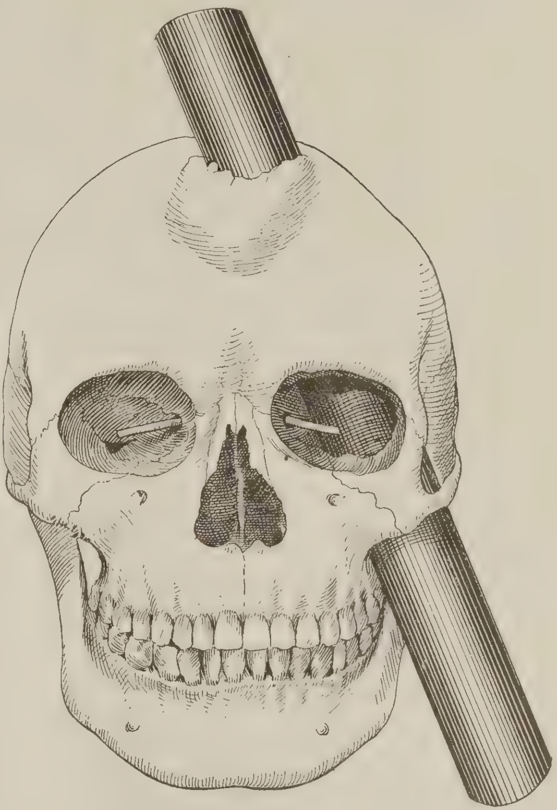

FIG. 2542.—Case Reported by Dr. Bigelow, of an Iron Bar (43 inches long and 1¼ inches in diameter) Driven Upward through the Skull. Recovery.

"While it would appear that the thicker portions of the base—as, for instance, the condyles on either side of the foramen magnum, the mastoid portions of the temporal, the median portion of the sphenoid, and the elevated ridges on the occipital bone—add considerable strength, in reality they do not furnish as much additional support as would at first appear; for if we make sections of these above-mentioned thicker portions, we shall find that they have only an extremely thin layer of outer and inner table or solid bone, and that almost their entire thickness is made up of diploë. They do not nearly compensate for the extreme thinness of the greater portions of all the fossæ and for the numerous foramina. It will therefore appear evident that the base of the skull is relatively weak, and not calculated to withstand more than a moderate amount of violence. The greater portion of the base has little or no diploë. No diploë is to be found in the posterior fossa and in the orbital plates of the frontal bone.

"If it were not for the fact that the base of the skull, from its less exposed position and from its being to a great extent protected from direct violence by being enclosed by the structures of the neck beneath, and for the fact that its great mobility upon the cervical vertebræ lessens the danger from any direct violence, it would be much more frequently fractured.

"The under surface of the brain, that contiguous to the base of the skull, is of greater importance, and any injuries of it are much more serious than those of its upper surface, and it is principally for this reason that fractures of the base are more disastrous than those of the vertex.

"Hilton has drawn attention to the extremely important manner in which the cerebro-spinal fluid protects the base of the brain from injury. He has shown that almost the only part of the base of the brain which is in close apposition with the base of the skull is the inferior portion of the anterior lobes of the cerebrum, where they rest upon the orbital plates of the frontal bone, and that all the other portions of the base of the brain, including those parts most essential to life, do not rest upon the bones at all, nor even touch them, but that under these portions of the brain there is such an abundant accumulation of cerebro-spinal fluid that it forms what he aptly terms a water-bed. No other portions of the brain are thus protected by an abundant supply of cerebro-spinal fluid to break the force of any violence. The contour of the two posterior lobes of the brain does not, therefore, correspond to that of the portions of the skull over which they float on this water-bed.

"The most remarkable case which I have been able to find recorded is described in the *American Journal of the Medical Sciences* for July, 1850, by Dr. Bigelow. A solid bar of iron, three feet seven inches long and one and one-fourth inches in diameter, was driven by a premature explosion of a blast entirely through the skull of a man twenty-five years of age, high into the air, and fell several rods distant. The bar passed upward beneath the zygomatic process on the left side, and through the floor of the anterior fossa of the base of the skull, and emerged near the centre of the frontal bone close to the coronal suture. A considerable portion of brain substance was lost. The patient was almost immediately able to converse rationally, and rode three-quarters of a mile, sitting erect in an oxcart, and after alighting from the cart without aid walked up a long flight of stairs. His recovery was complete in all respects, excepting the loss of sight in the left eye (Fig. 2542).

"Perforations have also occurred in various parts of the base of the skull from gunshot wounds. Wounds from direct violence of this kind are much more common in the anterior fossa than in other portions of the base, its floor being so thin that but little force would be required to thrust any of the above-mentioned foreign bodies through into the brain. Punctured wounds through the anterior portion of the orbit by small slender instruments or weapons leave but very little external evidence of injury. If slender weapons be introduced under the upper lid, nothing is visible but a slight amount of ecchymosis of the conjunctiva. If the wound be external to the lid, there will be nothing visible but the small wound in the region of the eyelid or eyebrow; and as the brain symptoms from such a wound of the anterior portion of the brain may not appear for several days, the gravity of the case or the nature of the injury may be entirely overlooked.

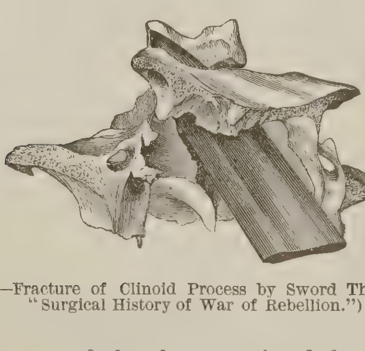

FIG. 2543.—Fracture of Clinoid Process by Sword Thrust. (From "Surgical History of War of Rebellion.")

"Nancrede has called attention to the fact that murderous wounds leaving no trace that can be detected, except upon a very careful examination, could be readily effected by passing a small pointed instrument through the retrotarsal conjunctival fold, and then penetrating the delicate orbital roof and superjacent brain. While this would not be difficult in an adult, it would be especially easy in children.

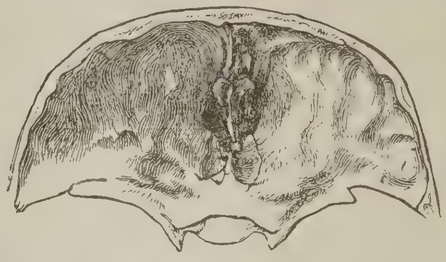

FIG. 2544.—Fracture of Anterior Fossa from a Blow on the Nose. (Bryant.)

"The ethmoid bone has been fractured by a blow upon the nose, driving it upward against the brain.

"The squamous portion of the temporal bone has been fractured by a blow upon the chin, driving the condyle of the lower maxilla through the glenoid fossa.

"It is easy to appreciate how, if a man fall from any considerable height, and especially if, falling upon his head, he strikes upon any soft surface, thus distributing the force of the blow over a considerable area of the vertex, the weight of the body being projected like a blow from a hammer, with the momentum gained by a descent of many feet, against the base of the skull, an extensive fracture of the base might easily be produced. These fractures should be considered as caused by direct violence. As the entire weight of the individual's body, projected from a height of a number of feet, constitutes the fracturing force, it would seem very easy for extensive fissure of the base to occur.

"The above-mentioned fractures, although considered by some as illustrations of *contre-coup*, are the result of direct violence by impact of the base of the skull against the cervical spine, and not properly from *contre-coup*, as formerly considered by Chopart and others, who have recorded their cases of *contre-coup*. Counter-stroke as a factor in the production of fractures of the base probably very rarely occurs, and is much less often referred to in modern medical literature. A fracture by *contre-coup* is one in which the fracture is produced on the side of the head opposite to that on which the blow is received. Grima's definition of *contre-coup* is: 'A lesion produced by a blow in another place than that which received the blow.' The fracture is caused by the violence being transmitted through and around the skull. In a considerable proportion of cases the fracture at the base is a result of the extension of a fissure from a fractured vertex. In those cases in which there is fracture of both vertex and base, the direction of the fracture is from the vertex toward the base. The theory of Aran, who made numerous experimental investigations, was that fractures of the base are always connected with fractures of the vault from which they radiate, following a line within the zone in which the former occurred, and taking a course which corresponds with the shortest route to the base. Aran based his theory upon numerous experiments with dead bodies, and upon old dried skulls.

"Fractures of the base are generally, if not in all cases, only fissured and without marked depression, as in fractures of the vertex.

"SYMPTOMS.—The symptoms are often obscure, and the diagnosis may not be made out with certainty at the outset. Symptoms usually appear early, but may be long delayed, and all may be absent until three or four hours before death, as in a case recorded by Jackson. Hilton mentions an interesting case of a gentleman who was thrown from his horse, striking upon the back of the head, and he was dragged by his foot catching in the stirrup. He subsequently disentangled his foot, mounted his horse again, and rode several miles home. He occupied himself about his usual duties for the following thirteen days, driving, walking, and attending to various business matters, previous to coming under Hilton's care. He then began to suffer from indications of paralysis and subsequently died, and an examination of his skull showed that he had suffered a fracture at the base. Yet during the thirteen days following the injury there was not the slightest evidence of any brain lesion.

"Owing to the location of a fracture of the base, and to the fact that such fractures are only fissured and with little or no depression, it is not possible to make out by inspection or palpation the lines of fractures, as can be done in those of the vertex. The manner in which the violence has been inflicted would guide us very much in our diagnosis, and the symptoms will depend upon the portion of the base which is fractured.

"Hemorrhage from the ears alone is of only moderate importance, for it may occur without fracture, simply from any laceration of the small vessels of the external auditory meatus or the membrana tympani; but if the hemorrhage be prolonged and copious, and especially if it be evidently arterial, as shown by pulsation, and if it be accompanied by other symptoms, or the nature of the accident be such as would be likely to produce fracture of the base, it is a symptom of considerable importance, but is not alone quite conclusive. Severe hemorrhage from the ear has occurred without fracture of the base. This symptom does not occur even in all fractures of the middle fossa, but only when a fracture through the petrous portion of the temporal bone establishes a communication between the injured intracranial vessels and the cavity of the tympanum, the membrana tympani being also ruptured. If, in such cases, the membrana tympani was not ruptured, the blood would escape through the Eustachian tube into the throat.

"Serous discharge from the ear is the most important and almost characteristic symptom of fracture of the base. This discharge is sometimes very copious, so much so that it is recorded that as much as a tumblerful has been discharged in a short time. It has been pretty conclusively proven that this consists of cerebro-spinal fluid, for its composition, whenever examined, has proved to be the same, and there would appear to be no other possible source for such a copious discharge of fluid corresponding in chemical composition. It was at one time erroneously supposed that it was the serum of the blood, or the fluid secreted by the internal ear. The cerebro-spinal fluid is a perfectly clear fluid of a very pale yellow color, and having a specific gravity of about 1.010. It has a saltish taste and its reaction is alkaline. It contains a substance which, according to Foster, although not sugar, acts like dextrose when tested with Fehling's solution. Five cases have been recorded by Wilder (*Medical News*, Philadelphia, 1885, vol. xlvi., pp. 625–627), in which brain substance escaped through one ear. Of these, three were fatal and two recovered. The discharge of cerebro-spinal fluid is possible only when there has been a fracture of the petrous portion of the temporal bone, with rupture of the dura mater and arachnoid, and of the membrana tympani. Cerebro-spinal fluid has rarely been discharged through the nose, when the line of fracture extends through the anterior fossa. In a case recorded by Cameron in *The Lancet* (London, 1884, vol. i., p. 205), there was copious discharge of cerebro-spinal fluid through the nostril and one ear; but the patient, although seventy-five years of age, recovered. Erichsen reports a case (fatal) of a boy who received a wound on the back of the head, with depressed and comminuted fracture of the skull, through the wound in whose scalp a large quantity of cerebro-spinal fluid escaped. This discharge of serous fluid by itself is a very characteristic symptom, and when taken in connection with an accident the nature of which would be likely to produce fracture of the skull, would constitute almost positive proof. A very noteworthy case has, however, been reported by Page (London *Lancet*, 1888, vol. i., p. 774) of a sailor who, after a fall of twenty feet, had ptosis of right eye, partial loss of vision in left eye, and hemorrhage from left ear and nose, followed by copious, clear serous discharge from left ear, and insensibility. Nearly complete recovery soon followed, but he died seven weeks after the accident, and at the autopsy no fracture could be found, but only purulent meningitis. Paralysis of one or several cranial nerves has occurred as a result of fracture of the base. Hemorrhage from the nose and mouth, and subsequent vomiting of blood, may arise in many cases in which there is no fracture. But if the hemorrhage be considerable, and if the nature of the accident were such as was likely to cause a fracture of the base, it may be supposed that the source of the hemorrhage is probably from rupture of an intracranial vessel, the blood escaping from a fracture of the sphenoid or ethmoid bones forming the roof of the nasal fossa. Vomiting of blood in considerable quantity, without hemorrhage from nose and mouth, has occurred from fracture of the base, the blood having been previously swallowed.

"Hemorrhage into the orbit may occur to a very noticeable extent when a fracture implicates the orbital plates, the blood then escaping from the intracranial vessels into the areolar tissue of the orbit, and appearing very noticeably under the ocular or palpebral conjunctiva. The discoloration of the lids from such a cause would not usually make its appearance as promptly after the injury, nor be accompanied by as much swelling, as when due to contusions of the lids from direct violence.

"Loss of vision from hemorrhage into the orbit may occur, as recorded by Rohrbach.

"The only objective evidence of hemorrhage from fracture of the base may be the appearance, after a number of hours, of extravasated blood beneath the skin on the back or side of the neck. In such cases the blood flowing from the broken skull finds its way down along the cellular tissue until it appears beneath the skin, in the neck. Such extravasations beneath the skin are of considerable diagnostic importance, if there has been no direct violence at the location of such extravasations to account for them.

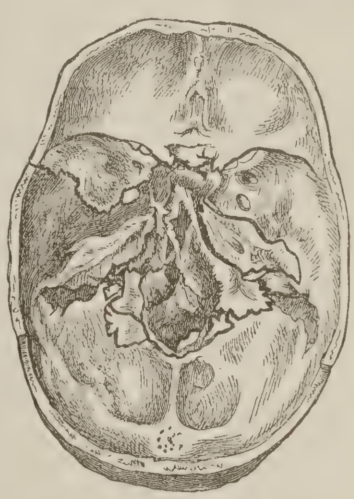

FIG. 2545.—Fracture of the Base by a Fall on the Vertex, which was Fissured. (Erichsen.)

"Vertigo, deafness, otorrhœa, hemiplegia, impairment of vision, and priapism have also been recorded as symptoms. There is no one symptom constantly present in all fractures of the base.

"PROGNOSIS.—Fractures at the base are not as invariably fatal as was formerly supposed. There can be no doubt that recovery occasionally occurs. The prognosis as to the injury of this portion of the skull itself, if there were no accompanying lesion of the brain, would not differ from fractures of other portions, for repair may take place here as in other portions of the cranium. If the patient survived long, union would probably take place, although slowly. According to Hewett, in some cases, even after months and years, no trace of union of the fragments could be found. In others the line of fracture was found partly united by dense fibrous tissue and partly by a thin layer of inlaid bone, while in others bony union was perfect. In some instances of bony union there was an excessive formation of porous bone, it being heaped up along the line of fracture. Usually, however, the injury to the brain results fatally. It is hardly possible for an amount of violence sufficient to produce fracture of the base to fail to produce concussion, laceration, or compression of this, the most delicate part of the brain. As in fractures of other portions of the skull, the prognosis depends almost entirely upon the amount of injury to the brain. Bryant, however, reports a series of thirty cases, with twelve recoveries. In these twelve the injury to the brain consisted of simple concussion."

The importance of a fracture of some part of the skull is subordinate to the importance of the presence or absence of compression symptoms. Along with a simple fracture of the vertex may happen a rupture of some vessel, and the formation of a clot of such size as to determine a fatal ending; on the other hand, we may have a compound comminuted fracture with a minimum of compression or of cerebral disturbance. We need, then, to diagnose the intracranial lesions with greater exactness, if possible, than those of the bone. For the diagnostic signs and symptoms of compression, the reader is referred to the article "*Brain, Compression of*" (Vol. II.). When after injury to the head such evidences of compression are noticed as are there detailed, no matter whether they appear at once, indicating depressed bone, after a few hours, as from a blood clot, or after a few days, as when caused by pus resulting from purulent meningitis, then there is sufficient justification for exploration, and this usually means the employment of the trephine.

After all, in theory at least, it is not difficult to decide on the appropriate course in a given case. In cases of concussion without serious external lesion, we are called on to do but little. If a scalp wound be present, it should be first utilized for purposes of exploration and then closed, as already advised. In cases of contusion of the brain, unless external indications are sufficient, we must pursue a tentative policy. Later, if circumstances call for it, the trephine may be employed. But in cases of distinct compression the trephine is almost always indicated. To be sure, its proper application may call for anatomical knowledge of the construction of the brain of high order; nevertheless, this is no contraindication to operate, it simply calls for expert skill.

American surgeons are now almost a unit on the subject of early trephining, or what may be called the early exploratory use of the trephine. They hold that, inasmuch as the operation is *per se, when properly* (*antiseptically*) *performed*, one of very small danger, we are likely to gain more than we shall lose by employing it for purposes of exploration when in doubt. Personally, the writer thoroughly believes in and advises operation when it seems as if any benefit, either in a diagnostic or in a therapeutic way, may be gained. But before finally deciding on instrumental interference, valuable hints may be gathered from external incision and exploration. The indication for the trephine may be in this way placed beyond the limits of doubt. The writer would then advise, in all but the most plain and typical cases, the following order of procedures in cases of serious injury to the head:

1. Careful external examination and consideration of the general condition of the patient.
2. Exploration with the finger by means of suitable incisions, provided the cerebral condition be other than manifest concussion.
3. Exploratory or therapeutic use of the trephine according to the revelations of the second procedure, or when concussion and contusion symptoms give way to those of compression.

Twenty-five years of experience have impressed upon the writer this lesson: *When in doubt as to the wisdom of trephining, operate.* The case that admits of serious doubt will be safer if operated than without an operation. This is the same rule which I follow in appendicitis; it represents the truest conservatism. Delay in doubtful cases is hazardous, dangerous.

Guided by this aphorism, it would seem as if the practitioner should be much less likely to err than when actuated by the teaching of a certain past era, and of men who are passing away, that the trephine should never be used unless its application seems, even to the novice, plainly and unmistakably necessary.

For the details of the operation the reader is referred to the article under the heading *Trephining*.

WOUNDS OF THE ORBIT.—Those involving the eye or its adnexa are discussed under *Eye, Injuries of;* while those which do not injure the globe are to be treated on the general principles already laid down. We would simply remind the practitioner that, in case of a penetrating wound of the orbit of this character, there is necessity for providing adequate drainage; otherwise pus may infiltrate or burrow into localities where its presence would be most undesirable.

WOUNDS OF INTRACRANIAL VESSELS AND SINUSES.—These most often involve the longitudinal and transverse sinuses and the middle meningeal artery. Wounds of these channels have also occurred during the operation of trephining, and have not been fatal; in fact, in more than one case the effect was rather that of a venesection, and was consequently good. If, by a small punctured wound, a superficial sinus be penetrated, an antiseptic compress may be sufficient to check bleeding; over this an ice-cold application should be made. The cases are numerous in which recovery has followed this simple measure. Death is unusual in such cases, and results rather from other complications, such as injury to the brain, partial escape of blood into the cranial cavity, septic processes, or air embolism. Volkmann has lost a case by entrance of air into a sinus during extirpation of a sarcoma from the bone and dura mater. But under most conditions this would not happen. Wounds of the cavernous sinus through the orbit have always been fatal.

A splinter of bone or a foreign body having perforated a sinus wall, the blood may escape at once or only after its removal. These cases are very rare. Hemorrhage may be checked by antiseptic tampons with ice applications, or the sinus walls may be sewed together with fine catgut or silk, as was first done in one notable case by Dr. C. T. Parkes. Provided they do not prove rapidly fatal, these sinus wounds usually heal well, with only a thickening of walls; but entire obliteration of the channel, should it occur, would be of no great import, as Schellmann's researches have proved. The principal danger comes from softening of thrombi.

Wounds of the middle meningeal artery may be recognized sometimes by the supervention of compression symptoms, even though there be no external lesion indicating them. Among causes of the injury may be mentioned: a direct wound by some sharp object; laceration by projectiles or bone spicula; rupture by changes in relative situation of neighboring bones; rupture without fracture of bones, occurring especially on the side opposite the injury. Rupture having occurred, commotion may retard the formation of clot, but it will form sooner or later. It may even putrefy without visible exposure to the air.

Symptoms of this accident are: An interval of consciousnsess following injury before supervention of somnolence, sopor, and coma—these are sometimes preceded by irritation symptoms, and the compression symptoms may occur at any time after hemorrhage begins, from fifteen minutes up to eleven days; hemiplegia on the side opposite the injury, the artery being right over the motor centres for the opposite arm and leg; changes in the pulse (infrequency and hardness); slow, embarrassed, stertorous respiration; vomiting; loss of reaction to light of the pupil on the same side as the clot; occasional unilateral impairment of sensation; aphasia; disordered bladder and rectum; rise of temperature. If the first four of these symptoms be present, the diagnosis may be regarded as sufficiently accurate to justify operation. The gradual supervention of aphasia indicates extension of the clot anteriorly, disorders of sensation its extension posteriorly, while paralysis of the third pair means that it has extended toward the base of the brain.

Numerous cases of penetrating wounds with lesion of this vessel have been reported. Not infrequently it has required a ligature during removal of fragments after severe injury. During our Civil War the common carotid was seven times ligated for this same purpose, with three recoveries; while now, twenty years later, probably no competent surgeon would hesitate to trephine over its course. A case of Parker's will be instructive in this connection. In this there was no external wound of soft parts; nevertheless he trephined over the artery on one side, but found no lesion; he then trephined over the artery on the other side, but finding no coagulum outside the dura, and noticing that this was discolored and distended, he incised it and removed a considerable amount of blood. In three days the patient became conscious, and afterward quickly recovered.

Symptoms of compression, supervening with varying rapidity, not improbably without external wound, require exploration by means of the trephine, the operation of trephining, with proper antiseptic precautions, being by no means a serious or hazardous one. In trephining with the purpose of finding the artery in question, the point of the instrument should be applied an inch and a fourth to an inch and a half back of the external angle of the orbit; otherwise the instrument should be kept away from this spot. It should be borne in mind that sometimes the vessel lies in a very shallow groove on the under side of the bone, sometimes in a deep groove, and sometimes in a complete bony canal. The instrument must, therefore, be worked with gentleness and care (*vide Trephining*).

If a satisfactory cause of the compression be not discovered on one side, it will be well to take a hint from the case mentioned above, and, remembering the possibility of rupture by *contre-coup* and lesion of the vessel on the other side, to explore there also. Certainly cases of compression are usually desperate enough to justify any search which may reveal the cause and permit its removal.

Wounds of vessels in the brain call for treatment only when diagnosed, and the circumstances which permit diagnosis will also at once indicate the proper thing to do. Could hemorrhage in the subdural space be diagnosed, it would be good practice to trephine, open the dura, and wash out the extravasated blood. One such case was reported during our Civil War (Gross: *Am. Jour. Med. Sci.*, July, 1873).

Injuries to the cerebral portion of the internal carotid are much rarer than those to the meningeal. Longmore relates how a bullet penetrated, in one case, through the orbit into the petrous bone and lodged there, leading later to erosion of this vessel and fatal hemorrhage. Some injury of this kind might, if not rapidly fatal, lead to the formation of an arterio-venous aneurism, calling for ligation of the common trunk.

WOUNDS OF CRANIAL NERVES.—The treatment of injuries to these nerves cannot be other than symptomatic. Should a depressed fragment or a foreign body press upon a nerve trunk, removal of the same would meet the principal indication, and, provided the injury were not too severe in other respects, the nerve might regain some or all of its function. Sometimes, after bruising or contusion of a terminal branch, *e.g.*, the infraorbital, there will ensue so violent a neuralgia as to call for section or exsection of the nerve on the proximal side of the injury. If it be certain that a nerve trunk outside the cranium has been severed, and if the locality of the lesion be reasonably accessible, it would be good practice to cut down upon it and unite the severed ends with a fine catgut suture.

WOUNDS OF BRAIN SUBSTANCE.—Since these are by necessity complicated by those of external parts, we can draw no abrupt therapeutical distinctions. Obviously, if antiseptic measures are indicated for more superficial injuries, they are vitally essential here. The majority of these wounds are inflicted by firearms, and we wish here to emphasize what is elsewhere in this HANDBOOK detailed, viz., the futility—nay, even the homicidal effect—of careless or ineffectual probing for bullets. From time to time in current literature the writer has denounced this practice as vigorously as he could. The array of cases set forth by German military surgeons, in which most dangerous wounds—such as, when treated by old methods of promiscuous bullet-hunting, were surely fatal—primarily and antiseptically occluded, and never probed nor investigated, have gone on to speedy recovery; this array should be most convincing as to the merits of this practice.

Gunshot wounds of the cranial cavity virtually always call for the trephine; but with elevation of depressed bone, attention to bleeding, and smoothing off the edges of the bone wound, the indications are fairly met in the majority of cases. Blood clot is always to be removed, and the source of the hemorrhage attended to; a discolored, pouting dura may justify incision and exploration; while in the effort to remove pieces of bone which have been detached and driven into the brain, the bullet may be found and also removed. But the idea of introducing a probe into the brain through a small penetrating wound of the skull is one which must be abhorrent to every modern surgeon. Random exploration of the brain is never justifiable, and the circumstances which would seem to call for the introduction of the probe through its bony roof would call much more loudly for the use of the trephine. Moreover, many recorded cases prove with what apparent freedom from serious consequences patients may recover with such foreign bodies as bullets in their brains. When circumstances seem to call for a hunt for the missile it may be located with the Roentgen rays, or with the telephonic probe of Girdner, or its equivalent signaling instrument, and when so located it may perhaps be removed by an appropriately planned and perfected operation, done deliberately with every facility at hand, but not otherwise. The safest rule, then, to follow is to *abstain from all operative measures for the removal of missiles when indications are obscure, or such as do not to promise a compensating advantage.*

TRAUMATIC ABSCESS OF THE BRAIN.—By this term is meant abscess formation supervening on injury, as distinct from those cases in which the cause of the abscess is uncertain or unknown. Such traumatic abscesses are more likely to result from gunshot injury than from any other, though they may follow a simple contused wound of the exterior. The symptoms of cerebral abscess, often much resembling those of compression, have already been considered (*vide Brain, Abscess of*). We wish here only to put in a plea, not only for the exploratory use of the trephine when there is good reason to suspect abscess, but of the aspirating needle as well. Should the presence of pus be thus revealed the aspirator should be disengaged, and the needle used as a guide or director upon which to pass a small knife, perhaps a tenotome, and by thus making a freer opening, not only permit escape of pus, but the introduction of a drainage tube and careful washing out of the cavity.

This operative procedure, though bold and radical, is not half so dangerous as to permit the abscess to take its own course, and will fully justify itself.

HERNIA OR PROLAPSUS CEREBRI.—When from a recent wound, or one of a few days' standing, protrusion of brain substance takes place, it may seem doubtful whether it would be better to excise the protruding mass or to endeavor to repress it by suitable pressure. Of course, the careful practitioner will dress all fresh cases with such a judicious amount of pressure as shall guard against this condition; nevertheless, he may be called on to treat it after it has occurred. If the hernial mass has begun to slough there can be no question; excision by ligature, elastic or otherwise, or by the knife, must be practised, and hemorrhage carefully watched for and checked. When the mass is small and appears healthy, gentle and continuous pressure, as by an elastic outside bandage, will usually coax back into the cranium that which belongs there. After complete reduction a lead or caoutchouc plate may be adapted to the shape of the part and applied externally as a part of the bandage technique.

An abscess may underlie the hernial mass; this is to be discovered and treated as above.

Adams has reported a case of irreducible hernia cerebri, in which he succeeded in covering the hernial mass with a flap of skin by a plastic operation, and Kusmin has reported another case, similar to it in many respects, excepting that he resorted to skin-grafting.

Purulent Meningitis.—When compression symptoms supervene several days after injury, there is frequently good reason to suspect the presence of pus. This may be in the form of a circumscribed collection, *i.e.*, an *abscess*, which has already been spoken of, or it may mean purulent or suppurative meningitis. This accession of compression symptoms always, or nearly always, justifies the exploratory use of the trephine. Should it prove to mean compression from suppurative meningitis, there is no reason why the arachnoid cavity should not be washed out, but every reason why it should. In other words, it should be treated just as purulent peritonitis is now treated, that is, by washing out and draining the cavity. Recovery will not always follow this procedure, but it will in a fair proportion of cases, which are inevitably doomed if some such measure be not instituted.

Irritative Lesions following Head Injuries.—These are mostly to be grouped under two classes, viz., convulsive (epileptic) and mental disturbances (mania, dementia, etc.). This hardly seems the appropriate place in which to discuss these at length, the pathological lesions being so varied, including depression of the skull, cystic formations, abscess, etc. Nevertheless there is each year a stronger tendency, on the part of advanced surgeons, to explore these cases when any external scar or depression may indicate rudely a point of attack. The element of risk is small, the prospect of at least alleviation sufficiently hopeful, in conjunction with the otherwise hopeless nature of the case, to justify the attempt, and besides, the degree of success attending these efforts is affording more and more encouragement. In cases of this general nature the exact condition is yet, in individual instances, too uncertain to permit of more than general operative directions. Those which have not already been given in this article can be found in their appropriate places elsewhere in these volumes. This paragraph has been made, therefore, suggestive rather than explicit.

Wounds of the Head during Birth.—With reference to injuries to the fœtal head during artificial or natural delivery, it is necessary to add but little. Even large extravasations of blood are usually absorbed; in extreme cases, after waiting a few days, it might be well to incise, turn out the clot, and sew up the edges of the wound. Excoriations and bruises made by instruments need only conventional treatment. Fatal phlegmonous inflammation has been known to result from injury done by forceps; hence the advisability of antiseptic precautions and attention to detail. Symptoms and appearances arising from compression caused by the forceps will commonly subside as the head resumes its shape. Should positive fracture take place, it will probably run its course uninfluenced by therapeutic measures. No hesitation should be felt about surgical intervention in these cases, when otherwise indicated, simply because of the tender age of the infant or child. The prognosis must be based on the amount of injury.

Roswell Park.

HEALING SPRINGS, ALA.—Healing Springs, Washington County, Alabama.

Post-Office.—Healing Springs. Numerous Cottages.

Access.—Buy ticket to Buckatunna, Miss., on the Mobile and Ohio Railroad, seventy miles north of Mobile; then take hack to springs, fourteen miles east. These springs were discovered in 1870, and have since attained considerable prominence as a health resort. The surface of the country about the springs is broken by high ridges and slopes, and covered by the long-leaved yellow pine. The soil is sandy, and the location has an elevation of about 400 feet above tide water. Like all resorts in this latitude, the winters are mild, the temperature seldom dropping below freezing point. The summers are not exceptionally hot, the mercury almost always sinking to 68° or 70° F. at night. During the recent summer the highest temperature observed was 92° F. The springs are eleven in number, but only four are much used. The "Creek" Spring boils up in the centre of a small stream and flows about eight gallons per minute. It is said to contain lithia, iron, and a trace of arsenic. "Mound" Spring, yielding thirteen and a half gallons per minute, issues from a small mound five or six feet higher than the ground around it. Iron, magnesia, lithia, and sulphur are said to be among its ingredients. "McCarty" Spring, supplying seven gallons per minute, is supposed to contain an acid of some kind and also iron. Its waters are used extensively for chronic diarrhœa. "Scholes" Spring contains iron and sulphur. Many varieties of skin affections, chronic renal diseases, and disorders of the bladder, alimentary tract, and liver are said to receive benefit from the waters of the Healing Springs.

James K. Crook.

HEALING SPRINGS, VA.—See *Hot Springs, Va.*

HEALTH RESORTS.—A change of climate and environment is one of the most valuable means we possess for the treatment or prevention of disease, and this is also to a large extent true in the thorough use of such climate as exists wherever the patient happens to be,—the home climate. To obtain the maximum benefit from any climate, however, one must live in it, *i.e.*, out of doors; hence the beneficial results from an indifferent climate rigorously utilized may be, and perhaps most frequently are, better than those from a much superior climate only partly made use of. An illustration of this statement is found in the results obtained in those sanitoria for pulmonary tuberculosis which are situated in ordinary temperate climates like Falkenstein, or Rutland, Mass., such results being more favorable than those obtained in open resorts with more advantageous climatic conditions. The use of the health resort should be regarded as a therapeutic measure to be as carefully considered and watched as the administration of a drug. Many climates like many drugs are, and must be, empirically used. We can only try them and await the effect. Asthma is a striking example of this use. Why one climate avails and another not we cannot always say, and we can refer the effect only to individual idiosyncrasy, or to some subtle undiscoverable influence in the resort, or to the morbid state of the patient.

Ease and rapidity of accomplishment are always alluring factors in any undertaking. It is easier to take drugs and keep on in the same accustomed way of life than to make the sacrifice which a change of climate so often entails. Hence the inestimable value of climatic therapeutics remains so largely unappreciated and unused, even by the profession. And, further, there is the obstacle, often insurmountable, of the expense involved in a change of climate. Hygiene, dietetics, hydrotherapeutics, and climate are, and always will be, the principal agents in producing cure or amelioration in a large proportion of diseases, and drugs, after all, are only aids in better applying or restoring to their legitimate place these great natural bulwarks of health.

When a physician advises a change of climate he means that his patient should take up a temporary residence in some place known as a health resort and supposed to possess climatic conditions more favorable for the disease of which his patient is suffering than the climate where he is. Intelligently to prescribe a health resort, then, one must consider: first, the classification of climates and their geographical distribution; second, the value of the various climatic factors and their influence upon the human organism; third, the adaptability of special climates to the treatment of special diseases; fourth, the qualifications other than those of a purely climatological character which should be possessed by a health resort. Various classifications of climate have been made by different authors. Weber's appears to be the simplest. He makes two general divisions: *marine* and *inland* climates.

Under the former Solly makes the subdivisions of ocean, island, and coast climates; and under the latter, of low, medium, and high climates. The ocean climate is obtained by means of sea voyages—such, for instance, as the one to San Francisco, viâ the Isthmus of Panama, or to the Mediterranean, or from England to the Cape of Good Hope or to Australia, or, best of all, when possible, a yachting trip which can be prolonged at pleasure.

The ocean climate is characterized by purity of atmosphere, moisture, and equability of temperature; the impregnation of the air with salt, iodine, and bromine may also be of value. Of course many of the weather characteristics depend upon the latitude in which the voyage is taken. Such a climate is a sedative to the nervous system and a stimulant to the appetite and digestion; it is a *sedative tonic*. A sea voyage is applicable to some forms of tuberculous disease, mental exhaustion from overwork, insomnia, various forms of scrofulous disease, anæmia, and chlorosis.

The climate of small islands sufficiently removed from the mainland is much like that of the ocean, modified more or less by currents and by the configuration of the coast. Bermuda, Block Island, the Isles of Shoals are good examples of island climate.

Coast climates resemble that of the ocean, modified by the land influence. Here we have the land as well as the sea breezes, causing less equability and less constant purity of air. A coast climate is also influenced by the configuration and character of the adjacent land. For example, the Alps influence the climate of the Riviera, giving rise to the cold winds which sweep down upon the coast; the desert influences the character of the climate upon the African coast; the inland desert the littoral of Australia. The Undercliff at Ventnor, by its shelter from land influences, is rendered a more purely marine climate.

Weber also divides marine climates into *humid marine* and marine with *moderate* or *slight humidity*. Moreover, for health-resort purposes, such climates as fall under the above subdivision, and at the same time are warm, are chiefly to be considered.

Of the humid marine warm climates, Madeira, the Canaries, the West Indies, the peninsula of Florida are examples. Such climates exercise a sedative effect upon the nervous system and mucous membranes, and are useful in chronic bronchitis with emphysema, bronchial catarrh, and pulmonary congestion in elderly people without cardiac complications. Of the warm marine climates with moderate or slight humidity, we have the Riviera, the coast resorts of southern California, southeastern Georgia, and Solly also includes Florida under this head. The effect and uses of such climates are practically the same as those of the previous class. All the seacoast resorts of the North may be classed under *cool* marine climates with moderate humidity.

Of the inland climates we have first the low ones, such as Egypt, Pau in France, Lakewood, the interior health resorts in the Southern States, the low plains of Arizona, portions of Texas, and the inland resorts of southern California, such as Riverside and Redlands.

Such climates are also susceptible of classification according to temperature and humidity. Their uses as health resorts are very varied; pulmonary tuberculosis, bronchitis, cardiac and renal disease, gout, rheumatism, are some of the diseases likely to be benefited by a low, dry, warm inland climate.

Medium and high altitude climates can be considered together as the difference is only one of degree. Solly makes the distinction depend upon the amount of altitude; from 4,500 feet up he calls elevated climate. Not alone does the elevation influence the character of the climate, but the latitude, the proximity to the ocean and to mountain ranges, and the configuration of the surrounding country; thus Estes Park in Colorado is comparable with Davos in Switzerland, although the former is 1,000 or more feet higher than the latter. The general climatic characteristics of the mountain health resorts are: a rarefied atmosphere, aseptic air, increased diathermancy, dryness, abundant sunshine, and a comparatively low temperature. The chief peculiarity is the lessened barometric pressure, and upon this feature probably depends a large part of the value of such a climate in the treatment of pulmonary tuberculosis. The purity of the air of high altitudes has been compared to that of the ocean and of the desert.

High-altitude climates are found in all the four quarters of the globe: the Alps in Europe; the Andes in South America; the Himalayas in Asia; the Rocky Mountains in North America; the lofty plateaux of Mexico; and the high altitudes of Australia and South Africa. Davos, St. Moritz, Arosa, and Leysen are examples of high-altitude health resorts in Europe; while Les Avants, Goerbersdorf, St. Blasien, and many others in the Black Forest, Harz Mountains, and Alpine foothills are illustrations of mountain resorts of moderate elevation.

The elevated resorts of the Rocky Mountains, from 5,000 to 7,000 feet, have a dryer climate and more sunshine than those of Europe. The principal resorts are found in Colorado, New Mexico, Arizona, Utah, and Texas. Many which are climatically valuable are unavailable on account of the absence of suitable accommodations.

In Colorado we have Colorado Springs, Denver, Estes Park, Glenwood Springs, and others; in New Mexico, Santa Fé, Albuquerque, Las Cruces (3,800 feet) and Silver City; in Arizona, Prescott, Phœnix (1,100 feet), and Tucson (2,400 feet); in Utah, Salt Lake City; in Texas, El Paso. There are also many resorts of lesser elevation in the Adirondacks, Alleghenies, Appalachian and White Mountains, such as Saranac, Asheville, Bethlehem, Kane, and Mount Pocono. In Mexico we have the City of Mexico, Guadalajara, Aguæ Calientes, Toluca, all over 5,000 feet high, and many others. In South America we have the region upon the Pacific slopes of the Andes, many years ago made known as favorable for phthisis by Dr. Archibald Smith. The elevation varies from 8,000 to 12,000 feet, and the chief climatic characteristics are: (1) Moderate warmth; (2) equability of temperature; (3) abundant sunshine; and (4) moderate dryness. There may be mentioned Jauja, Bogota, Quito, Arequipa, and Huancayo.

"Unfortunately," says Weber, "at none of the resorts is the accommodation good enough for invalids."

In India, Darjiling (8,200 feet), Simla, Landour, Naini Tal, and Murree are some of the best spoken-of stations. According to Weber, the testimony of Indian medical officers appears to be rather against the use of the Himalayas in the treatment of lung diseases "and apparently this is on account of the heavy rainfall." In South Africa, Kimberley, Bloemfontein, and Pretoria, all 4,000 feet high or over, are some of the places used as health resorts. "The accommodations for invalids," remarks Williams, "are not up to the European standard," but the climate, he says, has yielded excellent results in his hands.

In Australia, there is the highland region embracing the slopes of the Australian Alps, with an elevation of from 2,000 to 7,000 feet, but only Mount Macedon in Victoria (2,500 feet) and Mount Victoria, New South Wales (3,490 feet) offer satisfactory accommodations to invalids.

There is also the Darling Downs in Queensland (2,000 feet).

To consider now briefly the value of the various climatic factors and their influence upon the human organism:

Temperature.—Extremes of temperature, unless more or less neutralized by some modifying influence like the greater diathermancy of the air in altitudes or extreme dryness, are incompatible with a genuine health resort. That a normally well man can endure great extremes of heat or cold with impunity for a limited season we know, but for very many invalids a moderately warm or cool temperature is to be desired, with a moderate variability. Extreme or rapid changes of temperature are dangerous.

Humidity.—In the majority of health resorts a dry or moderately dry air is desirable. Moist air renders the cold more intense, and the heat more oppressive; moist heat debilitates, favors decomposition, retards evaporation from the skin and lungs. Moist cold increases the functional activity of the kidneys and predisposes to the catarrhal affections of the respiratory and genitourinary tracts.

When judging of the dryness or moisture of the air of a resort, the relative humidity is generally taken as a guide, but it must always be considered in connection with the temperature; and, in order to make a fair comparison, some standard temperature should be taken. 55° F. is given by Wendt as the mean annual temperature of the United States, and this can be taken as the standard.

Assuming this standard, we can, according to Solly ("Medical Climatology," p. 34), make the generalization that 50 per cent. or less relative humidity is dry; 65 to 75 per cent. is medium; 75 to 85 per cent. is moist, and any above very moist. The dew-point and evaporation are also to be taken into account in considering the humidity.

Rainfall.—"It is generally assumed," says Weber (Allbutt's "System of Medicine," vol. i., p. 252), "that considerable rainfall is an injurious condition, but this is not always correct. Provided time enough be left for the invalid to take exercise and sit in the open air, rain is to some degree useful, as it has a purifying influence upon the atmosphere. The notion that *snow* is injurious is even more incorrect." This is especially true when it remains on the ground without melting for a long time, as at Davos, for example.

Whether or not a given amount of the rainfall is a disadvantage is also to be considered in connection with the character of the soil; if the latter is porous, quickly absorbing moisture, the amount of rainfall is of less importance than if the soil is clayey and holds the water.

Wind.—Winds vary in their effects according to the temperature, humidity, purity, and velocity of the air in motion. They often produce great and sudden changes which are always undesirable for an invalid. Cold, damp winds are never good, and cold or hot dry winds, like the Mistral of the Riviera or the Föhn of Switzerland, are too irritating or debilitating.

The direction of the wind is also an important factor in its influence upon the invalid, for from one direction it comes fresh and pure, blowing over forest expanses or from the hills, while from another it may come laden with dust and germs, exhausted of its ozone and deficient in oxygen. From another direction they "bring with them, so to speak, the climates of distant regions."

Beside their direct action upon the human organism, winds are great ventilators and purifiers of the atmosphere.

Light and Sunshine.—A large amount of sunlight is requisite for a good health resort; it cheers the mind, has a stimulant and tonic effect upon the nervous system, probably favors tissue metabolism, and destroys various bacteria, notably the tubercle bacillus. A cool, dry air and sunshine such as is met with in the high altitudes, is a combination of striking value for the tuberculous patient.

The influence of light and sunshine upon the naked body is probably far more potent for good than we realize. The reader is referred to two interesting papers upon this subject by Dr. William Duffield Robinson in the Transactions of the American Climatological Association for the years 1898 and 1899.

In considering any health resort, then, the average number of clear, fair, and cloudy days is to be especially noted. Outdoor life is what is desired, and without a large amount of good weather this is seriously interfered with.

Atmospheric Pressure.—The physiological effects of a diminution in atmospheric density has been fully considered in the article upon "*Altitudes, High,*" and the reader is referred to it for a discussion of this subject.

Electricity.—What effects atmospheric electricity produces upon the human organism is not sufficiently understood to enable one to make any definite statement regarding it. This much we know, that the presence of a large amount of electricity in the atmosphere, as in elevated regions, appears to enhance the favorable influence of a climate.

The configuration of the land often modifies the climate of a health resort, for better or for worse; a hill or mountain range may afford protection from high winds or those blowing from an injurious quarter; or if the resort is in a valley the daily amount of sunshine may be reduced, as at Davos. Moderate ascents are often of value for exercise, as Brehmer utilizes them at Görbersdorf for his consumptives, or as they are used in the Oertel "cure de terrain."

Vegetation is an important factor to consider in the selection of a health resort. The existence and character of the vegetation not infrequently modify materially some of the purely climatic factors. Forests render the climate more equable, lead to increased rainfall, and have a higher relative humidity. The fir, pine, spruce, and other evergreen trees are generally considered beneficial to a health resort on account of their balsamic exudations, their shade, and soothing effect. Lakewood, Summerville, and Aiken are illustrations of resorts among the pines; the Adirondacks, and many portions of the White Mountains, of resorts among the fir and spruce.

"The covering of the soil with vegetation," says Williams ("Aero-Therapeutics," 1894), "protects it from the sun's direct rays, and the temperature of plants exposed to the sun does not rise so high as the soil itself, because much of the heat is lost through the large evaporation which takes place from the leaves and stems, and which gives rise to air currents tending to reduce the temperature. The result is that the heat is more evenly distributed over the twenty-four hours, and is less intense in the hottest time of the day." A knowledge of plant life is desirable on account of its bearing upon hay fever.

The character of the soil of a health resort is an important fact to know; dryness of soil and subsoil is obviously of advantage. Dampness favors disease, especially phthisis. The condition of the soil influences the temperature and moisture of the lower zone of air by the quantity of moisture it absorbs, the rate at which evaporation takes place, its porousness, capacity for warmth, and rapidity with which the ground is heated or cooled.

The sandy soil of the desert, for example, has great power of accumulating heat, and equal power at night of radiating it and producing a great lowering of temperature; hence the great range of temperature during the twenty-four hours.

There are other essential qualifications than those of a purely climatic character which should be possessed by a health resort. For example, it is important for the invalid to know what facilities exist for comfortable living, without which the best of climatic conditions are likely to prove elusive. Pure drinking water, good sanitary arrangements and sewerage, proper accommodations as to ventilation and heating, food of proper quality and properly cooked, efficient attendants, and facilities for an outdoor life, especially if the open-air "Liege Kur" is to be taken, are all matters of the first importance for the success of the health-resort cure. There should exist an intelligent and active board of health, the members of which should supervise not only the general sanitary condition of the resort, but the hotels, boarding-houses, or rented cottages where consumptives have resided; and they should see to it that after such residence renovation and disinfection are satisfactorily performed, as, for example, is done at Cannes (*vide* article on *Cannes* in the HANDBOOK). Facilities for out-of-door exercise, amusement, and mental occupation are important features of a health resort. Is there a library? Are there schools? What are the churches?

Ease of accessibility is often a strong point in favor of a resort; and equally important is it to know the method of reaching the place selected, the expense of the journey and of residence there. No resort should be chosen for a genuine invalid which does not contain one or more good physicians known either by reputation or personally to the physician who sends the patient away; and the latter should be referred to the local physician by a letter from the home physician, briefly stating the case. Honest statistics of cases treated at health resorts are perhaps the most valuable indications of the actual benefits to be expected from a residence at the resort for whatever disease its climate is supposed to be especially curative.

The establishment of good sanatoria under careful, expert medical supervision, especially for pulmonary tuberculosis, is greatly to be desired in such health regions as Colorado, New Mexico, the pine belt of the South and elsewhere. Some few already exist, such as Trudeau's at Saranac, the Loomis Sanatorium at Liberty, and others. For many invalids a well-conducted hotel or boarding-house, and a competent local practitioner in the neighborhood answer well.

A practice which is not unusual, but which is to be strongly deprecated, is for the home physician to attempt to retain the guidance of his patient while at the health resort. The local physician of necessity must be better acquainted with the local hygiene, the local risks, and all the local conditions, so important for the invalid to be made aware of in order to obtain the best results from the climate of the resort.

Regarding the adaptability of certain climates to the treatment of special diseases, only a few general indications will be given here, and the reader is referred to the articles upon the various health resorts in the HANDBOOK for a more detailed consideration of this portion of the subject.

For phthisis, for which a health resort is sought more frequently than for any other disease, the essential climatic conditions, as has been more than once before stated in this HANDBOOK, are pure air free from dust, protection from high winds, moderate dryness and equability, and a dry soil. Such a combination of conditions is not hard to find nor does one have to travel far to obtain it. With it, however, must be associated, as has so often been insisted upon, the most careful, continuous, medical supervision; hence the great value of sanatoria.

It must also ever be borne in mind that the stage of the disease, its activity, and the general condition of the patient are always to be carefully considered in deciding upon a resort, or if any change is advisable.

Assuming that the patient is in the incipient, curable stage, and that there are no other contraindicating conditions, the writer would arrange the favorable climates in the following order of excellence: (*a*) High altitudes, like Colorado, New Mexico, the Alps; (*b*) low altitudes, like the Adirondacks, Asheville, the Southern pine belt, and southern California; (*c*) coast climates, represented by the Riviera resorts; (*d*) island climates, like Madeira and the Canaries; (*e*) ocean voyages. As to results, according to Solly ("Medical Climatology," p. 141), the high altitudes are the best, the sanatoria the next, and the lowland climates come third.

Bronchitis.—When expectoration is abundant, a dry, warm, inland climate like Thomasville, Augusta, Summerville, and Camden, S. C., southern California, in the winter; and the seaside or mountains in the summer. If the expectoration is scanty, a warm moist climate like Florida, Nassau, Algiers, Madeira, in winter; and Newport, the Jersey coast, Nantucket, Cape Cod, etc., in the summer.

Pleurisy.—In the convalescent stage when recovery is delayed, or the lung does not expand—the higher altitudes, provided the condition of the heart permits. Likewise in retarded pneumonia, in individuals under thirty-five years of age, and when the heart is normal, and the lungs are not too seriously involved, Solly recommends the higher altitudes, under proper restrictions.

Asthma (*Bronchial*).—Although the climatic treatment of this complex disease is largely a matter of trial, yet the high-altitude resorts appear to give the best results, especially when the neurotic element seems to be the prominent factor in the case. If the bronchitis, the determining cause, seems to be the most important element, either a sedative or a stimulant climate is to be selected according to the character of the bronchitis. Or if the exciting cause appears to be the most important, especial consideration must be given to that in the selection of a resort.

Hay Fever (*Nasal Asthma*).—The Adirondacks, White, Catskill, and Allegheny Mountains, Mackinac Island, Georgian Bay, Cape Breton, the "North Woods," Beach Haven, Fire Island, and Halifax, Nova Scotia, are some of the many resorts which afford more or less immunity. An ocean voyage and travelling in Europe are also prophylactic.

Tuberculous Glands.—Seaside resorts, sea voyages, and high altitudes. The seaside preferably, with salt baths.

Rheumatism.—Warmth, dryness, equability, and sunshine are essential factors in the climatic treatment of rheumatism; such conditions are found in Texas, Arizona, the Southern Pine Belt, some portions of southern California, the inland Florida resorts, the desert of Egypt, and Algeria.

It is also to be remembered that the hydrotherapeutic treatment of this disease as exhibited at such resorts as Richfield Springs, the Virginia Hot Springs, the Arkansas Hot Springs, Aix-les-Bains, and others, is most efficacious.

Renal Disease.—A warm, equable, windless climate, such as is found in many low inland or coast resorts, examples of which are Arizona, Madeira, the Southern Pine Belt, Florida, southern California, etc. The West Indies are highly extolled by Burney Yeo.

Cardiac Affections. — Warmth, equability, sunshine, and in some cases moderate elevation. "With regard to the heart and great vessels," says Solly ("Hare's System of Practical Therapeutics"), "it may be stated as a generality that they are much more apt to be improved on the sea than on the mountains."

Chronic Diseases of the Genito-Urinary Organs.—Warm and moderately dry climates. Renal tuberculosis requires in general the same climate as pulmonary tuberculosis.

Nervous Maladies.—Each disease must receive its own especial consideration in regard to climate. Some, perhaps the most, require a mild, low climate; others a mildly stimulating one.

Neurasthenia.—Any climate which affords rest, a change of scene and diet, with life in the open air, such as a life in the woods, at sea, or on the plains, is likely to be beneficial. Solly is of the opinion that the larger proportion of cases of neurasthenia are most surely and quickly benefited by high climates, when no especial contraindications exist. When any one symptom is predominant, a climate which is favorable to that is to be selected. If it is insomnia, for instance, the climate which best relieves that—sometimes high altitudes, sometimes the low resorts or the seashore—will prove most beneficial to the general condition.

Senility with its Accompanying Changes.—A warm, sunny, equable climate, where the individual can exist comfortably with the least expenditure of vital force; in winter Florida, southern California, the Riviera, many resorts in the Southern States. Whatever the resort selected it is of the first importance that good accommodations and food should be assured.

Convalescence from Acute Diseases—such as typhoid fever, epidemic influenza, whooping-cough, diphtheria, etc. A warm, sunny climate, inland or seashore, where the patient can live out of doors, protected from wind, and can bathe in the sunshine. Atlantic City, Old Point Comfort, Lakewood, are examples.

Many other diseases and conditions are amenable to climatic treatment with more or less success, and in selecting a health resort for them the writer cannot do better than to repeat for the guidance of the practitioner the three principles enunciated in the previous edition of this HANDBOOK by the accomplished author of the articles upon health resorts: "1. A thoughtful, conscientious, and painstaking consideration of the precise pathological condition of the individual patient, and of his constitutional peculiarities. 2. A careful study of the effects produced upon the human organism, both in health and disease, by variations in each and all of the meteorological factors of climate. 3. The detailed study of these factors as they exist in the climate of each place which experience has proved to be, or analogy has led us to regard as likely to be, well suited for use as a health resort"; and, to this may be added the statement with which Solly wisely concludes his article upon "Climate" in "Hare's System of Practical Therapeutics": "In selecting a climate for an invalid let us above all remember to examine not only the suitable application of the climatic factors to the disease, but also into the peculiarities of the individual and his attendant circumstances."

A word in conclusion regarding home climates. It is true with climates as with other things, that familiarity often breeds contempt. In looking for a health resort we too often forget the possibilities of our own home climate. In the treatment of phthisis as well as other diseases we can, not infrequently, obtain surprising results by a painstaking utilization of the favorable climatic conditions existing in the patient's own locality.

A judicious arrangement of rooms and verandas so as to obtain the utmost possible sunshine and out-of-door life, ingenuity in providing shelter from the wind, ample ventilation, and an equal attention to the hygienic-dietetic *régime* which we would give in a health resort, with the same assiduous devotion to getting well, may produce as happy results as those obtained in many well-known health resorts.

Therefore the physician or his patient should not give up hope by any manner of means, if the conditions preclude a change of climate. "I can cure consumption in any climate," said Dettweiler. *Edward O. Otis.*

HEALTH, STATE BOARDS OF*.—The recognition of the necessity of general or central boards of health or sanitary organizations in each of the States may be said to date from the middle of the nineteenth century. A resolve of the Massachusetts Legislature of 1849 authorized the governor to appoint a commission whose duty it was to make a sanitary survey of the State and to report upon the same. This extremely thorough and comprehensive document presented a plan of organization for a general or state board of health, and although it was nearly twenty years before such a board was organized, the plan laid down in that report was very closely followed in the act of 1869 which authorized the establishment of a state board of health.

The first three state boards of health were organized in three widely separated States, Louisiana,† Massachusetts, and California, in the order named, and these were followed by the establishment of similar general boards in Virginia, Minnesota, and Michigan. The States and Territories which have thus far established state boards of health, with the dates of their organization, are given in the following list:

Louisiana, 1855.
Massachusetts, June, 1869.
California, March, 1870.
Virginia, February, 1872.
Minnesota, March, 1872.
Michigan, 1873.
Maryland, April, 1874.
Alabama, January, 1875.
Georgia, June, 1875.
Colorado, February, 1876.
Wisconsin, March, 1876.
Mississippi, February, 1877.
New Jersey, March, 1877.
Tennessee, March, 1877.
Illinois, May, 1877.
Connecticut, January, 1878.
Kentucky, March, 1878.
Rhode Island, April, 1878.
South Carolina, December, 1878.
Delaware, 1879.
North Carolina, 1879.
Iowa, March, 1880.
New York, May, 1880.
Arkansas, March, 1881.
Indiana, March, 1881.
West Virginia, March, 1881.
New Hampshire, August, 1881.
Missouri, March, 1883.
Maine, February, 1885.
Kansas, March, 1885.
Pennsylvania, June, 1885.
Ohio, April, 1886.
Vermont, November, 1886.
Florida, February, 1889.
North Dakota, 1889.
Nebraska, March, 1891.
Washington, March, 1891.
Oklahoma, March, 1891.
South Dakota, March, 1891.
Nevada, March, 1893.
New Mexico, February, 1895.
Utah, February, 1898.

In general, it may be said that the work of state boards of health has not been largely of an executive character, but has been eminently didactic, and much good has been accomplished by the publication and distribution of tracts, circulars, and pamphlets, relating to the various departments of sanitary work, and by the holding of frequent conventions or assemblies for the free discussion of sanitary subjects.

As a general rule, state boards do not have authority over local boards in sanitary matters, but in some instances they are authorized to exercise co-ordinate power with local boards in preventing the spread of infectious diseases, either within the limits of municipalities or along the border of other States and countries.

The most important duty of sanitary authorities is the management and control of infectious diseases, and while the state boards of health are, from their essential composition, not so closely in touch with the people as municipal boards, yet they are capable of doing excellent service in educating the people in this important sanitary question. In those States which are the most densely settled, and are of comparatively small area, it has been possible for the general boards to perform a considerable amount of executive work, and to carry out the provisions of such laws as have given them authority to act for the protection of the public health.

In several of the States, notably those of the western part of the Union, the function of regulating the practice of medicine has been added to the more distincive duties of public sanitation.

A valuable summary of the powers and duties of state boards of health as they existed in 1879 may be found in Dr. Billings' Introduction to the volumes on "Hygiene" published in New York by Dr. A. H. Buck. In this summary Dr. Billings says: "The state board of health should be the central supervising authority, having much the same relation to local boards that the local board has to the households. Its functions may be classed as follows: (1) To promote the organization of local and municipal boards; (2) to obtain medical and vital statistics; (3) to investigate the causes of undue sickness and mortality; (4) the removal of these causes, acting as far as possible through the local sanitary authorities; (5) the supervision of the hygiene of state institutions; (6) the supervision of quarantine."

ANNUAL PER CAPITA EXPENDITURE OF STATE BOARDS OF HEALTH IN THE YEAR 1898.

(Population Estimated to 1898.)

---

* Condensed from article in "Past and Present Condition of Public Hygiene and State Medicine in the United States," 1900.

† The Louisiana board created in 1855 could hardly be classed as a state board of health, though so named in its organic act, since it was created almost entirely for the purpose of maintaining a quarantine to protect the city of New Orleans.

ANNUAL PER CAPITA EXPENDITURE OF STATE BOARDS OF HEALTH IN THE YEAR 1898.—*Continued.*

(Population Estimated to 1898.)

Groups.	States and Territories.	Fraction of dollar.	Groups.	States and Territories.	Fraction of dollar.
5 mills to 1 cent	Utah	.0098	Less than 2 mills	South Dakota	.0010—
	Connecticut	.0092		Washington	.0007—
	New Jersey	.0089		Nebraska	.0001
	Delaware	.0070	0	Arizona	.0000
	New Mexico	.0055		Georgia	.0000
	New York	.0052		Idaho	.0000
2 mills to 5 mills.	Maryland	.0049		Montana	.0000
	Colorado	.0042		Oregon	.0000
	North Dakota	.0040		Wyoming	.0000
	Ohio	.0040			
	Louisiana	.0040			
	Arkansas	.0036			
	Michigan	.0035			
	Oklahoma	.0032			
	Tennessee	.0029			
	Wisconsin	.0038			
	California	.0027			
	Iowa	.0023			
	Indiana	.0021 +			
	Illinois	.0021			
	Alabama	.0020			

The preceding table presents the per capita expenditure of each state board of health in 1898, upon an estimated population for that year. The comparatively high expenditure of the Gulf States of Florida, Texas, and Mississippi was employed chiefly for the maintenance of quarantine in preventing the introduction of yellow fever from other States and countries.

Samuel W. Abbott.

HEART.—The heart is a four-chambered hollow muscle, divisible functionally into two parts, each consisting of two chambers, an auricle and a ventricle. The right half of the heart comprises the right auricle which receives the venous blood from the body general through the venæ cavæ, and the right ventricle which receives the blood from the auricle through the auriculo-ventricular orifice, and sends it by the pulmonary artery to the lungs. From the lungs the aërated blood is received by the left auricle through the pulmonary veins, and by it transmitted to the left ventricle through the left auriculo-ventricular orifice, the left ventricle in turn pumping the blood by way of the aorta back again to the body. This pump is supplied with appropriate valves to determine the direction of the blood stream (see *Circulation of the Blood,* Fig. 1328).

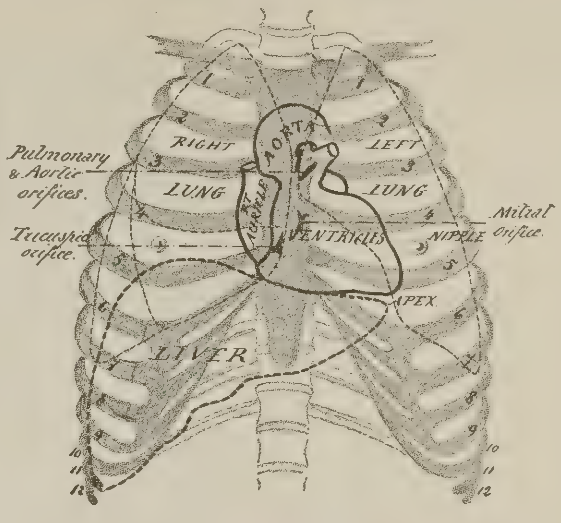

FIG. 2546.—Outline of Heart, Lungs, and Liver to Show their Relations to Each Other and to the Chest Wall. Heusman and Fisher's "Anatomical Outlines."

If the heart be removed from a cadaver that has been preserved by injection with a solution of formalin, which so hardens the tissues that they preserve after removal

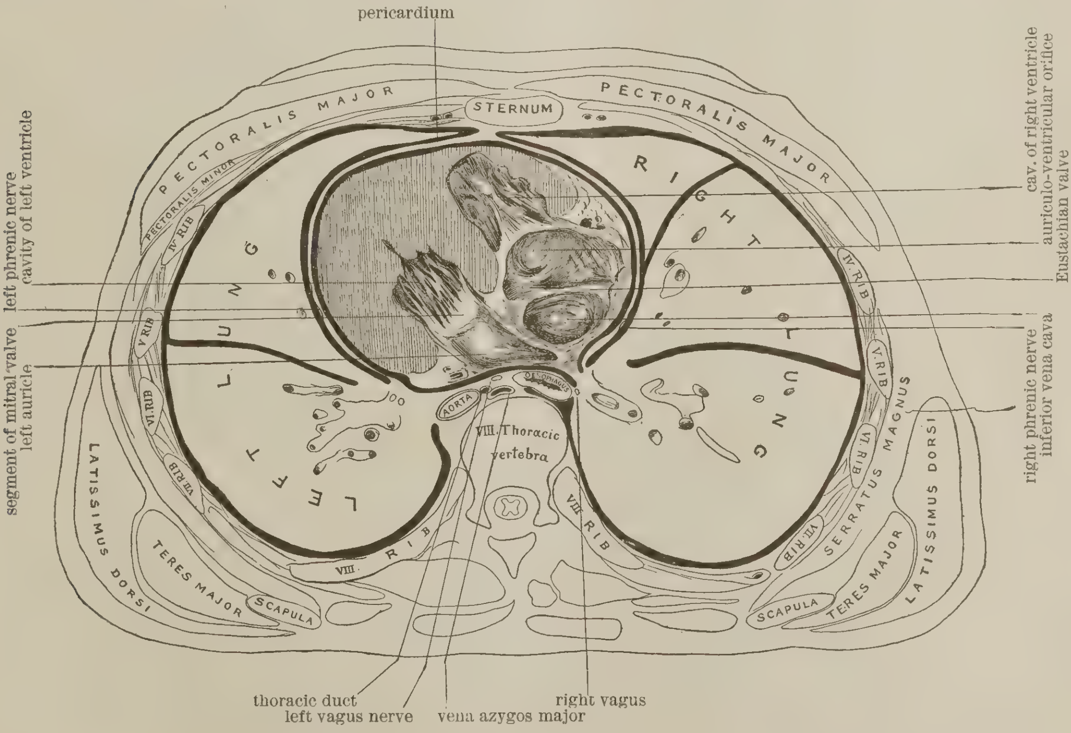

FIG. 2547.—Cross Section of Thorax at Level of Eighth Thoracic Vertebra. (Braune.)

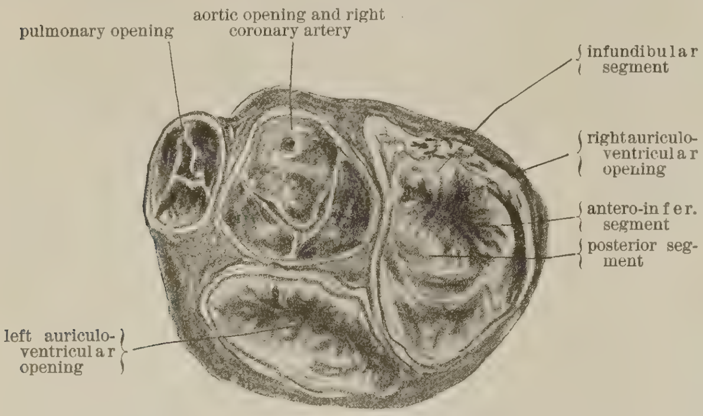
the form they had *in situ,* it is seen to be not so much a conical as a distinctly six-sided organ; the sixth side or upper surface being, however, obscured by the fact that it is almost entirely occupied by the openings of three great vessels, the superior vena cava, aorta, and pulmonary artery (Fig. 2548 and 2553). Two well-marked grooves are distinguishable on the surface of the organ (Figs. 2549 and 2553): the *auriculo-ventricular groove* which marks the separation of the auricles from the ventricles and lodges the main trunks of the cardiac vessels and corresponding nervous plexuses; and the *interventricular groove* seen on the anterior and inferior surfaces of the heart, which marks the separation of the two ventricles and larger branches of the cardiac vessels. A considerable amount of fat in which the vessels are embedded fills up these grooves and obscures them till dissection makes them more prominent. The heart, with the orifices of the vessels that spring from it, occupies a separate serous cavity in the thorax between the two lungs and pleuræ, called the *pericardium,* the heart with its fibro-serous pericardial sac forming the contents of the middle mediastinum (Fig. 2547). Its situation and relations will be readily understood by reference to Figs. 2546 and 2547, the former being self-explanatory, the latter a horizontal section through a frozen body at the level of the eighth thoracic vertebra. Both figures show that the organ is markedly deflected to the left side. Before considering the relations in detail we will make ourselves acquainted with the excised heart. Examined externally the *auricles* are conspicuous by the thinness of their walls, and mainly occupy the right and posterior aspects of the heart. The *ventricles* are thick-walled, form the greater part of its anterior, left and inferior aspects, and the left ventricle is drawn to a blunt point, which is the meeting place of the three just-named surfaces, and is known as the *apex* of the heart.



aortic opening and right coronary artery
pulmonary opening
infundibular segment
right auriculo-ventricular opening
antero-infer. segment
posterior segment
left auriculo-ventricular opening

FIG. 2548.—View of Ventricular Orifices, the Auricles and Arteries being Removed Close to the Ventricles. W. Keiller ad naturam del.

The *right auricle* (Figs. 2549, 2550, and 2554) on the surface presents a quadrangular outline, and occupies the whole right and part of the anterior, posterior, inferior, and superior surfaces of the heart. At its posterior inferior angle is the *inferior vena cava;* at its postero-superior angle the *superior vena cava;* while its antero-superior angle is prolonged into an angular diverticulum which extends round in front of the aorta and is called the *auricular appendix.* The anterior limits of the two cavæ are united by a groove on the surface of the auricle called the *sulcus terminalis* (Fig. 2549) which marks off the portion of the auricle formed by union of the two venæ cavæ from that portion which belongs to the primitive auricle. On opening the auricle (Fig. 2550) this latter portion is found to present on its inner surface a large number of branching muscular ridges united by a membrane so thin as to be translucent. Over the right wall of the auricle these ridges are fairly regular and nearly parallel. They extend from a prominent crest, the *crista terminalis* (which corresponds in position to the sulcus terminalis), to the region of the auriculo-ventricular groove and are called *musculi pectinati.* In the appendix they are much branched, and run vertically across its cavity.

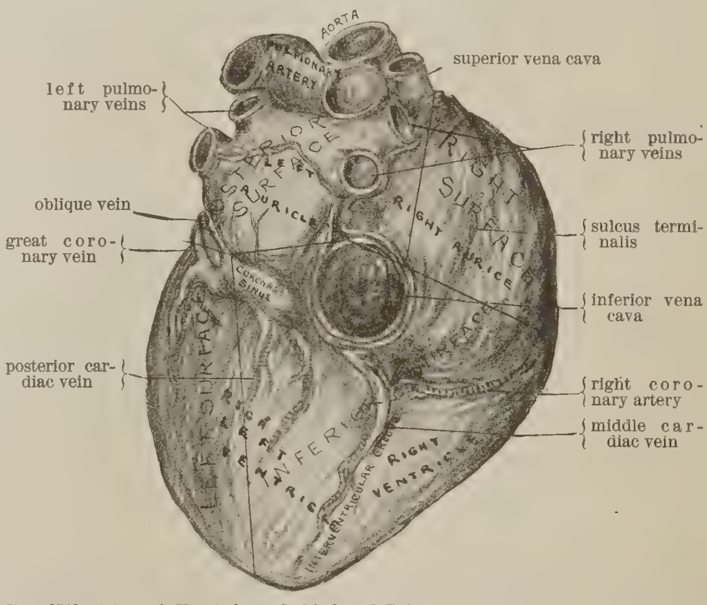


FIG. 2549.—View of Heart from Behind and Below. The surfaces are outlined in black lines. (His, two-thirds.) W. Keiller del.

The rest of the interior of the auricle is smooth and is called the *sinus venosus.* Its left wall in front is in close contact with the commencement of the aorta, and behind this is formed by the septum between the auricles. Here there is a circular depression where the septum is translucent. This is called the *fossa ovalis,* is about five-eighths of an inch in diameter, and is surrounded, except at its lower part, by a prominent muscular ridge, the *annulus ovalis.* The ridge is specially prominent above, and under it is a deep recess, closed after birth except for an occasional minute canal through which a probe can be passed, but open during fœtal life for the free passage of blood from the right to the left auricle. The opening in the fœtal condition is the *foramen ovale.* At the postero-superior angle of the cavity will be found the orifice of the superior vena cava, large enough to admit the little finger, and unguarded by any valve. At the posterior inferior angle is the orifice of the inferior vena cava, which will admit two fingers. Stretching from the right anterior margin of the inferior caval opening to the anterior limb of the annulus ovalis is a prominent musculo-membranous ridge, the *Eustachian valve,* whose function in the fœtus is evidently to guide the blood from the inferior vena cava through the foramen ovale. Its prominence and constancy in the adult seem to show that though its fœtal function is lost, it still serves an important purpose in directing the intra-auricular blood currents. Its muscular portion consists of a strong bundle of fibres which surround the inferior cava and are attached to the septum, thus possibly constricting the caval opening during auricular systole. On the floor of the auricle, just in front and to the left of the inferior caval opening, is the orifice of the *coronary sinus*, guarded below by a delicate semicircular valve which is frequently fenestrated and is called the *valve of Thebesius*. The antero-inferior angle of the right auricle runs into a large funnel-shaped opening, the *auriculo-ventricular orifice*. (Figs. 2548 and 2550). This opening is oval or triangular in shape, readily admits three fingers, and is guarded by the *tricuspid valve*. In addition to these openings there are scattered over the walls of the auricle numerous small pits and little openings called *foramina Thebesii*, some of which are blind depressions, while others are the orifices of small veins.

FIG. 2550.—Right Auricle and Ventricle Opened, Somewhat Stretched Out for Better Display. Drawn from nature by W. Keiller, 1901.

The *right ventricle* (Figs. 2550, 2553, 2557) occupies the greater part of the anterior surface, and about half the inferior surface of the heart. It practically forms the whole anterior inferior border, but stops short of the left inferior angle of the heart, the so-called apex. When opened it is seen to present a floor and three walls, anterior, left, and posterior, the three walls tapering upward to form a smooth funnel, the *conus arteriosus*, which leads into the pulmonary artery. This orifice is guarded by three semilunar flaps which together form the *pulmonary valve*. The left wall of this cavity is convex, owing to the great thickness of the wall of the left ventricle, and here the blending of the walls of the two ventricles forms the interventricular septum (Fig. 2551). The lower two-thirds of the posterior wall of the right ventricle is occupied by the large *auriculo-ventricular* orifice, the upper third tapering into the conus arteriosus and lying in close relation with the aorta. With the exception of the conus arteriosus, the walls of the ventricles are marked by an intricate network of muscular ridges and bands called *columnæ carneæ*, the ridges being mere thickenings of the wall, the bands attached at both extremities and free in the middle. A varying number of these fleshy columns, called *musculi papillares*, end in fibrous string-like bands, the *chordæ tendineæ*, which are attached to the segments of the tricuspid valve. The *tricuspid valve* (Figs. 2548 and 2550), which guards the auriculo-ventricular orifice, is composed of three triangular segments; consisting of fibrous tissue clothed with endocardium, thick at their bases where they are attached around the opening, and thinning off toward their free margins, which are trans-

lucent and jagged. The extent to which the flaps are separated varies greatly, while sometimes there are small intermediate lobes between the main segments. Branched, thread-like chordæ tendineæ pass from the ventricular wall or papillary muscles to the free margins, ventricular surfaces, and attached bases of the segments, each papillary muscle or group of muscles sending cords to the contiguous margins of two separate flaps. Thus when the ventricle contracts the blood is forced in behind the cusps which come together and, being prevented by the chordæ tendineæ from bulging too much into the auricle, effectively prevent reflux of blood into the auricle and compel its flow into the pulmonary artery. Of the three segments the antero-superior is the largest, and separates the conus arteriosus from the auriculo-ventricular orifice. It is therefore called the infundibular segment. It is smooth on both its auricular and infundibular surfaces. The other segments are placed antero-inferiorly and posteriorly, and the last (being in contact with the septum) is called the septal segment. The *musculi papillares* in the right ventricle vary exceedingly. The best marked springs from the anterior wall and has usually a muscular band of varying thickness, called the *moderator band,* attaching its base to the ventricular septum. It sends chordæ to the infundibular and antero-inferior segments. A group of small papillary muscles occupies the floor and lower part of the septum and supplies chordæ to the contiguous margins of the antero-inferior and septal segments; while from the upper part of the septum, in the conus arteriosus, a few chordæ pass directly without a distinct papillary muscle to the contiguous margins of the infundibular and septal segments. The pulmonary valve is so similar to the aortic that one description will do for both.

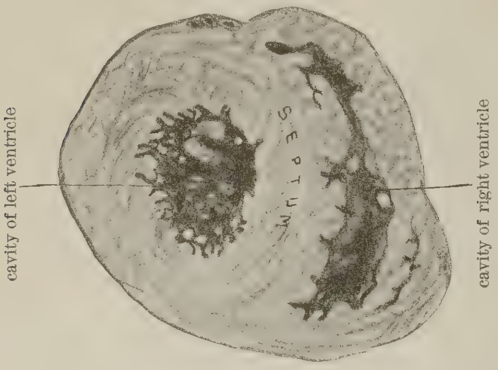

FIG. 2552.—Cross Section of Heart through Ventricles. W. Keiller, ad naturam del.

The *left auricle* (Figs. 2549 and 2556), which occupies the whole posterior surface of the heart, is quadrilateral in outline and slightly convex. At its right and left margins are the openings of the *right and left pulmonary* veins, usually two of each. They vary greatly in size and situation. The *auricular appendix* extends upward and forward from its left superior angle and slightly overlaps the pulmonary artery in front and to the left of that vessel (Fig. 2553). The left auricle is somewhat thicker-walled than the right. On the interior the walls are smooth and the musculi pectinati are few and short and almost entirely confined to a small part of the roof and appendix. The posterior wall and floor are smooth. The left wall is narrow and presents the openings (usually two) of the left pulmonary veins; the right wall has posteriorly usually two, seldom three openings of the right pulmonary veins; none of these has valves. In front of these the right wall is formed by the interauricular septum, and presents superiorly one or two semilunar slits which mark the remains of the foramen ovale. They correspond in position to the upper part of the fossa ovalis and one of these may be still patulous. In five average specimens before me the foramen is not completely closed in any one, but an oblique slit varying from .01 to 1 cm. long occupies its place, and there is no evidence of the last having caused any cardiac embarrassment. The anterior wall in the upper part lies in close relation with the conus arteriosus of the left ventricle and commencement of the aorta; and its lower half is occupied by the obliquely placed somewhat oval *auriculo-ventricular orifice* (Fig. 2548) which admits two fingers easily, thus being distinctly smaller than the corresponding orifice on the right side. It is guarded by the *mitral valve.*

The *left ventricle* (Figs. 2555 and 2551) forms the whole left surface of the heart, a small portion of its anterior, and about half its inferior surfaces. On cross section its outline is seen to be almost circular, its walls being at least twice as thick as those of the right ventricle, which therefore moulds itself to the thicker-walled cavity and assumes a crescentic outline (see Fig. 2552). Its cavity is long and conical, the apex of the cone running to the extremity of the so-called apex of the heart which is thus formed by the left ventricle. The base of this conical cavity presents two orifices (Fig. 2551), the lower of which points backward and opens into the left auricle, and is guarded by the *mitral valve;* while a smooth funnel-like portion runs upward, backward, and to the left into the *aortic opening,* this last being somewhat smaller than the auriculo-ventricular opening, and guarded by the *aortic valve.* The *columnæ carneæ* are short, thin, much branched and best marked at the apex of the conical cavity. The *mitral valve* is composed of two large, well-marked segments, thicker and stronger than those of the tricuspid valve, and between them are two distinct subsidiary flaps. Two large prominent *musculi papillares,* springing respectively from the left and inferior walls of the cavity, send chordæ tendineæ to the upper and lower margins of the valvular segments respectively. They are so situated that when contracted with the ventricular systole they pull the margins of the segments together. Of these two segments, the anterior or *aortic*

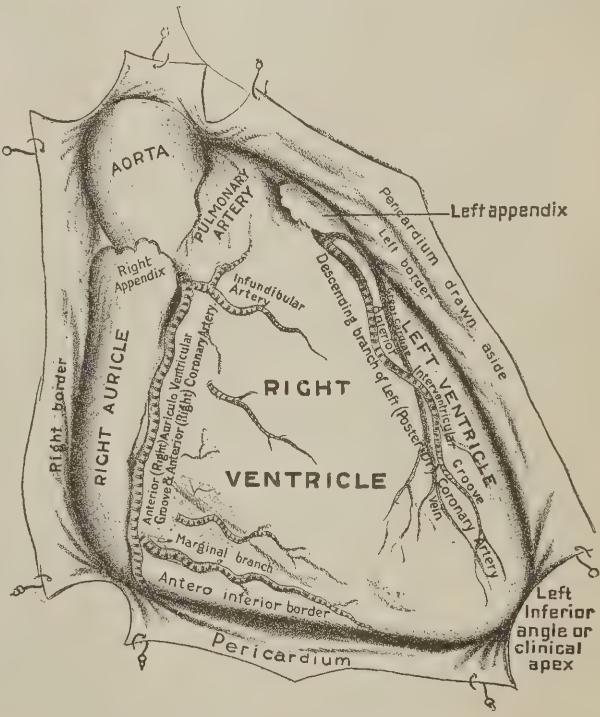

FIG. 2553.—Anterior Surface of the Heart, Pericardium Opened. W. Keiller ad naturam del.

segment separates the auriculo-ventricular from the aortic orifice (Fig. 2551), and is smooth on both its auricular and its ventricular surfaces, the chordæ being attached to its margins only. The *aortic valve* is composed of three semicircular or semilunar folds of fibrous tissue lined below by the endocardium and above by the intima of the aorta. Their convex margins are attached to the ring round the aortic orifice, and their straight edges are free. Thus three pouches are formed open toward the aorta, into which the blood flows when the systole passes off, and thus brings the three segments together so as effectively to stop regurgitation of blood into the ventricle. The aortic wall bulges slightly at each pouch, and each bulging is named a *sinus of Valsalva.* These sinuses in the aorta are arranged, one anteriorly, two posteriorly, and from the anterior sinus springs the *right coronary artery* (Fig. 2548), while the *left coronary artery* springs from the left posterior sinus. Each segment of the valve has at the middle of its free edge a fibrous nodule, the *corpus or nodulus Arantii,* toward which the stronger fibres radiate so as to leave an exceedingly thin, sometimes fenestrated lunated margin on either side of it, called the *lunula.* The free margin of the valve is strengthened by a fibrous band. The portion of the ventricle which leads up to the aortic orifice is so strengthened by fibrous or fibro-cartilaginous tissue as to remain uncollapsed during diastole. The septum between the ventricles is thick and muscular, except for a small area where the aorta springs from the septum. This is the *pars membranacea* of the septum, and here a congenital defect in the septum may cause an abnormal communication between the ventricles.

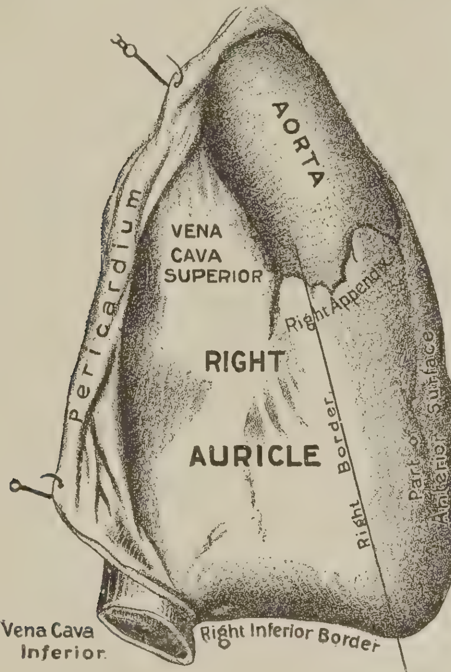

FIG. 2554.—Right Surface of the Heart. W. Keiller ad naturam del.

Relations and Surfaces of the Heart.—As has been already pointed out, the heart is a six-sided or cuboidal body, presenting anterior, right, left, posterior, inferior, and superior surfaces. The *anterior* surface (Fig. 2553) is the first which meets the eye when the thorax is opened. It is triangular in shape, the apex of the triangle being completed by the merging of its upper limit into the aorta and pulmonary artery. It is slightly convex and is directed forward and a little upward, being in sagittal mesial section parallel with the sternum. In it are included the greater part of the right ventricle and portions of the left ventricle, left auricular appendix, right appendix, and part of the right auricle. It is bounded below by the sharp, almost straight *antero-inferior* border (*margo acutus,* inferior border of clinicians), on the right by the nearly vertical and convex *right anterior* border (right border of clinicians), and on the left by the oblique, convex, and slightly rounded *left anterior border* (left border of clinicians). Its left inferior angle forms the *clinical apex. Relations:* Separated from it by the pericardium (Fig. 2547) are the margins of the lungs and pleuræ, sterno-pericardial ligaments, triangularis sterni, internal mammary vessels and sternum, with the fourth, fifth, and sixth left costal cartilages.

The *right surface* (Fig. 2554) is markedly convex, four-sided, lies almost vertically, and is directed toward the right. It is composed of the greater part of the right auricle. Its anterior, posterior, and inferior borders are only slightly rounded and are therefore well defined. At its superior extremity the surface blends with the wall of the vena cava superior and its posterior inferior angle is similarly related to the vena cava inferior. *Relations* (Fig. 2547): It is separated by pericardium from the phrenic nerve and vessels, pleura, and inner surface of right lung.

The *left surface* (Fig. 2555) is a convex triangular area directed mainly upward and toward the left. It includes about one-half of the free surface of the left ventricle and left auricular appendix. It is separated from the anterior surface by the left anterior border; from the inferior surface by a rather sharp left inferior border; and behind it is bounded by the left pulmonary veins and left auriculo-ventricular groove, with the great coronary vein embedded therein. *Relations* (Fig. 2547): It is separated by the pericardium from the left phrenic

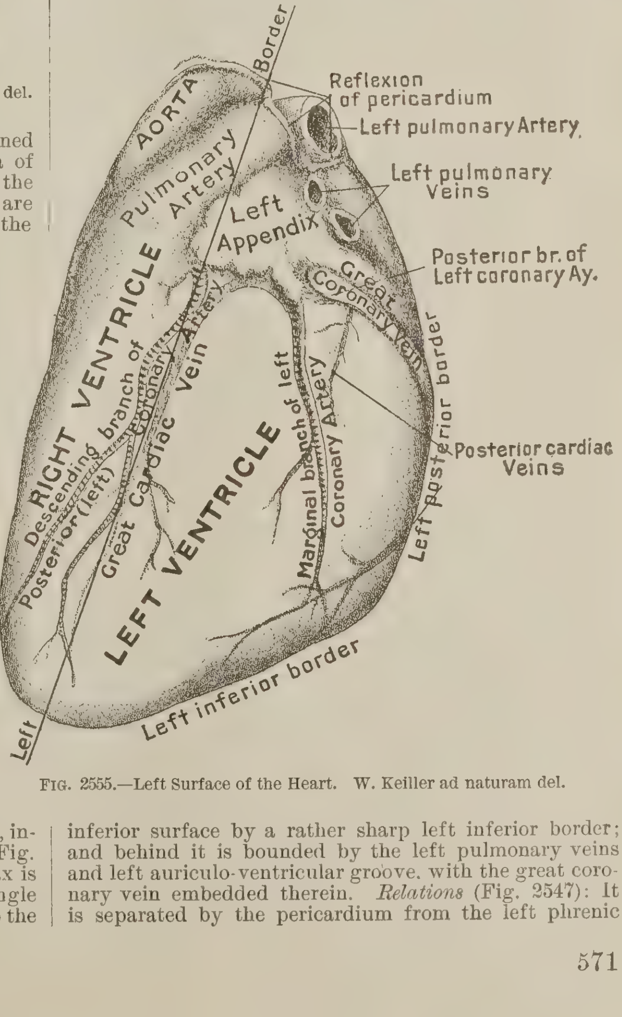

FIG. 2555.—Left Surface of the Heart. W. Keiller ad naturam del.

nerve and vessels, left pleura, and inner surface of left lung.

The *posterior surface* (Fig. 2556) is called the base in text-book descriptions. It is four-sided, convex, vertical, and directed backward. It is formed by the left auricle, and by the portion of the right auricle which joins the two venæ cavæ, and is bounded below by the inferior vena cava and coronary sinus, above by the right pulmonary artery, on the right by a fairly defined border joining the two venæ cavæ, and on the left by the left pulmonary veins and great coronary vein. It is only partially invested by the visceral layer of the pericardium. *Relations* (Fig. 2547): It is separated by pericardium from the bronchi, œsophagus, vagi, descending aorta, vena azygos major and thoracic duct.

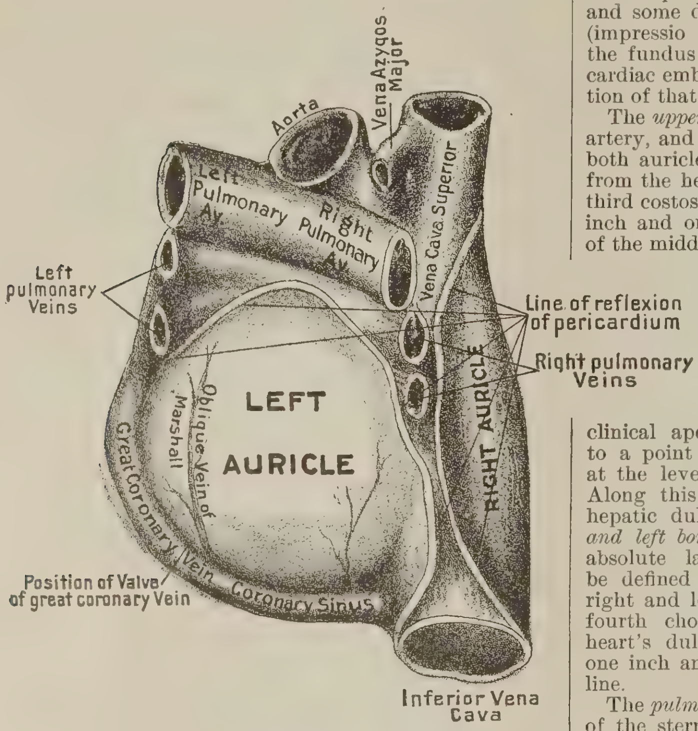

FIG. 2556.—Posterior Surface of the Heart. W. Keiller ad naturam del.

The *inferior, diaphragmatic surface or true base* (Fig. 2557) is quadrilateral, slightly convex when the ventricles are distended or in systole, slightly concave when they are relaxed and empty. It is directed downward and a little backward and toward the right, and is bounded by rather sharp and well-defined borders. It includes a small portion of the right auricle and opening of the inferior vena cava, the rest of the surface being about equally divided between the right and left ventricles. Behind the inferior vena cava is seen a small portion of the left auricle. It presents the inferior extremities of the right and left auriculo-ventricular grooves, and the inferior interventricular groove. *Relations* (Fig. 2546): It is separated by the central tendon of the diaphragm and some diaphragm muscle from the superior surface (impressio cardiaca) of the liver. Its close relation to the fundus of the stomach will help to account for the cardiac embarrassment apt to be caused by acute distention of that viscus.

The *upper surface* gives origin to the aorta, pulmonary artery, and superior vena cava, and is partly formed by both auricles, especially the left. These vessels spring from the heart on a level with the upper margin of the third costosternal articulation, along a line extending one inch and one-half to the left and one inch to the right of the middle line.

Superficial indications (Fig. 2546): The *upper limit* of the heart has just been indicated. The *clinical apex*, or apex beat, is felt between the fifth and sixth ribs, three and a half inches to the left of the middle line. The *antero-inferior border* is indicated on the chest wall by an oblique line, slightly convex downward, extending from the clinical apex on the left, across and slightly upward to a point one inch to the right of the middle line at the level of the sixth chondro-sternal articulation. Along this line the cardiac blends insensibly with the hepatic dulness. These lines being drawn, the *right and left borders* of the heart's anterior surface or the absolute lateral limits of the heart's dulness will be defined by convex lines joining respectively their right and left extremities. Thus, on a level with the fourth chondrosternal articulations, the area of the heart's dulness extends three inches to the left and one inch and three-quarters to the right of the middle line.

The *pulmonary* and *aortic valves* lie behind the left half of the sternum on a level with the lower border of the third costal cartilage. The *right auriculo-ventricular* opening lies behind the sternum on a level with the fourth intercostal space and fifth cartilage. The *left opening* is a little higher and more to the left. (Compare Figs. 2546 and 2548, it being remembered that the surface represented in Fig. 2548 lies obliquely so as to point very decidedly toward the right).

In children the heart is relatively broader and projects more to the left than in the adult, and the apex beat may be in line with the nipple or external to it.

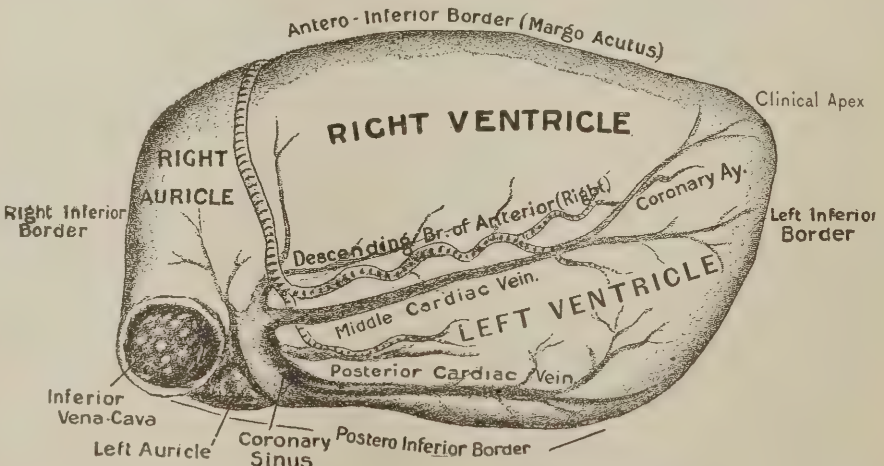

FIG. 2557.—Inferior Surface of the Heart. W. Keiller ad naturam del.

Structure of the Heart.—The heart is invested externally by a fibro-serous membrane, the *epicardium*, under which lies, especially along the interventricular and auriculo-ventricular grooves, a variable amount of fat with the main trunks of the cardiac vessels embedded therein. Its cavities are lined internally by a smooth endothelial lining, supported by a delicate fibrous membrane (the *endocardium*); the main substance of the heart is composed of muscular tissue (*myocardium*), the intricate arrangement of whose fibres will be found described under the heading *Circulation of the Blood* (Vol. III., p. 105). The valves are avascular and composed of fibrous tissue with an endocardial lining; while in the region of the ventricular orifices are fibrous rings, and between the aorta and auriculo-ventricular orifices there is a central fibro-cartilage.

Blood-Vessels of the Heart.—The *right coronary artery* (Figs. 2548, 2553, and 2557) arises from the anterior sinus of Valsalva, passes forward between the pulmonary artery and right appendix, and follows the right auriculo-ventricular groove till it reaches the inferior interventricular groove where it divides into two branches, of which the smaller *transverse* or *auriculo-ventricular* branch continues in the left auriculo-ventricular groove for some little distance, and the larger *descending* (or better, *interventricular*) branch follows the inferior interventricular groove, supplying both ventricles and the septum. This vessel in its course supplies the right auricle and ventricle, aorta and pulmonary artery. Besides the terminals it gives off two named branches, an *infundibular* branch to the front of the right conus arteriosus, and a *marginal* branch which follows the antero-inferior border to the apex. The *left coronary artery* (Figs. 2553 and 2555) arises from the left sinus of Valsalva, passes behind and then to the left of the pulmonary artery, and appears between that vessel and the left auricular appendix. Here it divides into two branches, the *anterior descending* or *interventricular* branch following the anterior interventricular groove to the apex of the heart; the *transverse* or *auriculo-ventricular* branch following the left auriculo-ventricular groove. A considerable marginal branch follows the left anterior border of the heart. It supplies the aorta, pulmonary artery, left auricle, and ventricle. The two vessels anastomose minutely with each other on the heart and with the pericardial and bronchial vessels on the walls of the aorta and pulmonary artery.

The great cardiac or coronary vein, commencing near the apex of the heart (Fig. 2553), accompanies the interventricular branch of the left coronary artery in the anterior interventricular groove; beneath the left appendix it curves backward in the auriculo-ventricular groove and joins the left end of the coronary sinus (Fig. 2556) where its opening is guarded by a valve. Three or four veins, called *posterior cardiac*, but better called left and inferior cardiac veins, course over the left and inferior surfaces of the left ventricle, joining the great coronary vein and coronary sinus. The *middle cardiac vein* (Fig. 2557), commences at the apex of the heart and follows the inferior interventricular groove with the descending (interventricular) branch of the right coronary artery. It joins the right extremity of the coronary sinus. The *small* or *right coronary vein* (Fig. 2557) runs toward the left in the right auriculo-ventricular groove to join the right end of the coronary sinus. The *coronary sinus*, about one inch in length, occupies the inferior extremity of the left auriculo-ventricular groove (Fig. 2557). It receives the veins above mentioned, all of which are guarded by valves where they join the sinus; and empties into the right auricle in front of the inferior canal opening. Its opening is guarded by the valve of Thebesius (Fig. 2550). In addition to the above a small vein, the *oblique vein* of Marshall, runs downward and over the back of the left ventricle to join the coronary sinus (Fig. 2556). This vein is interesting inasmuch as it, with the coronary sinus, represents the left superior cava of the embryo.

The *anterior cardiac veins* are two or three small veins which pass from the anterior surface of the right ventricle directly into the right auricle. They have no valves. Minute veins (the *venæ cordis minimæ*) open directly into the auricle and ventricles.

Lymphatics.—The cardiac lymphatics, found in great number beneath the lining membranes, open into both the right lymphatic and the thoracic ducts. The former are interrupted in a gland which lies between the aorta and the trachea.

The cardiac nerves are described in the article on the *Circulation of the Blood* (Vol. III., p. 113).

William Keiller.

HEART, DEVELOPMENT OF THE.—The vertebrate heart arises in two distinct ways, each of which is intimately associated with the origin of the blood-vessels in general. In the lower vertebrates its first appearance is in the form of a single tube on the ventral median line of the embryo, quite near the head. Fig. 2558 is a section of a salamander embryo in which the heart is just beginning to form. The body cavity, *lh*, is composed of two lateral halves (see *Cœlom*) separated from each other by a median septum. It is in this septum that the heart first makes its appearance. The two layers which contain this septum become separated, and the opening soon becomes lined with a layer of cells, *end*, the endocardium. The cells of the septum surrounding the opening give rise to the muscle walls of the heart.

In higher vertebrates the heart is first formed by the union of two tubes arising from what may be called the outside of the body. Fig. 2559 is a surface view of a young rabbit embryo in which the heart is beginning to form on either side of the body. The omphalomesenteric veins on either side run toward the ventral median line, and later on unite. Their appearance is such, however, that before they are united they may be spoken of as two hearts. Fig. 2560 is from a section through an embryo of the same stage as that pictured in Fig. 2559. The neural canal, *rf*, is just beginning to close, and in the splanchnopleure on either side there is a large fold, *ahh*, which already contains the endothelial tube coming from the omphalomesenteric vein. The tubes grow toward the median lines, but before they unite each has its descending aorta, as shown in Fig. 2561. The rudimentary hearts are formed between the splanchnopleure and entoderm, and as the former surrounds the heart to form its muscular layer the heart protrudes into the cœlomic cavity (Fig. 2560), much as does the single heart of lower vertebrates (Fig. 2558). Soon the two halves unite as indicated in Fig. 2561, and then we have a single heart with two veins entering from behind and two arteries, aortæ, leaving from in front. Although this primary division has nothing whatever to do with the later separation of the heart into its two halves, yet before the two primary hearts are united into a single tube the position

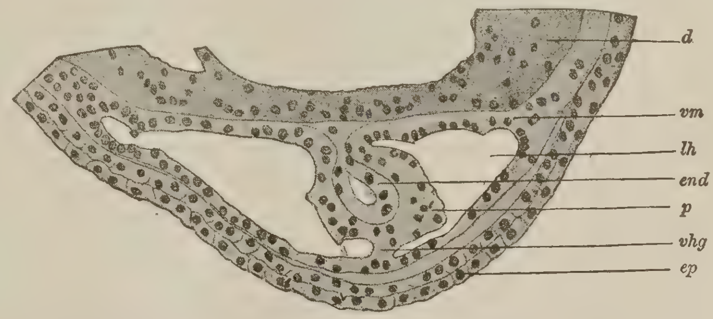

FIG. 2558.—Section through a Salamander Embryo, to Show the Origin of the Heart. (From Hertwig, after Rabl.) *d*, Yolk; *vm*, pericardium; *lh*, body cavity; *end*, endocardium; *p*, muscle layer of the heart; *ep*, epidermis.

of the ventricle is already marked (Fig. 2561, *h*). So, to sum up, in the lower vertebrates the heart appears as a single tube which in general remains such during the life of the animal, and it must be viewed as the primitive form of heart. Higher in the animal scale the heart arises before the foregut is formed, from that portion of the splanchnopleure which later on lies in the median line of the embryo. It is this part which is to give rise to the heart, and in the higher animals the heart arises before the lateral parts have reached the median line (Hertwig).

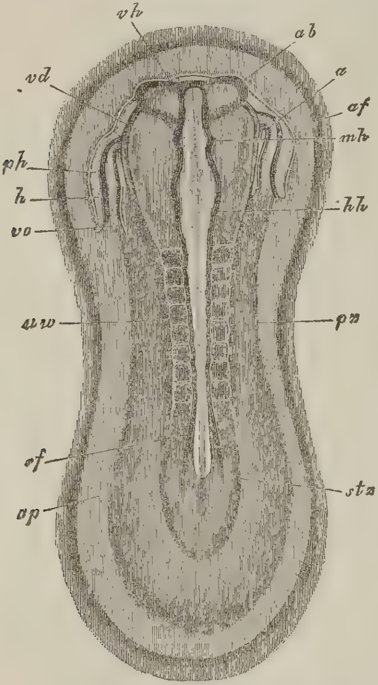

Fig. 2559.—Rabbit Embryo of the Ninth Day. (After von Kölliker.) × 10 times. *h*, Double origin of the heart; *ab*, optic vesicle; *vh*, forebrain; *mh*, midbrain; *hh*, hindbrain; *rf*, medullary groove; *uw*, myotomes; *h*, heart; *vo*, vena omphalo-mesenterica.

The two hearts then unite into a straight tube which is destined to become separated into the right and left hearts of the adult.

Fig. 2562 is a ventral view of two chicks just after the two primary tubes of the heart have united. It is seen that the veins (1) enter from behind, but the relation is soon changed by the heart becoming bent as is already indicated in Fig. 2564.

Fig. 2563 shows the general form of the heart in a very young human embryo. The front of the thorax has been cut away, the incision also extending through the transverse septum and opening the body cavities. The entrance of the veins still lies behind, and the aorta in front, but the heart has already formed one complete loop, making of it an S. Fig. 2564 is a profile of the same embryo, and the heart is indicated as a cast of its cavity. It shows the variations in calibre of the tube throughout its length. At a somewhat later stage the heart is bent upon itself more, and its walls have also become thickened. Figs. 2565 and 2566 are ventral and lateral views of a reconstruction at this stage. The profile view again gives a cast of the heart cavity, which now shows the beginning of the auricle (*V.h.*). At this time the heart is partly tilted over and the veins enter on the dorsal side. Viewed from in front, the auricles, which are just appearing, cannot be seen because they now lie on the dorsal side. A stage later (Figs. 2567 and 2568), the adult form can already be recognized. The heart has undergone a half revolution and has reached the S form. The veins enter nearer the head and the artery arises behind, or away from the head.

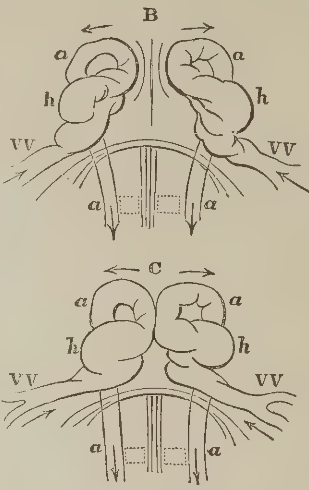

Fig. 2561.—Sketches Showing the more Advanced Condition of the Bitubular Heart of the Rabbit. × 22 times. (After Allen Thompson.) *C* is more advanced than *B*. *VV*, omphalo-mesenteric veins; *h*, heart; *a*, aorta; the arrows indicate the direction of the circulation.

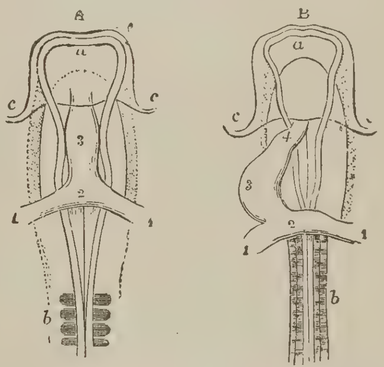

Fig. 2562.—Outlines of the Anterior Half of the Chick Viewed from the Ventral Side, Showing the Heart in its Earlier Stages of Development. × 20 times. (From Quain, after Remak.) *A*, Thirty hours; *B*, forty hours; *a*, anterior cerebral vesicle; *b*, myotomes; *c*, cephalic fold; 1, omphalo-mesenteric veins; 2, 3, 4, the heart.

The aorta lies upon the ventral side and the auricles clasp it from the dorsal. Fig. 2568 shows the great irregularity of the cavity.

A profile view of a heart of this stage is shown in Fig. 2569, which shows the relation of the heart to the surrounding organs. The auricle (*A*) is now in front and the ventricle (*V*) behind. The larger veins enter on the dorsal side by one common opening into the right side of the auricle, the future right auricle.

After the heart has once reached this stage it is only to be separated into its right and left tubes to produce the mammalian heart. In some of the lower animals this never takes place, and in others it is only partial. In cases of arrested development the human

heart in the adult may show any of its embryological forms, as, for instance, an open foramen ovale.

Figs. 2570 and 2571 show the interior of two stages of early human hearts, taken from models made by His. In Fig. 2570, the auricle is enlarged and the vein enters on the right side. The ventricle is considerably smaller and its walls are much thicker than those of the auricle. This is usually the case with the hearts of embryos, as they die with the ventricles contracted and the auricles filled with blood. Between the two there is a narrowed auriculo-ventricular canal and with a corresponding constriction on the outside of the heart. Fig. 2571 shows a more advanced stage. The general state of the heart is much as it is in the Fig. 2570, only that the auricles are "shoved" into the ventricle. This is of considerable importance, as we shall see later on. In both cases the aorta arises from the right side of the ventricle, and in its further development one-half of it must be transferred to the left side in order to produce the aorta proper, while the half which remains becomes the pulmonary artery.

The first important change in the separation of the heart into its two lobes is the formation of two septa, one arising in the auricle, *S.s.*, which grows backward, and one in the ventricle, *S.inf.*, which grows forward. At the same time that these are growing toward each other, a cushion of connective tissue, *s.i.*, is formed upon the two lips of the slit-like auriculo-ventricular opening which aids to complete the septum of the heart. This cushion, or septum intermedium, soon separates the auriculo-ventricular opening into two canals, the right and the left, to become the right and left auriculo-ventricular canals, respectively.

The septum of the auricle is com-

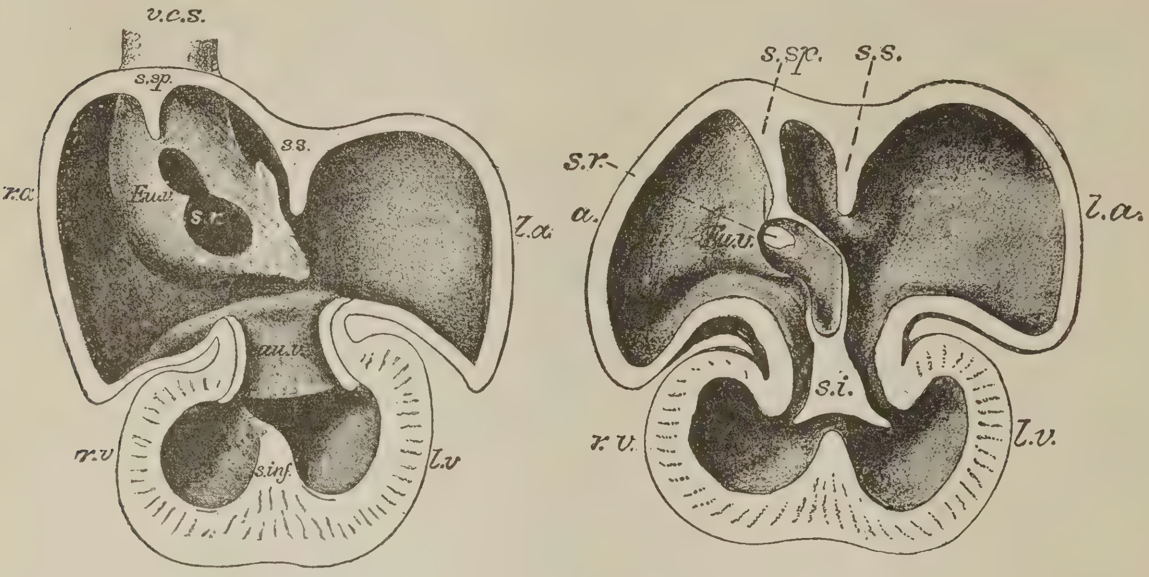

FIG. 2570.

FIG. 2571.

FIGS. 2570 AND 2571.—Two Stages in the Formation of the Septum Intermedium in the Heart of the Human Embryo. (From Quain, after His.) In Fig. 2570 the septum is represented as growing from a triangular area to the left of the sino-auricular orifice; in Fig. 2571 it has coalesced with the endocardial cushions, and lies like a stopper in the auricular canal. *r.a.* and *l.a.*, right and left auricle; *r.v.* and *l.v.*, right and left ventricle; *s.r.*, sinus reuniens; *Eu.v.*, Eustachian valve; *s.sp.* septum spurium; *s.s.*, septum superior; *s.inf.*, septum inferior; *s.i.*, septum intermedium; *v.c.s.*, vena cava superior dextra.

pleted by the septum superior growing backward to unite with the septum intermedium. Before this takes place, however, several changes take place in the septum (Figs. 2572, 2573, and 2574). These figures represent three stages of a lateral view of the two septa above named, with the opening between them. In Fig. 2572, the septum superior is forming, but the S. intermedium is not yet complete. It was at first thought that the opening between them, *O′*, produced the foramen ovale, but later observations by Born showed that there is a

A partial septum of the heart is first met with in certain classes of ganoid fishes (Dipnoi), where it arises by a union of muscle columns in the auricle. This is a very incomplete septum, which is gradually increased in the amphibia. In neither of these cases has the septum reached the auriculo-ventricular opening. This gives us an auricle partly divided, both compartments communicating with each other, and through a common opening with a single ventricle, much as is shown in the heart of the human embryo pictured in Fig. 2570. In the reptiles the septum is complete, and we have two distinct auricles communicating independently with the ventricle. We can view this as the completion of the second stage, *i.e.*, a complete union of the septum superior and the septum intermedium. In birds and mammals, however, there is a secondary rupture of the septum of the auricle; in the former it is multiple, and in the latter, as a rule, single. It is therefore seen that the formation of a secondary or true foramen ovale, as described by Born, is confirmed by the comparative anatomical evidence (see Born, *Arch.*

The opening of the vein is guarded by two folds of the walls of the heart, which really form a complete bicuspid valve (Fig. 2571). An additional fold extends to this from in front, the sectum spurium, *S.sp.* Later on, the orifice enlarges to incorporate a portion of the veins into the auricle, but the right lip of the opening remains permanently as the Eustachian valve. The pulmonary veins are formed later. They grow from the lungs to the left auricle.

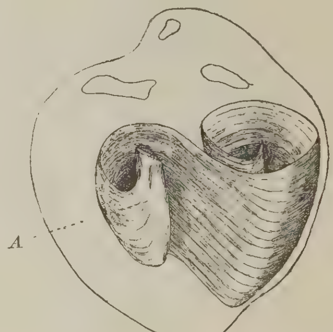

FIG. 2584.—Diagram of the Course of the Deepest Layer of Muscle of the Left Ventricle. (After MacCallum.) *A*, Posterior papillary muscle.

Returning to a stage of heart as represented in Fig. 2571, we notice that the common ventricle shows a constriction on the outside which corresponds to a septum forming on the inside. As this septum from the inside, the septum inferius, grows toward the S. intermedium, it must also grow toward the aorta to join a septum aorticum which is forming there. Figs. 2575–2577, show how this is brought about. Fig. 2575 represents a stage in which the auricles empty wholly on the left side and the aorta arises wholly on the right. As the inferior septum arises the auriculo-ventricular opening moves, as it were, toward the aorta; and when the septum inferius unites with the S. intermedium it cuts the auriculo-ventricular opening in such a manner that the blood coming from the right auricle passes to the right ventricle, and the blood from the left auricle to the left ventricle. A small opening exists for quite a while between the two ventricles, but, later on, this is closed by a membrane of connective tissue. Before the ventricles are completely separated from each other, a view of the septum appears much as is shown in Fig. 2578. The aorta is already completely separated into two vessels: the one which communicates with the right ventricle, communicating above with the fifth aortic arch, and the one from the left with the fourth. The fourth is destined to become the aorta, and the fifth the ductus arteriosus from which the pulmonary artery arises.

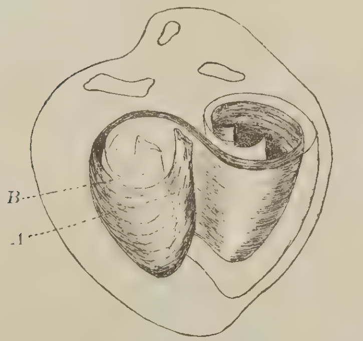

FIG. 2585.—Diagram of the Course of the Layer Superficial to that Shown in Fig. 2584. The outline of the deep layer is also shown. (After MacCallum.) *A*, Posterior papillary muscle; *B*, papillary muscle of the septum.

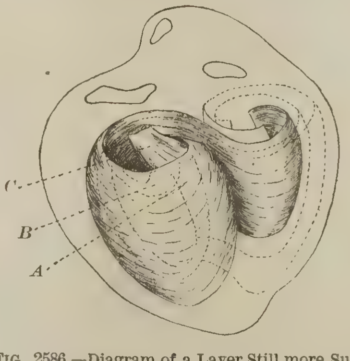

FIG. 2586.—Diagram of a Layer Still more Superficial to that Shown in Fig. 2585, and Ending in the Anterior Papillary Muscle. The other layers are represented in dotted lines. (After MacCallum.) *A*, Posterior papillary muscle; *B*, papillary muscle of septum; *C*, anterior papillary muscle.

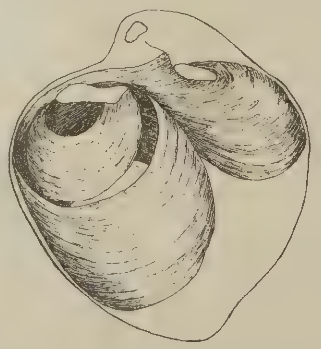

FIG. 2587.—Diagram of the Muscle Originating in the Tendon of the Conus and Upper Part of the Right Ventricle. (After MacCallum.) This layer surrounds the layers represented in the left ventricle in Figs. 2584, 2585, and 2586.

At an early stage the tissue of the ventricle walls becomes spongy on the inside. These meshes and columns play a very important part in the formation of the valves, muscle columns, and the tendons to the valves. We have seen that the septum intermedium is formed in the auriculo-ventricular canal and divides it into a right and a left half. When this is complete a section of the heart gives a picture as shown in Fig. 2579. At the same time a portion of the auricle is, as it were, pushed into the ventricle, as the figure shows. This invagination takes with it a portion of the epicardium, to be incorporated in the formation of the valve. Connective tissue is incorporated in the formation of the valve at its beginning, although the great bulk of the valve is at this time composed of muscular fibres. The burrowing of the ventricle walls includes also the valves, and in this way, as the figure indicates, the primitive chordæ tendineæ are formed. Soon, however, the bands lose their muscle fibres, in the portions which form the chordæ, and in other portions, farther away from the valve, the muscle fibres increase to form the papillary muscle. The valves have therefore a double origin: (1) Peripheral, and (2) from the septum intermedium. According to His, the tendons attached to the valves arising from the periphery, have their permanent attachment to the valve from the beginning, while a portion of those passing to the valve and arising from the septum intermedium may possibly shift their valvular attachment.

The muscle walls of the two ventricles are at first of the same thickness, but, later on, that of the left becomes heavier than that of the right. The spongy layer in the ventricle is covered with endocardium, and from this layer the columnæ carneæ arise.

Recently MacCallum has made extensive studies on the development of the heart muscle cells as well as of the arrangement of the fibre bundles in the hearts of embryos.* MacCallum has found that the heart muscle cell in its development undergoes certain changes by which younger and newly developed cells can be distinguished from fully developed cells. The difference between the older and younger cells is well shown in Fig. 2580, taken from the heart of a very young pig's embryo. It is seen that the younger cells are immediately under the endocardium and that the older cells have been pushed toward the outside and lie immediately below the pericardium. In the younger cells the nuclei multiply by indirect cell division and the distribution of such cells is shown by the letter *A* in Fig. 2581. Here again the growing point of the muscle of the heart is found to be immediately below the endocardium. It appears then that the growth of the heart after the organ is well formed is on the inside immediately below the endocardium. In some way, not yet definitely known, the heart is then gradually rolled up, becoming more and more complex in the higher animals. MacCallum has succeeded in unravelling the musculature in the embryo pig and the human fœtus before the fibres have become interlaced too much. According to him, the fibre bundles can be divided into four groups: (1) Those arising from the auriculo-ventricular ring on one side and passing to the papillary muscle of the opposite side (Figs. 2582 and 2583); (2) those bundles arising from the papillary muscles on one side and passing to the papillary muscles on the opposite side (Figs. 2584, 2585, and 2586); (3) those fibres arising from the auriculo-ventricular ring on one side and passing to the auriculo-ventricular ring of the opposite side (Fig. 2587); and (4) those fibres which simply encircle the left auriculo-ventricular ring and the aorta (Fig. 2588).

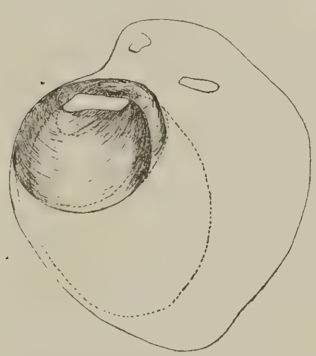

FIG. 2588.—Diagram of the Layer of Muscle Surrounding the Aorta, and Left Auriculo-ventricular Ring. (After MacCallum.) Fig. 2587 is represented in dotted lines.

According to MacCallum, the points to be emphasized in his work are as follows:

The heart consists of several layers of muscle, the course of which is shown in some detail in Figs. 2582–2588. Nearly all begin in the auriculo-ventricular ring of one ventricle and end in the papillary muscle of the other. Those fibres which begin near the outside of one ventricle end near the inside of the other ventricle.

The thin superficial muscle being removed, the left ventricle can be unrolled so that its cavity and papillary muscle are exposed. This shows it to be a flat band of muscle continuous with the muscle fibres which cross over in the septum from the right ventricle.

Grouping these layers together, it is plain that the heart in the embryo is a scroll-shaped band of muscle with tendons at each end. As it grows older the layer of muscle passing over in the septum from the right to the left ventricle remains comparatively thin, while the ventricular cells increase greatly in thickness. The place of most active cell growth is near the inside of the ventricular walls, and they are, therefore, at the two ends of the band of muscles making up the heart.

Franklin P. Mall.

HEART DISEASES: ACTINOMYCOSIS.—Actinomycosis of the heart has been observed a number of times within recent years, and it is very probable that as the reported cases of infection with actinomyces multiply this organ will be found to be not infrequently affected. Since the respiratory tract appears to be one of the most common avenues of entrance of this parasite, secondary involvement of the mediastinum is of frequent occurrence, whereby extension to the pericardium is very likely to take place. Besides infection by direct extension from the mediastinum hæmatogenous metastases in the heart wall may occur, or the heart may be primarily affected, the avenue of entrance being unknown. Paltauf found extensive actinomycosis of the wall of the right ventricle in a tuberculous subject, the condition having been diagnosed as tuberculous pericarditis. In cases observed by Israel, Ponfick, and others, metastases were found in the heart arising from primary foci in the liver, lungs, and other parts of the body (pyæmic actinomycosis). Occasionally a general infection of the body, acute or chronic, occurs, and the heart is involved in common with other organs. Actinomycosis of the heart presents no definite clinical picture. The diagnosis of the condition will rest entirely upon the demonstration of the presence of the parasite within the body. The treatment should be directed along general lines, with the internal use of potassium iodide, which in some cases has appeared to have a specific effect upon the fungus.

Aldred Scott Warthin.

HEART DISEASES: ANÆMIC INFARCTION.—The occlusion of a branch of a coronary artery, if not immediately fatal, is followed by an anæmic necrosis of the part of the heart wall supplied by the occluded vessel. The necrosed area is known as an anæmic or white infarct or as *myomalacia cordis.* The terminal branches of the coronary arteries are true end arteries, and possess but a very limited collateral anastomosis. The area of necrosis produced by the occlusion of a terminal branch corresponds to the physiological distribution of the affected vessel. Infarction occurs most frequently in the portion of the myocardium supplied by the anterior coronary artery, the most common location being in the wall of the left ventricle near the apex.

The occlusion is usually produced by thrombosis or embolism. These events are favored by sclerotic changes; under certain conditions cororonary sclerosis in itself may give rise to infarction without the occurrence of thrombosis or embolism. In such cases the nutrition of the muscle already impaired by the partial obstruction of the vessel caused by sclerosis may be so much further lowered by general circulatory disturbances that the integrity of the muscle can be no longer preserved. Thrombi are of much more frequent occurrence in the coronary vessels than emboli; their formation is directly dependent upon the occurrence of sclerotic changes in the vessel wall. The entrance of emboli into the coronary vessels is of rare occurrence. This fact is explained by the anatomical peculiarities of the coronary arteries, the location of their orifices, angle of divergence with the aorta, force of current, etc. Embolism, however, occasionally occurs; the embolus usually consists of a portion of a thrombus primary in the left heart, either parietal or formed upon the mitral or aortic valves. In other cases the embolus may consist of atheromatous material derived from the vessel wall above the point of occlusion. Septic emboli occur in cases of malignant endocarditis; they are more frequently derived from vegetations on the mitral than on the aortic valve. In whatever way produced, coronary occlusion leads immediately or very quickly to anæmic necrosis, the slight capillary anastomosis and the Thebesian vessels being inadequate to the task of supplying sufficient nutrition to the affected area.

---

* MacCallum: Anat. Anz., xiii., 1897; Journ. of Experimental Medicine, iv., 1899; and Welch Festschrift, Johns Hopkins Hospital Reports, ix., 1900.

The infarct is yellowish or grayish-red in color and of a cloudy, parboiled appearance. The consistence is somewhat softer than that of the normal muscle, and the recent infarct is slightly elevated. Subsequently it becomes softer and depressed. The heart infarct is rarely wedge-shaped, as is so frequently the case in infarction of other organs; but the contour is irregular, areas of living muscle alternating with dead tissue. This irregularity of distribution is due to the peculiar overlapping of the coronary branches, as a result of which adjacent muscle bundles may receive their blood supply from terminal branches arising from different main trunks of the third or fourth degrees. This fact is of great importance in the heart economy in so far as the occurrence of infarction is concerned. Occlusion of the smaller terminals does not lead to an infarction extending entirely through the heart wall, and the chances of rupture or aneurismal dilatation are thereby much lessened. Around the periphery of the infarcted area there is almost always a narrow zone of hemorrhage and congestion outlining the yellowish dead muscle with a border of red. This is to be regarded as being of the nature of a narrow zone of hemorrhagic infarction in the limited area of collateral anastomosis between the occluded vessel and the neighboring terminal. Large hemorrhages occasionally occur about the infarct; these may extend in between the dead muscle bands of the anæmic area, giving it the appearance of a hemorrhagic infarction. Infarcts of small size do not usually involve either the peri- or the endocardium, but larger ones are accompanied by the formation of thrombi on the endocardium and localized areas of pericarditis.

On microscopical examination the muscle fibres in the central portion of the infarct show a condition of simple necrosis, their nuclei having completely disappeared, and the muscle protoplasm presenting a more or less homogeneous appearance, staining deep red with eosin. Occasionally extensive fragmentation or Zenker's necrosis may be present. Around the periphery of the completely necrosed area there is usually found a zone of diffused chromatin, the muscle nuclei at this point showing beginning or partial disintegration. Bordering upon this zone is the area of partially damaged muscle with greatly congested vessels and extensive interstitial hemorrhage. If the infarct is not of very recent occurrence extensive leucocyte infiltration may be found around the periphery, or evidences of repair in the formation of granulation tissue. In older infarcts the dead muscle is almost or wholly replaced by new connective tissue at the periphery, in which numerous hypertrophic muscle fibres may be present. Scattered throughout infarcts of large size small islands of living heart muscle are usually found corresponding to the distribution of neighboring branches. The boundary between such areas and the necrosed muscle usually shows a narrow intermediate zone of partial necrosis, diffused chromatin, and hemorrhage. In the majority of infarcts there is usually present a narrow line of living muscle just beneath the peri- and endocardium, which is to be explained by the presence of small collateral branches running beneath these surfaces.

The regeneration of heart-muscle fibres in or around healing infarcts takes place only to a very limited extent. Evidences of this are seen in greatest degree in week-old infarcts. The division figures are never very numerous, and soon disappear. It is probable that the new cells formed quickly degenerate. Hypertrophic muscle fibres are often very numerous in the immediate neighborhood of a healing infarct. This must be regarded as being of the nature of a compensatory hypertrophy. Whether an increase in the number of fibres takes place or not cannot at present be positively stated. Ultimately infarcts of small size are completely replaced by scar tissue, and the area of induration thus formed appears as a white tendinous patch or band in the heart muscle. The designation of fibroid heart or fibrous myocarditis is applied to this condition as well as to the areas of sclerosis due to obliterating endarteritis.

Septic infarction may occur in cases of pyæmia, the smaller branches of the coronary arteries may be blocked with septic emboli. Purulent inflammation of the vessel wall and the neighboring tissue results, and the area of infarction becomes converted into an abscess. Usually death results from the general condition before these develop into abscesses of large size. In the majority of cases they appear as pinhead abscesses, rarely as large as a pea. Very rarely they may reach such a size as to perforate into the heart cavity or into the pericardium, forming what has been termed acute cardiac ulcer. Embolic aneurismal dilatation of the affected coronary branch may result at the point of embolism, and rupture of this may lead to the formation of a dissecting aneurism of the heart wall.

As a result of anæmic infarction of the heart death may occur instantaneously from the disturbance of the cardiac circulation and the arrest of the fibrillary contractions. In all cases of sudden death occlusion of the coronary vessels should be carefully sought for. Particularly is this the rule in medico-legal examinations. Death may occur before recognizable changes in the structure of the muscle take place. In other cases it may not result for some time after the occlusion of the vessel. It has been shown by animal experiments that the heart muscle is capable of contraction for nearly twelve hours after ligation of the coronaries. At the present time it is impossible to say whether death occurs at the moment of occlusion of the vessel or at the moment of muscle failure. With the softening of the infarcted area either rupture or aneurismal dilatation of the cardiac wall may take place. Sudden death may be caused by the former event. After healing of an infarct the cicatricial tissue may give before the blood pressure and produce an aneurism. In many cases there is a progressive occlusion of the coronary branches with the production of multiple infarcts. A very extensive degree of fibroid heart may result from the healing of these.

The symptoms of anæmic infarction are usually those of angina pectoris. The direct relation between the anginal attack and the moment of infarction has not been sufficiently emphasized. The cases of sudden death are quite frequently preceded by an intense but brief attack of this nature. In other cases there are no definite cardiac symptoms. After healing of the infarcted areas the clinical picture is that of fibrous myocarditis. Prognosis and treatment will be considered under that head.

Aldred Scott Warthin.

HEART DISEASES: ANEURISM.—The term aneurism of the heart is applied to three very different conditions: aneurisms of the coronary vessels, pouch-like projections of the valves, and local dilatations of the heart wall. The original use of the expression cardiac aneurism was that of Avenbrugger and Corvisart, who applied it to all cardiac enlargements of the nature of hypertrophy or dilatation, distinguishing the two as *aneurysma passivum* and *aneurysma activum.* This conception continued up to the time of John Hunter and Matthew Baillie with whom the term took on its modern significance of a partial dilatation of the cardiac wall. In accordance with this idea the condition is often spoken of as partial aneurism, though in the majority of cases cardiac aneurism is taken as referring to aneurism of the wall alone, coronary and valvular aneurisms being considered under separate heads.

ANEURISM OF THE CORONARY ARTERIES.—Aneurismal dilatations of the coronary branches of the second and third degree occur as the result of sclerosis or embolism. They are usually multiple, but may be found singly. They vary in size from a mustard seed to a large cherry, and occasionally form small nodular enlargements scattered over the heart, lying just beneath the epicardium. They are found in greatest numbers and of largest size when due to septic emboli. The symptoms are those of myocarditis. They may rupture either into the pericardial cavity or into the heart wall, in the latter case forming dissecting aneurisms which may be mistaken for true aneurisms of the cardiac wall.

Aneurism of the Valves.—(See article next beyond this.)

Aneurism of the Heart Walls.—Localized dilatation of the heart wall may be congenital or acquired. In the latter case it is due either to trauma or to some pathological condition diminishing the resistance of the heart muscle in localized areas.

Congenital Form.—In defective development of the heart muscle aneurismal or hernial projections of the endocardium may occur between the muscle bundles. As a result of congenital abnormal thinness of the cardiac wall aneurismal dilatations may occur in any part of the heart, most frequently in the membranous portion of the ventricular septum. The occurrence of congenital aneurisms in individuals reaching maturity is, however, very rare, the majority of the cases being found in infants or young children.

Acquired Form.—In the majority of cases this is due to fibroid changes in the heart muscle following coronary obstruction or syphilitic infiltration, less frequently to anæmic infarction, fatty degeneration, mural endocarditis and wounds of the heart. It is not of common occurrence, though cases have been reported with increasing frequency in late years. In 1867 Pelvet collected the cases published up to his time, and in 1883 a similar collection was made by Legg, who found in the literature the reports of 90 cases. Since his article new observations have been constantly made, and the number of recorded cases is now in the neighborhood of 300. According to Willigk, 170 cases of cardiac aneurism were found in 34,000 autopsies. The acquired dilatation may be acute or chronic; according to its manner of formation it may be a pouch-like dilatation communicating with the heart cavity through a large opening, or it may be saccular with a very small opening, or the aneurism may be of the dissecting variety. Rarely it may be multilocular, consisting of a number of intercommunicating sacs.

The majority of cases occur in males of advanced age, but a number of cases in young men have been reported, and one in a young girl of twelve years. In the younger cases the condition is almost always the result of syphilitic weakening of the wall. The usual seat of the aneurism is in the anterior wall of the left ventricle near the apex, occurring in this location in 59 of the 90 cases reviewed by Legg. The septum is involved next in point of frequency, while the auricles and right ventricle are only very rarely affected. Usually the aneurism is single, but very rarely localized dilatations have been found in all four of the heart cavities. In the auricles the whole wall may be involved in the dilatation. Occasionally a number of dilatations, in one of the reported cases four, have been found side by side, their walls in apposition. The aneurismal dilatation of the septum usually protrudes into the right ventricle, but one case having been recorded of its projecting into the left.

The size of the aneurism may vary greatly, from the size of a fist to a man's head. The larger the sac, the thinner the wall. In very large sacs it may be as thin as paper without any traces of heart muscle remaining. The sac may be filled with a soft or firm thrombus. This may become calcified and the sac thus obliterated. Induration and calcification of the sac wall may also occur. Usually the pericardium becomes adherent to the epicardium over the sac, so that eventually the wall of the sac may consist of the endocardium and both the visceral and the parietal portions of the pericardium.

The acute dilatation of the heart wall is usually due to anæmic infarction or septic myocarditis, rarely to direct trauma of the heart, as in the case of stab wounds. In some cases localized degeneration or necrosis of the endocardium may make the latter the place of least resistance. The softened membrane yields to the blood pressure, is torn, blood passes through the rent and gradually undermines the heart muscle. When the area of softening is primary in the muscle the endocardium overlying the weakened spot is stretched or torn, forming a cavity into which the blood forces its way. In this manner the weakened area gradually bulges out more and more until there is a definite pouch formed. Acute aneurisms usually increase very rapidly in size, in some cases becoming as large as the heart, so that the condition has been regarded as one of double heart. Though the sac may become filled with blood clot, the wall never acquires a sufficient power of resistance, and the dilatation usually proceeds until rupture occurs.

Chronic aneurism in the great majority of cases is the result of fibrous changes in the heart muscle. The connective tissue lacking the power of contraction against the blood pressure during systole gradually becomes stretched outward or a cavity may be formed in the wall connected with the ventricle by a narrow opening. By many writers syphilitic myocarditis is regarded as the most common cause of cardiac aneurism of the slowly progressive type. That the fibrous changes are directly the result of syphilis cannot be proved in the majority of cases; much rather is the process to be looked upon as being of the nature of a chronic anæmic infarction due to the progressive narrowing of the coronary arteries through sclerotic changes, which may be due to syphilis or to other causes. In a number of cases, however, the dilatation has been found to be the direct result of gummatous changes in the cardiac wall. Further, the occurrence of coronary sclerosis and fibrous changes in the heart muscle in young individuals may be quite safely regarded as being due to syphilis. Anæmic infarction plays a much greater part in the causation of chronic aneurism than is accorded to it by the majority of writers. Small infarcts are replaced by connective tissue, and up to certain limits the tone of the wall may be preserved, but if the general tone be diminished by fatty degeneration, atrophy, etc., the area of connective tissue offering the least resistance gives way and dilatation occurs at this point. Localized areas of fatty degeneration, atrophy, etc., may of themselves be the primary factor in the production of aneurism.

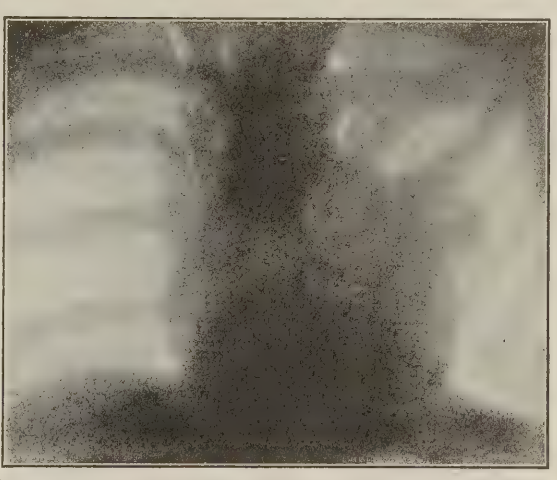

Fig. 2589.—Skiagram of a Case of Cardiac Aneurism. (After Walsham: *Edinb. Med. Journal*, April, 1901.)

Dissecting Aneurism.—The dissecting variety of cardiac aneurism deserves especial mention. Vestberg has made the most complete study of this condition. He defines it as a pathological cavity communicating with the heart or beginning of the aorta, caused by a separation of the layers of the cardiac wall by the blood. Four varieties are distinguished: parietal, septal, valvular, and interparietal. To these might be added a fifth variety when the cavity is formed between the layers of pericardial adhesions. According to Vestberg, the total number of dissecting aneurisms is 60. Of these 47 were interparietal or septal. In 30 cases the left ventricle was the site of the aneurism. The interparietal form occurs in the peri-aortic space of Vestberg, from which the blood may dissect into the auricular or ventricular septum. In 16 cases the point of origin was in the sinus of Valsalva. Acute ulcerative endocarditis is the cause in the majority of cases; in other cases abscess, atheroma, and trauma were the causal factors. Dissecting aneurisms of the aorta may extend into the walls of the heart and through secondary rupture become converted into dissecting cardiac aneurisms.

Diagnosis.—The diagnosis of cardiac aneurism is in the majority of cases impossible; it is usually made at the autopsy table. In the case of acute aneurism the symptoms are those of acute myocarditis; in the chronic form they cannot, as a rule, be separated from those of chronic myocarditis. The aneurism is usually so small as to present no characteristic physical signs. In rare cases the sac has caused erosion of the thoracic wall, forming a visible tumor. The results of percussion and auscultation are very uncertain guides, and though in individual cases unusual murmurs may be produced, they are not constant or characteristic enough to be of diagnostic significance. The Roentgen ray has recently been applied to the differential diagnosis of this condition, and the location, size, and form of the aneurismal dilatation have been shown by this means.

Prognosis.—The prognosis in the majority of cases is not favorable. In early and undoubted syphilitic cases it is relatively better. The terminations are very variable. After reaching a certain degree of dilatation the process may remain stationary. The sac may be obliterated by thrombosis; calcification of the thrombus may occur. Death usually results from cardiac insufficiency to which other factors than the aneurism may contribute. In other cases gradual increase of size with resulting rupture takes place.

Treatment.—The treatment in suspected cases is along the general lines indicated in myocardial and valvular diseases. The possibility of syphilis should always be considered. *Aldred Scott Warthin.*

HEART DISEASES: ANEURISM OF VALVES.

—A valvular aneurism is a cavity in the substance of the valve itself, containing pus and other inflammatory products, or blood clots and débris. The origin seems to be always in endocarditis of a more or less acute form, of which this is really only one of the possible results. If the process starts on the surface of the valve, ulceration may perforate one layer, after which the blood pressure dissects away the other, and so dilates the cavity that it may be as large as a pigeon's egg. On the other hand, the process may begin in the tissue of the valve and result in perforation of one of the layers from within, after which the blood pressure acts precisely as in the former case. These aneurisms are generally single, but may be multiple, and seem to be confined to the left heart. Though many authorities state that aneurisms are most commonly found in the aortic valves, the review of the literature made by Drasche shows that they are more frequently located in the mitral valve and that the anterior leaflet is more often affected than the posterior. Of the 23 cases collected by Pelvet, in 16 the aneurism was on the mitral, in 7 on the aortic valve. The perforation is almost always found on the side of the valve which is exposed to the highest pressure—the ventricular surface of the mitral, the distal surface of the aortic. The cavity may be lined by a laminated clot. The layer of the valve opposite to that containing the perforation may rupture, and the valve then suddenly become insufficient. The symptoms in such a case might be precisely similar to those of valvular rupture from any other cause.

Aneurisms have also been found, though rarely, in the valves of the right heart. As may be readily understood, valvular aneurism is of pathological rather than clinical interest, inasmuch as it betrays its presence by no distinctive diagnostic mark. Acute endocarditis can usually be detected, and so also valvular incompetence, but the precise steps which have led from one to the other in any given case must remain highly uncertain. This being the case there is, of course, no special treatment to be recommended other than that suitable to acute endocarditis. It would seem that the affection occasionally becomes chronic when seated in the mitral curtains, and is, therefore, somewhat less serious than in the semilunar cusps.

There is one other and more chronic condition which is sometimes classed as valvular aneurism. A portion of, or the whole valve, namely, may become so modified by inflammatory changes that its tissue generally yields and becomes stretched by the force of the blood pressure—both layers of the valve remaining in apposition, but being bellied out with the convexity toward the left auricle or ventricle respectively, according as the changes are seated in the mitral or in the aortic valve.

Frederick C. Shattuck.

HEART DISEASES: ANIMAL PARASITES.

—Animal parasites are but rarely found in the human heart. The echinococcus is the most frequent and the only one likely to give rise to serious symptoms. The heart is involved in about one per cent. of all cases of echinococcus infection. In a large per cent. of cases the heart alone was involved. The cysts are found much more frequently in the right side of the heart. They may vary in size from a pinhead to an orange or even larger. In one case in which the hydatid was situated in the left ventricle the enlargement of the heart was so great as to displace and compress both lungs. The cysts may be single or multiple; in one case eighty were found forming a grape-like cluster extending from the right auricle into the ventricle through the tricuspid orifice. As a rule the hydatid develops within the wall, but it may occasionally project as a pedunculated cyst into the heart cavity or into the pericardial sac. In both cases the origin of the cyst is in the myocardium, but as the hydatid increases in size the muscle is either pushed aside or becomes atrophic, and may finally disappear, the cyst then coming to project either upon the pericardial or upon the endocardial surface. The pedicle consists of a portion of the overlying pericardium or endocardium. In rare cases the cyst may extend entirely through the wall, forming a fluctuating tumor covered on one side by pericardium and on the other by endocardium. The large hydatids may contain numerous daughter cysts, varying in size from a pea to a pigeon's egg. The heart muscle in the immediate neighborhood of the cyst may show no changes or the muscle fibres may be atrophic. The thickness of the cyst wall varies from 1 to 5 mm., but this may be much increased by fibroid changes in the overlying peri- or endocardium.

Small hydatids of the myocardium not projecting into the pericardial sac or heart cavity produce no symptoms and are usually discovered only at autopsy. When the cyst projects into the cavity of the pericardium, pericarditis may be produced, and this may in turn give rise to a pleuritis by direct extension. Subpericardial hydatids, however, do not always excite pericarditis. In neither case are the symptoms characteristic. Hydatids projecting into the heart cavity are very likely to rupture. In this event sudden death may result from the embolism of the daughter cysts. In the great majority of cases the perforation is into the right heart, the cysts blocking either the tricuspid orifice or the pulmonary artery. Smaller cysts may pass through the main pulmonary branches and lead to embolism of the smaller arteries and the formation of multiple hydatids throughout the lung. Death may result in such cases from pneumonia, slowly developing pleuritis, general cachexia, etc. Partial obstruction of the pulmonary orifices may give rise to symptoms of pulmonary stenosis and insufficiency. Rupture of an echinococcus cyst into the left heart may lead to blocking of the aortic orifice with resulting stenosis and insufficiency, or smaller cysts may cause occlusion of peripheral arteries, leading to local gangrenous conditions. In one case rupture occurred into both the right and the left heart. Embolism of echinococcus cysts in the right heart or pulmonary vessels may also occur as the result of the rupture of primary hydatids into the large veins. This occurs most frequently in the case of liver hydatids.

The differential diagnosis of heart hydatids is in the majority of cases impossible. The condition may be suspected when hydatids are present in other parts of the body, or from the nature of the emboli when embolism occurs. In one of the reported cases, in which there were numerous metastases throughout the lung, small cysts were found in the sputum. Aspiration of the pericardial sac and microscopical examination of the fluid thus obtained may lead to the recognition of the condition. In those cases in which the cysts do not rupture or project into the pericardial sac the symptoms are of a very indefinite nature and may suggest either myocarditis or valvular lesions. The treatment is entirely symptomatic. In certain cases surgical interference may be of avail. Goodhart claimed to have cured a case of hydatid cyst of the cardiac wall.

The cysticercus cellulosæ is of rare occurrence in the heart, only about thirty cases having been reported. The left ventricle appears to be most frequently affected. The cysts are usually few in number, the size varying from a bean to a hazelnut, rarely larger. They may be found in the muscle or just beneath the endo- or pericardium. As in the case of the echinococcus hydatids they may project from the endocardial surface into the blood stream, being attached to the wall by a slender pedicle formed by the endocardium. The layer of endocardium over the cyst may become very much thickened. The condition cannot be diagnosed during life, the symptoms being of a very indefinite character or entirely wanting.

Trichina spiralis is stated by many writers never to occur in heart muscle, but cases of such occurrence have been observed by Leuckart, von Zenker, and Fiedler. Pentastoma denticulatum has also been found in the heart wall. In the case of both of these parasites the affection of the heart is of pathological interest only.

Aldred Scott Warthin.

HEART DISEASES: DISPLACEMENTS.—DEFINITIONS AND VARIETIES.—The heart, in a state of health, is subject to certain changes of position, caused, first, by the respiratory movements, and, second, by alterations in the bodily posture. Abnormal displacements of the organ may be either congenital or acquired. The latter only—or those that occur as the result of disease—will be considered.

In studying the displacements of the heart it is important to remember that the organ is held *in situ* directly by the great vessels, and only indirectly, through the pericardium, by the diaphragm. The attachments, fixing only the base of the heart, permit free play to the body of the organ, which hangs loosely in the pericardial sac, and very easily undergoes displacement laterally or vertically, while its dislocation either forward or backward is exceedingly rare. This statement, however, points only to a broad general classification of the disorders in question, since the heart is very seldom displaced in an absolutely horizontal, or in an absolutely vertical, plane.

MORBID ANATOMY.—It is noteworthy that the amount of dislocation actually found after death is usually less than the physical signs during life have led one to expect. The most obvious, though less important, change which the heart undergoes is a disturbance of its normal relations to adjacent structures. Compression of the cardiac walls, which may occur to a greater or less degree in the pressure class of cases, may be the more important condition. The pericardium is sometimes displaced with the heart, or greatly stretched, and the great vessels at the base of the heart and at the root of the neck may be stretched and twisted, their change in position varying with the direction and extent of cardiac displacement. In some instances the circulation in the vessels is seriously impeded. Occasionally the pericardium and heart become adherent, and adhesions between the pericardium and pleura fix the heart in its abnormal position.

The functional disturbances resulting from these alterations vary with the cause of the displacement. In those which are due to pressure, the heart, if healthy, suffers little or no real compression, even when the dislocation is effected rapidly; and if it is displaced in front of, and in contact with, a solid tumor, such as an aneurism, a solidified lung, or the spinal column, its impulses may be so vigorous and diffused as to be mistaken for cardiac hypertrophy. But if the heart is diseased, and especially if its walls are degenerated, or its cavities much dilated, sudden compression, although moderate, may cause embarrassment of the cardiac action, and even induce a fatal syncope. In those displacements which are due to retraction of either lung, the heart is displaced toward the retracted side, partly by traction, and partly by extra-distention of the opposite lung, and the effects upon the functional activity of the heart are comparatively slight. In very rare cases the heart, when displaced, becomes involved in the inflammatory process of the lung or pleura, which leads to the displacement, and fibroid changes in its walls, occurring secondary to adhesions, ultimately interfere greatly with the heart power.

ETIOLOGY.—The causes of acquired displacement of the heart are most conveniently arranged in two classes: first, conditions that exert pressure, and second, conditions that exert traction upon the heart. On the same principle all cardiac displacements have been placed under the two heads of "excentric" and "concentric." In the former of the above classes, the heart may be pressed or pushed out of position by fluid effusions into either pleural cavity. This is by far the most frequent cause of lateral displacement. Pneumothorax will also push the heart to one side, and when accompanied by perforation and inflammatory effusion, will carry the displacement to its utmost possible limit. Hydrothorax being usually double, and, therefore, pressing equally on both sides of the heart, does not displace the organ laterally, but downward. Intrathoracic tumors, aneurisms, and abscesses sometimes press the heart to the right or the left. Hypertrophy and emphysema, or other causes of enlargement of the lungs, occasionally operate in the same way, as also does extensive peumonic consolidation. Pericardial effusion, when considerable, but not extensive, may push the apex into a position corresponding to the left nipple, or even above it. Cardiac displacement may also depend upon various abdominal conditions, as gaseous distention of the stomach and intestines, enlargement of the liver or spleen, the pregnant uterus, abdominal tumors or ascites. Diaphragmatic hernia or abscesses in extremely rare cases cause displacement of the heart upward.

In the second class of cases the displacement is concentric, that is, toward the origin of the displacing force. This movement takes place during absorption of pleuritic effusions, with imperfect expansion of the lung; and in consequence of a fibroid phthisical process or cirrhosis of the lung causing a gradual decrease in its volume. The heart also suffers traction in some forms of deformity of the chest dependent upon curvature of the spine. It must be observed, however, that in all these instances the displacing force is in reality one of pressure, resulting in displacement from removal of the normal counter-pressure. In certain cases, however, actual traction undoubtedly occurs, as when the pericardium becomes involved in a cirrhotic process in the lungs, or in an adhesive pleurisy, and it and the heart are displaced by the subsequent retraction.

Since displacement of the heart is a purely mechanical process, its motion will be subject to the universal law of moving bodies; that is, it will take the direction of least resistance, or of the resultant of all the acting forces. The more common elements of this resultant are:

1. The restraining force of the cardiac attachments, particularly at its base.

2. The density and resistance of the surrounding tissues. This latter may be positive, as in case of a solid tumor, or negative, as in pneumothorax.

3. The weight of the heart is, as a rule, of slight importance. In cardiac hypertrophy, however, it may be sufficient to produce temporarily, during decubitus on the left side, a decided displacement.

4. The direct exciting cause either of pressure or of traction.

These elements may produce one or both of two forms of motion—either distinct displacement or rotation of the heart about one of its axes. Rotation, owing to the peculiar attachments of the heart, is almost invariably about the long axis, or a fixed point at the base.

Passing now to a special consideration of the causes operative in the several varieties of displacement, we find that displacement toward the left, which is most common, is brought about by contraction of the left lung by accumulation of fluid or air in the right pleural cavity, or by solid enlargements of the right lung or right lobe of the liver. Displacement toward the right is most frequently due to the presence of fluid or air in the left pleural sac, but may also result from contraction of the right lung consequent upon chronic pleurisy or fibroid phthisis; and from the development of tumors in the left side of the chest or mediastinum. Displacement downward may be caused by aneurisms or solid tumors, emphysema of the lungs, etc., in the thorax, or by collapse of the stomach or intestines. Displacement upward may be due to solid, liquid, or gaseous accumulations in the abdominal cavity, ovarian tumors, enlargement of the liver, fibroid tumors of the uterus, etc. Enlargement of the left lobe of the liver usually displaces the heart upward and to the left, while great enlargement of the spleen may push it upward and to the right. Enlargement of the liver from abscesses will also raise the organ somewhat, a fact which may become very valuable as a means of distinguishing between hepatic abscess and abscess in the abdominal wall over the liver. Another cause of this displacement is contraction of the upper part of either lung, the most common pathological condition being phthisis. Forward displacements are usually caused by an aneurism, or a solid tumor in the posterior mediastinum. Backward displacement may be produced by tumors in the anterior mediastinum, collections of air, pus, or blood in the same situations, or a posterior exostosis of the sternum.

Symptoms and Physical Signs.—Simple displacement of the heart, unattended by compression of its walls or torsion of the great vessels, causes no distinctive subjective symptoms. This is especially true when the displacement has been gradual. When it has been rapid, however, or is due to pressure, symptoms of embarrassed cardiac action may be developed suddenly. They commonly consist of præcordial oppression, more or less severe pain, amounting even to true angina; palpitation with its accompanying peculiar sense of lack of breath, which may increase until it becomes absolute dyspnœa; a weak, irregular pulse, and a pale or cyanotic countenance. Such sudden compression results most frequently from a rapidly developed gaseous distention of the stomach or intestines, and may quickly become dangerous, and, if not relieved, produce collapse and death.

Lateral displacements are usually more readily detected when occurring toward the right than toward the left side. In the former case the apex beat not infrequently corresponds to the right nipple, between the fifth and seventh ribs, the apex itself being usually raised by the width of an intercostal space above the normal level. In displacement toward the left the apex beat may be observed in the axillary region, with little or no perceptible movement at the normal situation of the apex.

Dr. Douglas Powell has shown that in right lateral displacement the apex of the heart is depressed, but never so as to occupy a position external to the base; whereas in displacements to the left the apex is relatively elevated, and the long axis of the heart is nearly or quite horizontal. According to Hayden, the distinctive features of lateral displacement from liquid effusion into the opposite pleura are the slow and mensurable mode of its occurrence; percussion dulness on the side whence the heart has been displaced, and clearness on the opposite side, beyond the limit of cardiac dulness; and, in the event of the removal of the displacing medium, return of the heart to its natural situation, or beyond it when the lung previously compressed has become incapable of expansion. Since the apex of the heart is so much more movable than its base, it is evident that, in cases of displacement, the maximum points of its sounds will not be equally removed from their normal situation. Thus, in left pleuritic effusion, when the maximum point of the first sound is carried out of place to the extent of seven or eight inches, the maximum point of the second sound is scarcely ever changed more than an inch and a half. In displacement to the right a systolic murmur has been noticed, which is ascribed to a twisting of the great vessels. When displacement of the heart is caused by cancer of the lung or pleura—with or without effusion of serum—two diagnostic symptoms of great value are especially to be noted, viz., enlargement of the subcutaneous veins of the affected side of the chest, and distinct transmission, on the same side, of the sounds of the heart. These signs, when accompanied by dulness on percussion, absence of respiratory sounds, and vocal fremitus, except at the root of the lung, and by excentric displacement of the heart, become pathognomonic of cancer of the lung or pleura.

In downward displacement the heart not only lies lower than usual, but it generally sways a little to the right. Displacement in this direction is limited by the diaphragm, and by the attachments at the base of the heart. It is most frequently caused by emphysema of the lungs, which constitutes, in fact, one of the most valuable signs in this form of displacement. If the apex beat is perceptible at all, it is situated below and to the left of its normal position. There is pulmonary resonance instead of dulness in the præcordial area, and the cardiac sounds are transferred to the epigastric triangle and the lower left cartilages.

Upward displacement appears to reach its maximum when resulting from ovarian dropsy. In some of these cases distinct impulse is not to be felt below the second interspace. The sounds of the heart are carried upward and weakened. In pericardial effusion the cardiac impulse may correspond in position to the left nipple, or even be shifted farther in that direction. When the effusion is very copious the apex beat may be completely obscured.

Backward displacement occurs most frequently in connection with other forms of dislocation. It is unaccompanied by any physical signs due directly to the condition itself.

Forward displacement is ascertained with difficulty. The physical signs are: Increase of the area and strength of pulsation and of præcordial dulness; bulging of the same sometimes is noticed in young subjects. The cardiac sounds are intensified.

Diagnosis.—The diagnosis of acquired displacements of the heart is to be made by the position of the apex beat, and of the impulse of the organ generally, by the altered locality of cardiac percussion dulness, and by the comparative intensity of the heart's sounds, more especially of the first, at different parts of the chest. The chief conditions which simulate cardiac dislocation are the following: Physiological displacements, to which reference was made at the outset; præcordial bulging in cardiac hypertrophy; intrathoracic tumors and aneurisms lying behind the heart and pushing it forward—thus producing the closest possible resemblance to cardiac hypertrophy; adhesions of the pericardium; atrophy of the lungs.

Prognosis.—Displacements of the heart being, in most instances, attended by only a slight amount of functional disturbance, and oftentimes by none at all, their prognosis is determined by the disease in which they originate. As already mentioned, when they are accompanied by sudden and violent compression of the heart, these symptoms, if not relieved in time, may result fatally. Usually, however, the direct consequences of these displacements are annoying rather than serious.

Treatment.—There is no direct treatment of cardiac displacements, they are to be remedied only by the removal of their cause; but this, in the traction class of cases, is very rarely possible. In those, however, which result from pressure, treatment is often both urgently indicated and highly successful. The troublesome pulsation which is sometimes experienced may frequently be relieved by the simple application of a belladonna plaster, with assurances as to the unimportance of the symptom. *Alfred L. Loomis.*

HEART DISEASES: ENDOCARDITIS.

HEART DISEASES: ENDOCARDITIS.—Endocarditis is an inflammation of the endocardium, *i.e.*, of the membrane lining the cavities and valves of the heart. In the great majority of cases the valvular endocardium is alone involved.

Classification.—Endocarditis is divided into two large classes, acute and chronic. We shall confine ourselves chiefly to a description of the acute form. Chronic endocarditis is practically synonymous with chronic valvular disease of the heart.

Acute endocarditis is divided into benign and malignant. These are differentiated both clinically and pathologically. The synonyms of benign are simple, rheumatic, verrucose and papillary; those of malignant are ulcerative and infective. It must be remembered that the distinction between benign and malignant is one not of kind, but of degree, as all stages between the two are found, and the same bacteria may be present in both.

History.—Bouillaud first recognized endocarditis as a distinct disease, publishing an account of it in his work on the heart and vessels in 1824. The discovery of the stethoscope by Laënnec made it possible to recognize endocarditis during life. Previous to this time it was impossible to diagnose this disease with any degree of certainty on account of its indefinite and unreliable symptomatology. In 1814 Kreysig of Dresden devoted special attention to inflammation of the lining membrane of the heart. Bouillaud by means of the signs furnished by Laënnec was able accurately to localize the endocarditis on certain valves. He declared there was a close relationship existing between rheumatism and endocarditis. He also called attention to the fact that other diseases than rheumatism, for instance, pneumonia, might produce endocarditis. He recognized likewise the fact that the acute form might be attended by symptoms of pyæmia. Virchow described the process of embolism, thus explaining the obscure complications on the part of the brain and kidneys, so intimately associated with endocarditis. Following this the important additions to our knowledge of the disease have been made by bacteriologists. Klebs in 1878 was the pioneer and insisted upon it that the various bacteria of any one of the infectious diseases might colonize on the endocardium and produce endocarditis. He showed that both the benign and the malignant forms were caused by bacteria. Litten found the same micro-organism in both forms and showed that there was no abrupt, but only a gradual difference between the two. Since this time multitudinous investigations have been made by bacteriologists all over the world, largely increasing our knowledge of the etiology of the disease.

Bacteriology.—The following bacteria have been found in the vegetations of endocarditis: Streptococci, staphylococci, pneumococci, and gonococci most frequently; less often the bacteria of typhoid fever, anthrax, diphtheria, tuberculosis, influenza, and the Bacterium coli communis.

Etiology.—Acute endocarditis is in most cases a product of bacterial activity. It is usually secondary to the various infectious diseases. When, as rarely happens, a causative factor cannot be found, it is termed cryptogenetic. Bacteria cannot always be demonstrated, but this may be due to the fact that they are likely to disappear as the vegetation becomes old. Sometimes it is possible to demonstrate them only by culture methods.

Since the time of Bouillaud acute articular rheumatism has been recognized as the most important associate of endocarditis. It is incorrect to speak of it as a cause, since it, like endocarditis, is the result of bacterial activity, with different localizations. When the germ or its toxin attacks the joint it is rheumatism; when the endocardium, endocarditis. In a certain percentage of cases, the pericardium is attacked either alone or together with the endocardium.

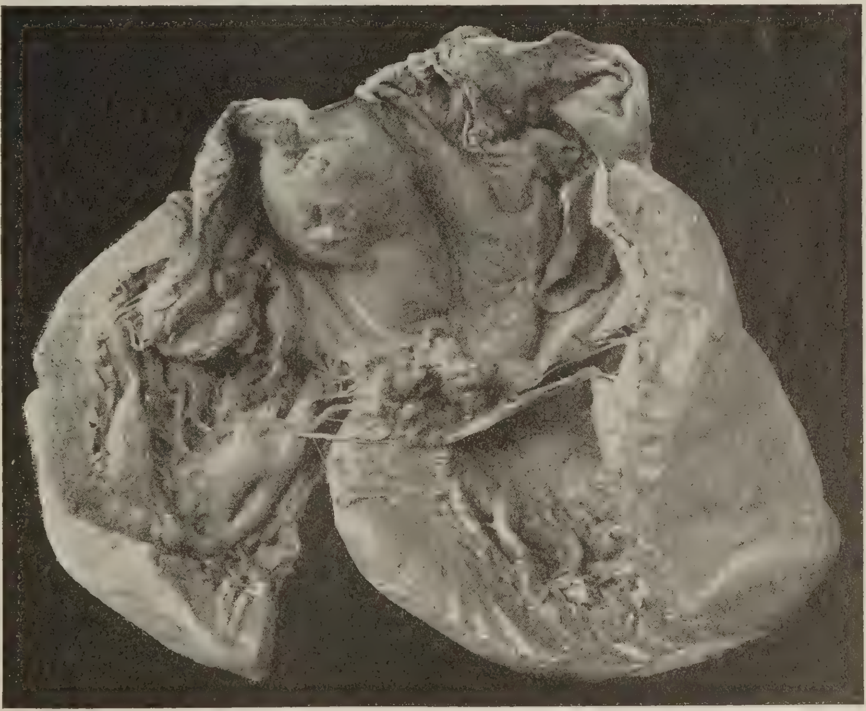

Fig. 2590.—Malignant Endocarditis Involving the Mitral Valves and the Left Auricle. (Original.)

Chorea seems to have a special association with endocarditis. The vast majority of fatal cases show endocarditis. During childhood scarlet fever is more often associated with endocarditis than any of the other diseases of early life. Thayer and Lazear have analyzed thirty cases of fatal ulcerative endocarditis which occurred in gonorrhœa.

Osler has demonstrated the frequent association of pneumonia with malignant endocarditis. Infected wounds, or septic processes, external or internal, such as puerperal fever, boils, gastric ulcer and bone necrosis may also be followed by the malignant variety. The infectious agent may find an entrance through lesions of the skin, mucous membranes of the throat, gastro-intestinal, respiratory, and genito-urinary tracts—and produce endocarditis.

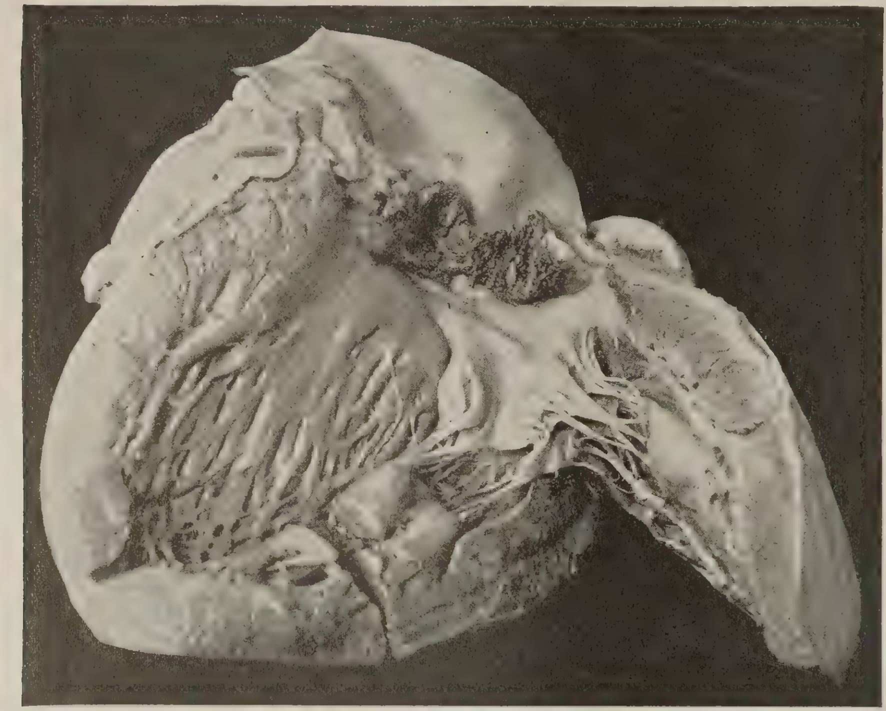

FIG. 2591.—Malignant Endocarditis; Ulceration of the Aortic Valves; Hole through One of the Valves; Old Atheroma. (Original.)

It is frequently found in debilitating diseases, such as Bright's disease, diabetes, cancer, etc. These diseases reduce the vitality of the patient, rendering him more susceptible to the action of the infectious agent.

Not many years ago in discussing the etiology of this disease a prominent authority wrote that it arose from exposure to cold or without any cause being discoverable. Our present certainty regarding its etiology is in pleasing contrast to former guesswork. Benign endocarditis is common to childhood. This is supposed to be due to the greater vulnerability to bacterial action during early life. The malignant form is rare in childhood.

MORBID ANATOMY.—*Benign Form.*—As a rule endocarditis involves the valves, but it is possible for it to be located upon the chordæ tendineæ, or the walls of the cavities (mural endocarditis). Grayish-yellow, opaque bodies, called vegetations, are seen upon the diseased valves, usually near their edges. They may be minute and in great numbers, may resemble venereal warts, or may be so large as to resemble an extensive cock's comb. Microscopically, they consist of a superficial layer of coagulated fibrin, in the upper layer of which are entangled numbers of leucocytes deposited from the blood stream. Deeper down is a layer of simple fibrin free from corpuscular elements and below this again is a layer of granulation tissue. In these vegetations bacteria are frequently found. Sometimes they are demonstrated only by culture methods. Again they are absent if the vegetation has existed for some time. These vegetations are a constant source of danger, as they are frequently whipped off by the blood current and carried as emboli to different parts of the body, producing striking symptoms. The mitral valves are most frequently attacked by this process. Next come the aortic and very infrequently the tricuspid and the pulmonary valves. Fœtal endocarditis is confined chiefly to the right side of the heart. The sequel of this morbid process may be resolution with no impairment of the function of the valve, or, more commonly, thickening, retraction, curling, or even calcification, resulting in chronic valvular lesions.

Malignant Form.—All stages of endocarditis are found from the benign through the transitional to the malignant form. The same bacteria are present in all, but are more numerous and virulent in the malignant. There is a deposit upon the inflamed area, resembling in many respects that of the benign form, but containing many bacteria of great virulence. If this becomes detached there is loss of tissue with the formation of an ulcer. This may penetrate both layers of the valve, or only one layer of the endocardium, thus producing a valvular aneurism. The destruction of tissue may be very rapid and extensive (Fig. 2592). As in the benign form, the left side of the heart is usually attacked. The tendinous cords, the wall, or the papillary muscles are more likely to be involved in the process than in the benign form. The changes produced by the bacterial emboli constitute an important part of the morbid anatomy of ulcerative endocarditis. Small masses of bacteria are whipped off by the blood current and are carried to the most diverse parts of the body: brain, lungs, kidneys, spleen, skin, mucous membranes, eye, etc. Inflammation and suppuration soon occur and we have the production of the so-called metastatic abscesses. Few of the viscera may escape.

SYMPTOMATOLOGY.—Flint truly says, authenticated cases of endocarditis disconnected from other diseases, which serve to mask its symptoms to a greater or less extent, are wanting.

Benign Form.—The symptoms are usually very indefinite, the patient rarely complaining of more than a præcordial distress. Almost never does this amount to an actual pain. There may be oppression and shortness of breath. The heart action may be rapid and irregular, furnishing symptoms of palpitation. The temperature is usually elevated as a result of the associated disease. A slight extra elevation, a degree or two, usually occurs with the advent of endocarditis. Naturally then, because of the unobtrusiveness of the symptoms, the disease is frequently latent and not recognized. The physician who keeps in mind the etiology of endocarditis and makes routine heart examinations in all cases of rheumatism, chorea, pneumonia, etc., most frequently recognizes the disease. It is extremely important to remember that in children and adolescents, a rheumatism followed by grave heart complications may be very insidious, and show itself only by a history of pain in joints or limbs—no appreciable swelling or tenderness of joints and very little fever.

The appearance of signs due to emboli frequently directs our attention to the heart.

Malignant Form.—In this variety we find grave constitutional symptoms. There are evidences of a most severe infection, which requires considerable skill in differential diagnosis. It may be impossible to separate the symptoms from those of the associated disease, such as sepsis or pneumonia. According to the symptomatology we distinguish two large classes: (1) The *typhoid*, in which the case resembles typhoid fever, showing continued fever, delirium, dry coated tongue, distended abdomen, roseola, splenic enlargement, and possibly diarrhœa. (2) The *septic*, resembling septicæmia. The temperature shows the streptococcus curve, *i.e.*, rapid elevation and descent several times daily, accompanied by chills and drenching sweats. There is profound intoxication and depression of vitality. The intermittent temperature and chills may suggest to some malaria. In these cases infective embolic processes are common, showing themselves in the skin, the mucous membrane, retina, and the various internal organs.

Certain authors mention a *cardiac* group in which patients with chronic valvular endocarditis show marked fever and evidences of recent endocarditis. Many of these cases resemble either the typhoid or the septic form and may run a very acute course. Others run a chronic course lasting for a year or so.

Another group of cases may be termed the *cerebral* in which the symptoms resemble meningitis, either basilar or cerebro-spinal.

Some authors also made a *cutaneous* group. Here petechial rashes are found; also skin abscesses from infected emboli. Erythematous rashes are not uncommon. Because of petechial rashes, cases of malignant endocarditis have been diagnosed cerebro-spinal meningitis and black smallpox.

Differential Diagnosis.—Attention to etiology will assist one. Benign endocarditis is more likely to follow rheumatism; malignant, infective processes and pneumonia. The symptoms of the malignant form are much more intense, suggesting septicæmia or typhoid fever. The positive Widal reaction, the absence of leucocytosis, the presence of the diazo reaction, would all point to typhoid fever. Unfortunately the Widal and diazo reactions may both be absent, and with the advent of a complication there may be a leucocytosis. So in some cases it is impossible to differentiate endocarditis from typhoid fever. Even a past master in the art of diagnosis like Osler diagnosed a case typhoid fever, which post mortem was proven to be endocarditis.

Osler gives the following points for guidance: The more abrupt onset in endocarditis, and the absence of any regularity of the pyrexia in the early stage of the disease, the cardiac pain, oppression, and shortness of breath may be early symptoms in malignant endocarditis. Rigors, too, are not uncommon. There is marked leucocytosis in infective endocarditis. Bacteriological examination of the blood as used by Cole of Johns Hopkins in the diagnosis of typhoid fever is of striking value, but unfortunately its field of application is limited. The specific variety of endocarditis has been diagnosed during life by the finding of the micro-organism in the blood.

Physical Signs.—These are very uncertain, because our main dependence is placed upon the presence of a soft blowing systolic murmur at the aortic or mitral areas. Such murmurs are extremely common and frequently do not mean endocarditis, but occur with the various acute febrile processes. Similar murmurs occur in anæmia, and in many conditions which cannot be explained. The size of the heart is not always of help to us, since an acute endocarditis may not enlarge it. If in the course of an acute disease a murmur develops under our observation, which cannot be accounted for by anæmia or weakness of the heart wall, and especially if accompanied by an increase in the fever, we are justified in diagnosing endocarditis. Sudden appearance and disappearance of murmurs may occur when vegetations are rapidly forming and changing their shape.

Prognosis.—In the vast majority of cases simple endocarditis entails no immediate danger. The danger in such cases is more or less remote and dependent upon the chronic valvular defects which follow.

Malignant Endocarditis.—Death may take place in three days. The disease may be protracted for months. Death results from progressive failure of strength or in consequence of secondary suppuration, or of embolism of an important cerebral vessel. The prognosis is almost always unfavorable.

Treatment.—This should combine treatment of the associated disease and the endocarditis. It will in most cases be necessary to treat the endocarditis after the patient has recovered from the associated pneumonia, rheu-

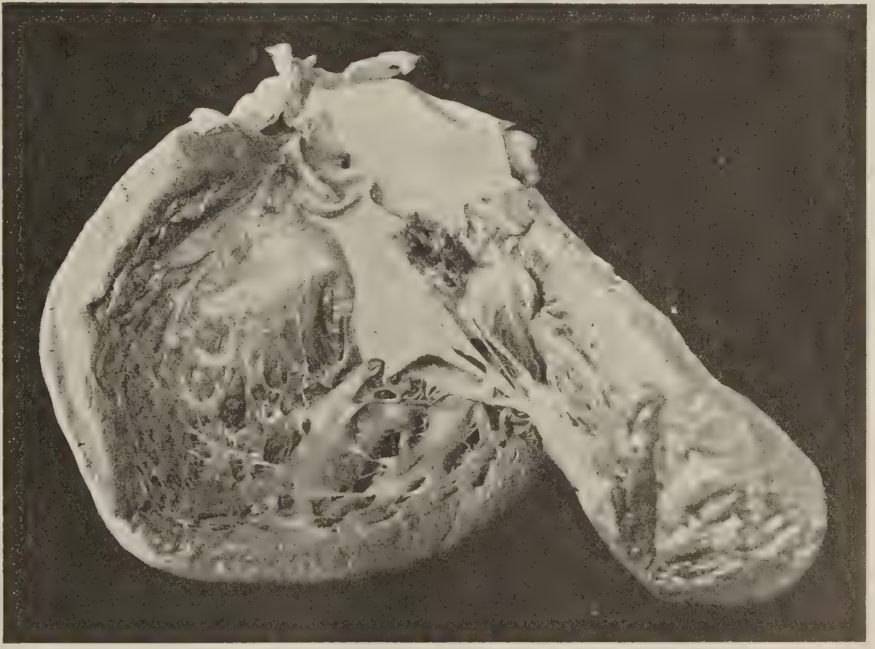

Fig. 2592.—Malignant Endocarditis; Destruction of Aortic Leaflet; Old Thickening of Aortic Valves; Dilatation of the Left Ventricle. (Original.)

matism, etc. Whether the salicylates have any effect upon endocarditis is a much mooted question. I am of the opinion that they have a decided indirect effect upon the valvular disease. Any one who has administered salicylates in proper dosage in acute articular rheumatism knows of their remarkable, almost specific control over the disease. Endocarditis may develop at any time during the progress of a rheumatic fever; consequently if we shorten the time of the disease we lessen the possibility of the development of endocarditis. If the valvular inflammation has already developed, the chances of resolution are increased, if the fever, pain, and restlessness are controlled by the giving of the salicyl compounds. Bruce advises the combination of digitalis with the salicylates if the heart seems weak. In the direct treatment of endocarditis *rest* is by all means the most essential thing. The work of the heart and the movement of the diseased valves must be reduced to a minimum. This is the best accomplished by putting the patient to bed. An ice bag over the præcordium is often of service in quieting the action of the heart. The time required in bed must be decided by the progress of the case. It may require months in order to guard against serious and permanent injury to the heart. At best this frequently cannot be avoided. The development of symptoms of incompensation will demand the administration of digitalis and strychnine. Anæmia frequently develops as the disease progresses, and requires iron, tonics, good food, and fresh air. Mercuric chloride and quinine have been employed in ulcerative endocarditis for the purpose of destroying the bacteria upon the endocardium, but it is very unlikely that they are of any use.

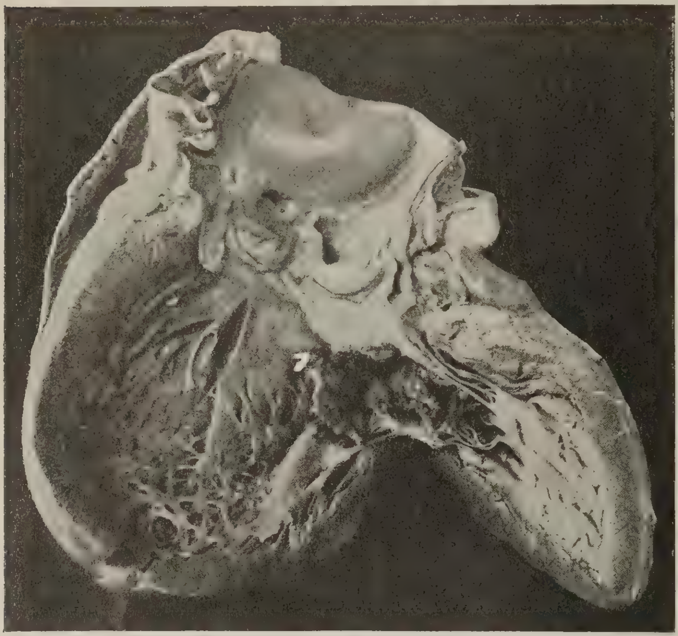

FIG. 2593.—Malignant Endocarditis on Top of Old Sclerosing Process. Marked Involvement of the mitral valves. (Original.)

ACUTE RECURRENT ENDOCARDITIS is a very interesting form occurring on old valve lesions. It may be benign or malignant (Fig. 2593).

CHRONIC ENDOCARDITIS is either a sequel of the acute form or is an evidence of senility, being a part of the process of arteriosclerosis, involving the general arterial system. This contracting endocarditis leads to thickening, curling, contraction, and frequently to calcification of the valves. The same causes which produce premature arteriosclerosis produce it, namely: excessive physical activity, excessive use of alcohol, syphilis, gout and diabetes, and chronic diseases of the kidneys. The chordæ tendineæ may gradually become shortened, greatly thickened, and in extreme cases the papillary muscles are implanted directly upon the sclerotic and deformed valves.

The effects and treatment of chronic endocarditis are those of chronic valvular lesions and will be considered under that heading. *James Rae Arneill.*

HEART DISEASES: FATTY DEGENERATION.

—Fatty degeneration of the heart muscle is a retrograde change characterized by the formation of minute fat droplets within the muscle protoplasm. It is distinguished from fatty infiltration, in that in the latter process the fat is deposited in connective-tissue cells, either beneath the pericardium or between the muscle fibres. The term *fat heart* is often used as a designation for both fatty degeneration and infiltration, but it should be applied to the latter condition only. It should be emphasized that the essential difference between these two conditions is, that in fatty degeneration the fat is in the muscle cell, formed there by the disorganization of the muscle protoplasm; while in fatty infiltration the fat is in connective-tissue cells, deposited there from the blood.

GROSS APPEARANCES.—Severe degrees of fatty degeneration may exist without recognizable changes in the appearance of the heart. The naked-eye diagnosis of this condition is in many cases difficult and uncertain. When the process is extreme the heart muscle becomes yellowish in color, and of softer consistence; it may have a fatty shine or give a fatty smear. The condition may be diffuse or localized to certain areas. The latter form is the more readily diagnosed, inasmuch as the heart muscle so affected presents a peculiar mottling of red and yellow, occasionally disposed in the form of stripes or broken bars, the so-called "tiger-heart." This appearance is best seen on the endocardial surface of the left ventricle. In the majority of cases the degeneration is most marked in the wall of the left ventricle near the apex; the septum, right ventricle and auricles being affected in degree according to the order given. In the left ventricle the papillary muscles and trabeculæ usually show the most severe change, and in some cases the process may be sharply localized to these, the yellowish color of the papillary muscles standing out in sharp contrast to the normal brownish-red of the remainder of the heart wall. The heart is usually increased in size without a corresponding increase of weight. Dilatation of greater or less degree occurs, and the organ as a whole is flabby, flattening when laid upon the table. On section into the muscle the color change may affect the wall uniformly throughout, but more often it is found in streaks and patches of varying form, size, and distribution. The discolored muscle is more opaque than normal, cloudy, easily torn, and gives a fatty smear to a warm knife. In very extreme cases the degeneration may be so severe in sharply outlined areas as to present an appearance closely resembling that of an abscess. It must be remembered that fatty degeneration of the heart muscle rarely exists alone, but is usually associated with cloudy swelling, atrophy, anæmia, etc., all of which processes complicate the diagnosis from the gross appearances.

MICROSCOPICAL APPEARANCES.—The diagnosis of fatty degeneration in many cases can be made only on microscopical examination. This should always be done with the fresh tissue when possible, inasmuch as the processes of fixation and hardening often completely destroy the appearances of the degeneration by the removal of the fat droplets and the contraction of the tissue. Fixation of the muscle in osmic acid or Flemming's solution will obviate this danger. Slight degrees of fatty change are, however, always best brought out by the treatment of freshly teased muscle with osmic acid. The affected muscle fibres are found to contain minute fat-droplets arranged in rows between the masses of interfibrillary sarcoplasm, beginning about the nucleus and extending linearly toward the ends of the fibres. In the early stages the transverse striations are usually not affected, but in severe degrees of the change they gradually disappear, first at the fibre-ends and then toward the nuclei. The staining power of the nucleus is always affected; in extreme degrees the nuclei may be entirely lost. The changes are usually most marked in the fibres lying just beneath the endo- and pericardium, the endocardium itself being rarely affected. In the acute forms of fatty degeneration cloudy swelling, segmentation, and fragmentation, etc., are usually found in association with the fatty change; in the chronic cases atrophy of the fibres, both simple and pigment, with increase of the interstitial connective tissue, is present.

Etiology.—The causes of fatty degeneration of the heart are both local and general. Of the former disturbed nutrition resulting from sclerosis or obstruction of the coronary arteries is the most common and important cause. Fatty degeneration of the muscle may also be caused by disturbances of nutrition secondary to myocarditis, cardiac abscess, pericarditis, and endocarditis. In pericarditis the degeneration may be confined to the layer of muscle immediately beneath the epicardium.

The two great general causes of this degeneration are anæmia and intoxication. It is of common occurrence in pernicious anæmia, chlorosis, leukæmia, and all forms of secondary anæmia. It occurs after long-continued or frequently repeated hemorrhage (epistaxis, hæmoptysis, hæmatemesis, menorrhagia, metrorrhagia, hemorrhage from the intestines, hæmaturia, etc.). It has been observed after venesection. Fatty degeneration is also commonly associated with the cachectic anæmias of chronic suppuration, chronic diarrhœas, syphilis, tuberculosis, malaria, malignant growths, etc. In all of these conditions the systemic intoxication is to be regarded also as a possible factor in the production of the condition. Deficient oxygenation due to cardiac insufficiency, valvular lesions, emphysema, fibroid pneumonia, etc., also causes fatty change of the heart muscle. The relation of fatty degeneration to cardiac insufficiency is not entirely clear; the condition is almost always present in the failure of compensation of the hypertrophied heart in chronic valvular disease, and while it is usually regarded as being the cause it is also possible that it may be the result of the cardiac insufficiency.

Extreme fatty degeneration of the cardiac muscle occurs in poisoning with phosphorus, arsenic, antimony, etc. It may also occur to an extensive degree in the acute infectious diseases, especially in typhus and typhoid fevers, recurrent fever, scarlet fever, diphtheria, pneumonia, puerperal fever, pyæmia, etc. In acute yellow atrophy of the liver and in puerperal eclampsia the fatty degeneration of the heart may be so marked as to resemble that seen in phosphorus poisoning. In the infectious diseases the fatty change is to be attributed chiefly to the action of the poisons produced in these conditions, but the effect of the increased temperature of the body must also be regarded as an important factor. Long-continued mercurial inunctions, iodoform and chloroform poisoning, morphinism, the camphor habit, the long-continued use of dilute mineral acids in beverages, or as adulterants of vinegar, mushroom poisoning, etc., are among the many other supposed factors of fatty degeneration of the myocardium. In the later stages of chronic nephritis and gout there is almost always present extensive fatty change in the heart, resulting partly from the general cachexia and anæmia, and partly from sclerotic changes in the coronary vessels. The habitual use of alcohol is one of the most important causes of slowly progressive fatty degeneration of the myocardium. The condition is found particularly in the case of habitual beer drinkers. The condition is of very frequent occurrence among the lower classes in Germany and Austria with whom beer forms a very important part of the daily diet. In France the use of dilute mineral acids in some of the beverages consumed by the lower classes is said to be an important factor in the production of fatty degeneration.

High living, over-eating, lack of exercise as well as excessive muscular activity are regarded as either primary or predisposing factors to cardiac degeneration. Idiopathic hypertrophy is practically always followed by fatty degeneration. Cardiac over-strain in laborers, athletes, etc., is another very important etiological factor. A slight amount of fatty change in the senile heart is to be regarded as physiological. The pathological fatty degeneration of the heart due to anæmia or cachexia is found more frequently in women than in males; that due to coronary sclerosis, alcoholism, etc., much more frequently in males. The majority of the cases are in individuals past fifty years of age. Cardiac fatty degeneration occurring in young individuals is almost always due to intoxication or infection.

Symptoms.—The symptoms of fatty degeneration do not differ from those of other forms of myocardial affections. It is usually impossible to differentiate between fatty and fibroid heart. The most extreme degrees of fatty degeneration, as found in severe cachexias, pernicious anæmia, etc., may give rise to no symptoms if cardiac dilatation has not taken place. It is the latter condition which produces the symptoms which are usually associated with fatty degeneration. Dyspnœa, cardiac irregularity, palpitation, præcordial distress, vertigo, the so-called pseudo-apoplectic attacks, rapid and weak pulse, etc., are symptoms of dilatation rather than of fatty degeneration. Very rarely anginal attacks may occur without coronary changes. In the late stages Cheyne-Stokes breathing may be present. The physical signs are those of dilatation. Death may occur from sudden over-strain or from slowly developing cardiac insufficiency. In rare cases aneurismal dilatation of the cardiac wall may result from local weakening of the myocardium due to fatty degeneration.

Prognosis.—In the majority of cases of myocardial disease the prognosis is very unfavorable, especially in the slowly developing or chronic form. Acute degeneration of mild degree caused by acute infections or poisoning may recover completely; the more severe forms may be very quickly fatal. Within certain limits chronic fatty change of mild degree does not quickly lead to a fatal issue.

Treatment.—The occurrence of fatty degeneration may be many times prevented by careful regulation of the daily life. In suspected cases strict diet should be enforced, the amount and character of muscular activity carefully planned, and the patient protected from excitement of all kinds. Sudden death during sexual intercourse, straining at stool, lifting, running, etc., is extremely common in this affection. Alcohol should be entirely withdrawn, and the amount of fluid limited. When the signs of dilatation have not appeared digitalis is usually not advisable. Strychnine and nitroglycerin may be given. When symptoms of cardiac insufficiency are present the treatment should be carried out along the lines indicated for the treatment of failure of compensation in chronic valvular disease.

Aldred Scott Warthin.

HEART DISEASES: FATTY INFILTRATION.—Fatty infiltration of the heart is that condition in which the subepicardial fat alone is greatly increased, or in connection with this increase there is also an extension of adipose tissue into the myocardium. Normally there should be but a small amount of subepicardial fat and this should be confined to the sulci and grooves along the superficial coronary vessels, being greatest in amount at the base of the heart. Over the greater part of the ventricular surfaces in the active, muscular male of early adult life there should be no fat, but after the age of forty there is a physiological increase in the amount of the cardiac panniculus. There are, however, wide individual variations in the amount of subepicardial fat within apparently normal limits, depending upon intrinsic peculiarities of metabolism, habits of life, etc. The presence of fat cells between the muscle fibres in the interstitial tissue of the myocardium is under all circumstances to be regarded as pathological. Such an encroachment upon the muscle is usually due to a direct extension of adipose tissue from the subepicardial fat, chiefly along the lines of the arterial branches. Secondary to the infiltration of adipose tissue there is an atrophy of the heart muscle. In extreme cases the greater part of the myocardium may be replaced by adipose tissue which may extend even to the endocardium. In some cases the deposit of fat in the cells of the interstitial tissue may be secondary to a primary atrophy or degeneration of the heart muscle, the formation of fatty tissue being of the nature of a compensatory process. Two forms of fatty infiltration may therefore be distinguished clinically: primary and secondary fatty heart. Of these the first variety is by far the most common and important.

In extensive hyperplasia of the subepicardial panniculus the heart is usually increased in size, partly from increased thickness of its wall, and partly from dilatation. The weight of the organ may or may not be above that of the normal. The entire heart may be encased in a thick layer of fat (lipoma capsulare cordis, obesitas cordis, lipomatosis cordis, fatty overgrowth, Mastfettherz, etc.). The most extensive deposit is found at the base of the ventricles along the auriculo-ventricular groove, in some cases having a distinct lobular arrangement. The heart muscle may not be visible through the epicardium at any point. On section through the heart the layer of adipose tissue may be found to form almost the entire thickness of the wall, the muscle consisting of a thin layer beneath the endocardium. In the most extreme cases the fat may reach to the endocardium in the form of trabeculæ extending along the intermuscular septa, gradually diminishing in size as they approach the endocardium. On microscopical examination groups of fat cells are seen between the muscle fibres. The latter may show varying stages of simple or pigment atrophy. Fatty degeneration of the atrophic muscle is not infrequently present.

Fatty infiltration of the heart may exist as a part of a general obesity, either congenital or acquired. Lack of exercise, over-eating, excessive use of carbohydrates, alcohol, etc., as well as excessive water drinking are the most important factors in the production of this condition. It is most common in males at middle age; in women it may exist as a part of general obesity associated with or following the menopause. Deficient oxygenation from anæmia or from chronic pulmonary disease also leads frequently to fatty infiltration of the heart. The condition is often found in the cachexias of chronic tuberculosis, carcinoma, etc. It occurs in the early stage of diabetes, and in certain forms of chronic poisoning, drug habits, etc. (iodoform, morphine, camphor, chloroform, dilute mineral acids, etc.).

A moderate degree of fatty infiltration may exist without signs or symptoms, but beyond a certain limit the over-accumulation of fat beneath the epicardium or its infiltration into the myocardium causes impairment of the cardiac function. In such cases the apex beat is lost, the cardiac impulse is very faint or not present at all, the area of dulness is increased, and the heart sounds are muffled. The pulse is soft, of low tension, often rapid and irregular. The affected individual is stout, with excessive abdominal panniculus, and usually shows signs of general venous congestion. Palpitation, præcordial distress, and dyspnœa are produced by slight exertion, and there is a tendency to excessive sweating. The urine is usually increased in amount, pale and of a low specific gravity. In an individual with general obesity these signs and symptoms may be taken as certain indications of fatty heart. In the cases of primary atrophy of the heart muscle with secondary fatty infiltration the differential diagnosis is not so easily made. In these cases the subcutaneous panniculus may be greatly decreased, and the cardiac symptoms obscured by those of the condition causing the myocardial atrophy. In the later stages of fatty infiltration the symptoms are those of cardiac dilatation, and the condition cannot be diagnosed from other forms of myocardial affections.

The prognosis on the whole is much more favorable than in the case of fatty degeneration. In cases of acquired obesity due to manner of living it is quite good. In congenital obesity it is much less favorable, and when secondary to other disease processes the prognosis rests wholly upon that of the more serious condition. It must be emphasized that the individual with fatty heart cannot meet without danger many conditions involving slight degrees of heart-strain. Intercurrent affections such as influenza, bronchitis, pneumonia, typhoid fever, etc., are very likely to cause death through cardiac insufficiency. Anæsthesia, surgical operations, excessive fatigue, muscular strain, intense emotion, etc., are to be regarded as dangerous factors in the case of individuals affected with fatty infiltration. While sudden death is not infrequent in this condition it is not nearly so common as in the case of fatty degeneration.

In the cases associated with obesity the treatment is very simple and if carefully followed very successful. The administration of drugs is of secondary importance and is usually limited to general tonics and to the improvement of elimination. The essential factors of the treatment are entirely hygienic. The diet should be chiefly nitrogenous, fats and carbohydrates being reduced to the smallest possible proportions. The use of alcohol should be entirely stopped, and but little fluid should be taken with the meals. The quantity of food and drink taken should be most carefully regulated. The amount and character of physical exercise taken are of prime importance and should be most carefully prescribed. The use of certain mineral waters is of great value in many cases as a means of promoting elimination. Turkish baths may be employed toward the same end. In the forms of fatty infiltration due to anæmia, etc., the treatment is carried out along lines depending upon the primary disease. *Aldred Scott Warthin.*

HEART DISEASES: FIBROID HEART.—The terms cardio-sclerosis and chronic fibrous myocarditis are synonyms. There is either a hyperplasia of interstitial connective tissue, or a replacement of heart muscle, more or less extensive, by fibrous tissue.

Etiology.—It is intimately associated in most instances with the process of arterio-sclerosis, especially in its involvement of the coronary arteries. The blocking of one of these arteries by a thrombus or an embolus leads to a condition termed anæmic necrosis, or white infarct. Fibrous myocarditis may result from the gradual transformation of such processes into fibrous tissue. It frequently follows the narrowing of a coronary branch in the process of obliterative endarteritis. According to Broadbent, syphilitic disease of the myocardium and chronic interstitial myocarditis in association with subacute pericarditis and adherent pericardium, are the commonest causes of diffuse interstitial fibrosis. Chronic nephritis, with associated high tension in the arterial system, produces thickening in the walls of the arterioles, and increase of connective tissue in their proximity. Chronic alcoholism may be associated with a diffuse fibroid infiltration. Myocarditic cicatrices may sometimes result from a previous pericarditis or endocarditis, the inflammation extending through to the heart muscle.

Morbid Anatomy.—This sclerosis occurs most frequently at the apex of the left ventricle and in the septum, but may occur in any portion. In the septum there are often streaks of fibroid degeneration which do not reach the endocardium; it may be necessary to divide the muscle in order to see them. This degeneration is the invariable precursor of aneurism of the heart.

Symptoms.—It occurs in men past middle life. The symptoms are extremely unreliable. The so-called classical symptoms are just as likely not to be present. In rare cases the pulse may be infrequent, even as low as 26; there may be shortness of breath and œdema. In other cases we may find a rapid, irregular, and unequal pulse, with signs of incompensation. Those cases in which coronary arterio-sclerosis is present frequently show symptoms of angina pectoris.

Physical signs are very indefinite. There may be some hypertrophy. Murmurs, systolic in time, may be present during incompensation. The sounds may be weak, irregular, and valvular in character; accentuation of the aortic second, and reduplication of some of the sounds, a diffuse slapping cardiac impulse, and even a gallop rhythm may be present. Post-mortem examination has proven the unreliability of symptoms and physical signs in the diagnosis of this condition, even in the hands of experts. Cabot states that a prominent Boston pathologist told him he had never seen a case of myocarditis correctly diagnosed. So far as symptoms and signs go it is impossible to distinguish the fibroid from the fatty heart. My observation is that physicians usually diagnose fatty heart if the patient is obese, fibroid heart if he is lean.

COURSE OF DISEASE.—These patients may die suddenly without having previously shown any symptoms; there may be rupture of the heart or a blocking of a coronary artery. Again, they may present symptoms exactly similar to those of an incompensated valvular lesion. Dilatation of the cavities with the development of murmurs of relative insufficiency make it impossible to distinguish it from valvular lesions.

PROGNOSIS.—It is distinctly unfavorable except in syphilitic cases, which may respond promptly to the use of iodides.

TREATMENT.—Appreciating the uncertainty of a diagnosis, our treatment of suspected cases must be based upon the broad lines of common sense and must depend mostly upon indications drawn from the symptoms and signs of weak heart. If symptoms of incompensation are present, the patient must be put to bed and placed upon digitalis and strychnine, with a light, nutritious diet. As routine measures these patients should observe moderation in food and drink, and avoid variations in blood pressure by a very even life; the bowels should be kept open with mild mercurials and saline purgatives. Strychnine, gr. $\frac{1}{30}$, every six hours, or in the form of nux vomica, gtt. xx. three or four times daily, is useful. If arterial tension is high, nitroglycerin is indicated.

James Rae Arneill.

HEART DISEASES: HYPERTROPHY AND DILATATION.—A discussion of these pathological conditions under a separate heading necessitates more or less repetition of facts stated in the articles on valvular and myocardial diseases.

These conditions usually go hand-in-hand; at times the hypertrophy exceeds the dilatation, at other times the dilatation exceeds the hypertrophy. It is very unusual to find a pure hypertrophy or a pure dilatation.

Hypertrophy is almost invariably a conservative process; *dilatation* on the other hand, though at times conservative, as in aortic insufficiency, is generally destructive. Both conditions may affect the whole heart, but are more likely to be limited to one part. We may even have hypertrophy limited to one papillary muscle and dilatation to a conus arteriosus.

Hypertrophy means an increase in the mass of muscular tissue, usually associated with an increase in volume. *Dilatation* means an enlargement of the cavities of the heart. The same laws which affect the development of muscular tissue in other parts of the body apply to the heart. Under conditions of proper nutrition, increased work causes an enlargement of the cardiac muscle. Ziegler says this increase in size takes place by enlargement of the muscle cells. Whether or not a proliferation of the cells also is present is not yet positively known. Some authorities believe there is a definite increase in the number of muscle cells.

Schroetter divides hypertrophy into three classes:

I. Simple hypertrophy,—increase of the heart in volume with normal cavities.

II. Concentric hypertrophy,—thickening of the walls with diminution in the size of cavities.

III. Excentric hypertrophy,—increase in muscular tissue, with enlargement of cavities.

Of these three classes only the third, excentric hypertrophy, is of special interest to us. The first two divisions are comparatively rare.

If work above its normal capacity is thrown upon any part of the heart, hypertrophy results. This is brought about by the presence of unusual obstruction to the flow of blood, and by excessive stimulation of the nervous mechanism of the heart.

Let us now consider in some detail the different causes which produce hypertrophy of special portions of the heart:

Left Ventricle.—The following are the conditions under which hypertrophy of this part takes place:

(*a*) Valvular lesions: Aortic insufficiency, aortic stenosis, mitral insufficiency; (*b*) the various conditions which cause increased resistance in the greater circulation, namely: aneurism, congenital narrowing of the aorta (rare), small arterial system (rare), arterio-sclerosis (very common) in which there may be both diminution in the calibre of the artery and loss of elasticity. The elasticity of the arterial wall is a powerful aid in propelling the blood current forward. Various intoxications cause a contraction of the peripheral circulation and thus raise blood pressure. Chief among these are the various forms of Bright's disease; also gout and lead poisoning. With these diseases, especially chronic interstitial nephritis, we frequently find a high grade of arterio-sclerosis. The entire heart may become involved in this hypertrophy. At present I have under observation a middle-aged patient who shows considerable cardiac hypertrophy, the apex being in the anterior axillary line. Valvular lesions have never been demonstrated in this case; there is, however, considerable arterio-sclerosis.

The excessive use of tea, coffee, alcohol, and tobacco, through their exciting action on the nervous mechanism of the heart, may produce slight hypertrophy. Exophthalmic goitre and various nervous conditions, such as neurasthenia, if of sufficient duration, may cause hypertrophy. But valvular lesions are a frequent complication of Graves' disease.

(*c*) Pathological conditions in the heart wall, such as chronic myocarditis and adherent pericardium, give rise to hypertrophy, because of the obstruction offered to the orderly and regular contractions of the heart.

Right Ventricle.—It is hypertrophied under the following conditions:

(*a*) Valvular lesions; most frequently, mitral insufficiency, and stenosis; the very rare lesions of the right heart, pulmonary stenosis and insufficiency, tricuspid stenosis and insufficiency. Relative tricuspid insufficiency secondary to left heart lesions is rather frequent.

(*b*) Increased resistance in the pulmonary circulation, due to narrowing of the calibre of the pulmonary artery by pressure from without, as by aneurism, tumors, and so forth; congenital narrowing and arterio-sclerosis of the pulmonary artery (rare); also the cutting off of capillary regions in the lungs by pleurisy, pneumothorax if of sufficient duration, chronic fibroid conditions, tumors, chronic infiltrations with or without cavities, *emphysema*, spinal curvature with dislocation of the heart.

Auricles.—Hypertrophy of these chambers is much rarer than dilatation, and is usually associated with a much greater degree of dilatation. The left auricle hypertrophies more than the right.

Hypertrophy of the whole heart takes place when there is a combination of several causes, for instance, aortic and mitral insufficiencies, combined with a relative tricuspid insufficiency; of valvular disease complicated by lung or arterial disease.

Athletic Heart.—Allbutt and Stengel have made special studies of the athletic heart among the students of Cambridge and the University of Pennsylvania. They have demonstrated by means of percussion and location of the apex, that several years of the severer forms of athletics, such as distance running, rowing and football, will increase the size of the heart considerably. In these cases the valves are healthy. It is true that in some instances a so-called athlete's heart is one enlarged by aortic or mitral insufficiency. Seitz in Germany, and Da Costa in this country, have called our attention to a very similar condition in soldiers who have undergone severe strain from long marches.

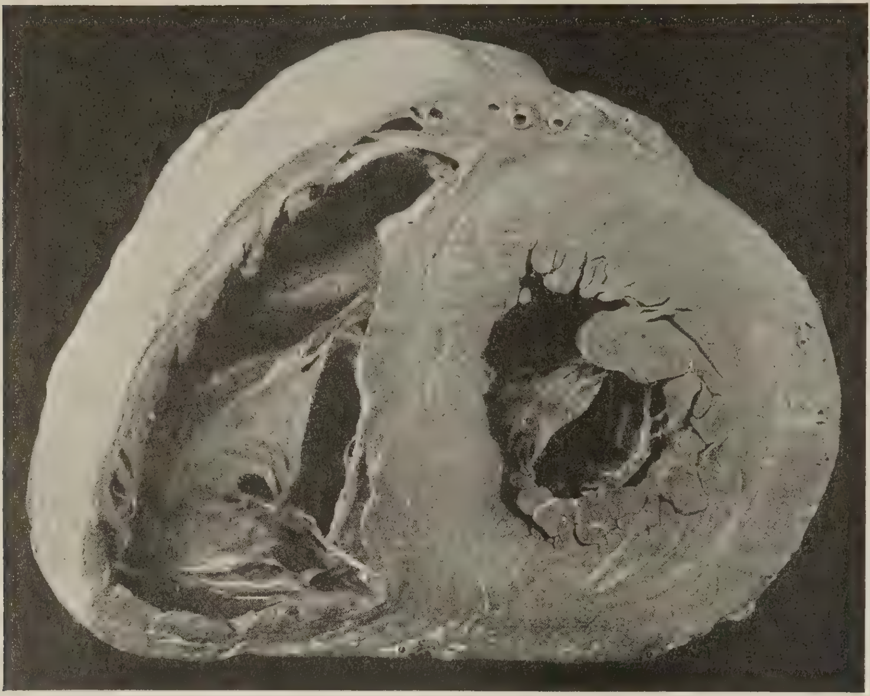

FIG. 2594.—Hypertrophy of the Left Ventricle and Dilatation of the Right. (Original.)

Morbid Anatomy.—The size of the average normal heart is about equal to the patient's closed right fist. The heart of the adult male weighs about nine ounces; of the female eight ounces. The majority of hypertrophied hearts weigh from sixteen to twenty ounces. Hearts of enormous size have been reported; Beverley Robinson has reported a heart weighing fifty-three ounces, Alonzo Clark one weighing fifty-seven ounces, and Stokes one weighing sixty-four ounces. Another good method of determining the extent of hypertrophy is by measuring the thickness of the wall after the heart has been thoroughly relaxed by soaking in water. The left ventricle normally has a thickness of 9 to 12 mm.; so a thickness of 20 to 25 mm. indicates hypertrophy. The right ventricle is thinner than the left, measuring on an average 4 to 7 mm. When hypertrophied it measures from 13 to 20 mm. The left auricle has a normal thickness of about 3 mm.; the right scarcely 2 mm. The auricles may be doubled in thickness when hypertrophied.

The conical shape of the heart is lost in hypertrophy and dilatation, by reason of the apex being greatly broadened and rounded. When the right ventricle is chiefly affected it occupies most of the apex. The hypertrophied muscle is deep red in color and firmer than the normal heart.

Dilatation. — Schroetter divides it into three classes:

I. Simple dilatation,—enlargement of cavities with normal thickness of the walls.

II. Active dilatation, —enlargement of the cavities of the heart with increased thickness of the walls, *i.e.*, excentric hypertrophy.

III. Passive dilatation, — enlargement of the cavities with thinning of their walls.

Active and passive dilatation are of special interest. The former has been discussed under its synonym, excentric hypertrophy.

Dilatation is always a secondary process and is due either to (*a*) increase of pressure within a cavity whose walls are not hypertrophied, or (*b*) normal pressure

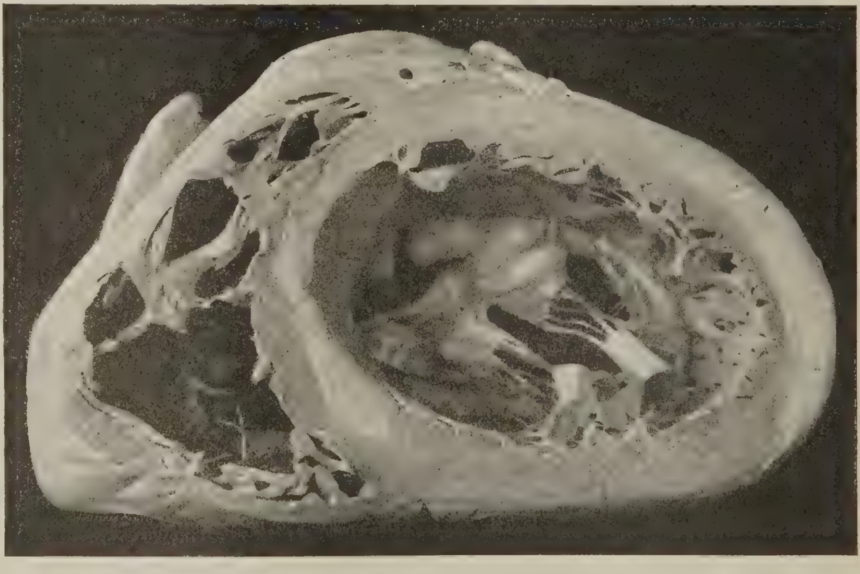

FIG. 2595.—Dilatation Involving Both Sides of the Heart. (Original.)

within cavities whose walls have been weakened by myocardial disease. Aortic insufficiency offers the best illustration of the first class. In it the dilatation of the left ventricle is due to the chamber being filled from two sides at once, the blood from the left auricle and that which regurgitates from the aorta. As a result of the increased pressure the ventricle yields. Soon hypertrophy develops, producing a typical example of excentric hypertrophy. Whether dilatation or hypertrophy will prevail depends on the nature and quality of the heart tissue.

When the capillary circulation of the lungs is overdistended, as it may be in mitral insufficiency and stenosis, the right heart meets an unusual resistance in discharging its blood into the pulmonary artery. This back pressure, together with the pressure of the blood which normally enters the ventricle from the right auricle, causes dilatation, and just so much sooner on this side than on the other, as the right ventricle is weaker than the left.

Pulmonary insufficiency and tricuspid insufficiency also cause dilatation of the right ventricle. Diseases of the lungs and pleura, especially if associated with myocardiac disease, as in lobar pneumonia, may cause a fatal dilatation of the right heart. Emphysema is usually associated with dilatation of the right ventricle.

The auricles are prone to extensive dilatation, not having muscular tissue enough for the development of much hypertrophy. The left auricle dilates in mitral insufficiency and stenosis, the right in tricuspid insufficiency and stenosis. The development of relative insufficiency of the auriculo-ventricular valves from dilatation of the ventricles, is a frequent cause of dilatation of the auricles. When incompensation develops in the course of the various heart lesions, marked dilatation of all the cavities is likely to follow.

Morbid Anatomy.—The cavities may be vastly increased in size, even trebled in capacity. The auricles may contain from eighteen to twenty ounces of blood. The auriculo-ventricular rings may be greatly dilated. The mitral orifice, which normally has a circumference of about three and one-half inches, may be increased to five and one-half inches and more; the tricuspid orifice normally has a circumference of about four and one-half inches and may be increased to six inches. The bundles of muscle fibres may be greatly thinned and separated. In Figs. 2594 and 2595 there was marked separation of the bundles of muscle with only a thin semitransparent membrane between; the endocardium and epicardium were in places in apposition.

SYMPTOMS AND PHYSICAL SIGNS.—Very little space need be devoted to them as they have been considered in detail under valvular lesions of the heart.

The so-called idiopathic hypertrophy produces a strong first sound at the apex and an accentuated aortic second, unaccompanied by murmurs. Hypertrophy of the right ventricle, due to disease in the lungs and pleura, produces a strong first sound in the tricuspid area with an accentuated pulmonary second. The apex beat is heaving and dislocated to the left, and usually downward. The pulse is likely to be much stronger than in the hypertrophy due to valvular lesions. The forcible heart action may or may not be perceptible to the individual.

In dilatation the apex beat loses its heaving character, is diffuse, undulatory and irregular, and taps against the chest rather than thrusts; dulness increases, especially to right and left. The heart sounds become weak, the first approaching the second in its valvular character; if murmurs are present they become weak, or even may disappear; fatal gallop rhythm may develop. The pulse becomes small, irregular, and unequal. All of the classical symptoms of incompensation may develop, such as cyanosis, dyspnœa, œdema, bronchitis, gastro-intestinal disturbances, and marked nervousness.

The treatment of these conditions has been discussed in detail in the article devoted to valvular lesions of the heart. *James Rae Arneill.*

HEART DISEASES: MYOCARDITIS.

—Under this heading I shall discuss (1) Acute Interstitial Myocarditis, (2) Parenchymatous Degeneration of the Myocardium, (3) Segmentation and Fragmentation, (4) Abscess of the Heart.

I. *Acute Interstitial Myocarditis.*—This is a disease in which the intermuscular connective tissue is swollen and infiltrated with small round cells and leucocytes; the blood-vessels are dilated and the muscle fibres the seat of granular, fatty, and hyaline degeneration. Acute endocarditis and pericarditis, diphtheria and typhoid fever are most commonly associated with it. Councilman has described a very similar condition as a sequel of gonorrhœa and was able to demonstrate gonococci in the diseased areas.

II. *Parenchymatous Degeneration.*—This is extremely common because of its intimate association with the numerous acute infectious diseases and toxæmias. It varies much in degree, in most cases being mild. In practically all of the continued fevers the myocardium is affected, but not so much from the fever as from the associated toxæmia. It may develop in the course of a pericarditis or an endocarditis.

The heart is pale, turbid, and extremely soft. Microscopically there is granular degeneration of the muscle fibres. They may even lose their striæ. The sudden deaths which occasionally occur during the convalescence of diphtheria, pneumonia, typhoid fever and influenza, are undoubtedly dependent on the presence of a severe grade of parenchymatous degeneration. Acute dilatation of the heart develops very readily under these circumstances and explains the fatal termination.

The physical signs are those of cardiac weakness. The pulse is feeble and may be both irregular and unequal; the first sound at the apex becomes weaker and more valvular in character. Soft blowing systolic murmurs may develop especially in the pulmonary regions. The patient is weak and becomes short of breath on slight exertion.

III. *Fragmentation and Segmentation.*—These conditions of the heart muscle interest the pathologist rather than the clinician. Renaut and Landouzy first called direct attention to the dissociation of the muscle cells in 1877. Renaut has gone so far as to consider this condition a distinct disease from the clinician's standpoint. However, it seems to us impossible to attempt to distinguish with any degree of certainty this from numerous other diseases of the myocardium, by means of signs and symptoms. In segmentation there is a separation of fibres at the cement line. In fragmentation the fracture is across the fibre and perhaps at the level of the nucleus; longitudinal division is very rare. Such hearts are soft and easily torn, and are often pale and cloudy. Renaut attributes the dissociation of cells to solution of the cement substance, on account of senile involutionary changes, alcoholism, infection, and the associated high temperature. Hektoen says "of the morbid changes of the myocardium proper, none occurs more frequently or under a greater variety of circumstances, than the lesions known as segmentation and fragmentation of the muscle fibres. They are due to a disproportion between the vigor and order of muscular contraction and muscular cohesion."

IV. *Abscess of the Heart.*—This develops in the course of a pyæmia or infective endocarditis. It is a metastatic pyæmic process localized in the heart. Infected emboli are carried into the coronary circulation with a resulting inflammation and suppuration. These abscesses vary much in size, from very small to fairly large.

James Rae Arneill.

HEART DISEASES: NEOPLASMS.

—Primary tumors of the heart are very rare. They may arise in the myocardium, or in the peri- and endocardium, from which points they may invade the heart muscle. They may also take their origin from the valves. They may be single or multiple. They may form nodular circumscribed masses in the heart wall, or project as polypoid growths into the heart cavity. Only rarely do they form diffusely infiltrating growths. Many are of congenital origin. The majority of cases occur in young or middle-aged individuals; a few have been found in old age.

The *myxoma* is the most frequent variety of primary neoplasm of the heart, eighteen cases having been observed. Of these the majority were pure myxomata, the others fibromyxomata. In one case the growth was described as an angiectatic myxoma. As a rule they form polypoid growths projecting into the heart cavities. It is very doubtful, however, if some of the polypoid formations found on the endocardium were really of the nature of neoplasms; rather is it probable that they were masses of newly formed connective tissue of myxomatous type resulting from the organization of thrombi. In a case of fibromyxoma of the left auricle occurring in a girl of four years, Jacobsthal found large numbers of newly developed fibres of yellow elastic tissue. In the majority of cases the myxomatous tumor has been found in the left auricle, very often being attached to the endocardium by a slender pedicle. Papillary myxomata have also been found upon the tricuspid flaps.

Next in order of frequency of the primary cardiac neoplasms is the *rhabdomyoma*. Its peculiar histological structure gives to it a great interest. Cases have been described by von Recklinghausen, Virchow, Hlava, Kolisko, Cesaris-Demel, and Seiffert. The tumor is of congenital origin, and is usually multiple. The nodules are not encapsulated, but are well outlined from the cardiac muscle, and quite sharply demarcated from the pericardium and endocardium. The growths may be as large as walnuts, and are scattered through the ventricular walls and the interventricular septum. On section the nodules are reddish-gray in color. The microscopical appearances are very striking. Trabeculæ of varying thickness showing transverse striations are arranged so as to form small spaces. These spaces do not communicate with each other; they contain large polygonal cells of irregular outline having one or more oval nuclei which are centrally situated. Their photoplasm shows a faint striation. In some cases the cell appears to form part of the wall of the space and sends prolongations across the latter. Both the protoplasm and prolongations of these cells stain like muscle. The spaces and their contents have received very different interpretations from the different observers who have studied this tumor. Hlava regarded them as intracellular, Kolisko as intercellular. According to Seiffert each space and its wall represents a greatly enlarged embryonal heart-muscle cell. The smallest tumor nodules may consist of bundles of delicately striated fibres only, without the peculiar spaces. Of the significance and mode of formation of the cardiac rhabdomyoma we as yet have no satisfactory explanation.

Primary *sarcoma* of the heart is much more rare; and it is very probable that some of the cases diagnosed as such were secondary to some undiscovered focus elsewhere in the body. The reported cases have been in both young and old individuals. The varieties observed were round and spindle-cell forms, myxosarcoma, fibrosarcoma, and angiosarcoma.

Cases of primary *fibroma* of the heart have also been reported, but the true nature of these cases is uncertain. It is quite probable that they represent organized thrombi. Observations have also been made of the primary occurrence of *lymphadenoma*, *cavernous angioma*, and *lipoma* in the heart. The polypoid *cysts* which have been described by a number of writers as primary cardiac neoplasms are without doubt to be regarded as degenerating or partly organized polypoid thrombi. They are found most frequently in the left auricle, are reddish-gray in color, and have a smooth shining surface. On section they show a cystic space filled with the products of the simple softening of the central portion of the thrombus. When organization of the periphery of the thrombus has begun the resemblance to a true cyst is very close.

Primary neoplasms of the valves are more rare than those of the heart wall. A *papillary myxoma* of the posterior tricuspid flap, *multiple myxomata* of the size of peas of the same valve, and *spindle-cell sarcoma* of the pulmonary valves have been reported.

Secondary neoplasms of the heart are also rare but much more frequent than the primary. Secondary *carcinoma* is the most common tumor of this organ. Primary cardiac cancer is of course an impossibility, though in the older literature descriptions of growths regarded as such are found. These cases were either cancer-secondaries, or, as was not infrequently the case, sarcomata were diagnosed as carcinomata. Secondary carcinoma of the heart may arise through metastasis, or by extension through continuity or contiguity through the pericardium from carcinomatous growths in the lungs, œsophagus, or secondary deposits in the mediastinal lymph glands. Metastatic carcinoma of the heart may arise from emboli of cancer cells in the coronary vessels, on the mural endocardium, between the papillary muscles, and on the valves. From a secondary focus thus formed further extension may take place through the cardiac lymph channels. In this manner diffuse carcinomatous infiltration of the entire cardiac wall may take place. In other cases multiple metastases in the heart may be found. These may be found in the walls of both auricles and ventricles. There does not appear to be any favorite seat of deposit. In the majority of cases the carcinoma is of the medullary type. In the event of carcinomata breaking into the vena cava large emboli of carcinomatous tissue may be carried to the right heart where they may become attached to the endocardium or develop as free carcinomatous masses.

Secondary *sarcoma* of the heart, while less common than secondary carcinoma, has been observed by a number of writers. The growths are usually metastatic, but the heart may be involved also by extension through the pericardium from primary mediastinal sarcomata. The tumors may be single or multiple. They may be nodular, diffusely infiltrating, or in the form of flattened plate-like growths more or less sharply outlined. Free sarcomatous masses may be found in the right heart in cases in which the primary tumor has invaded a large vein. In a case described by Osler of sudden death in a child the tricuspid orifice was found blocked by a sarcomatous mass coming from the renal vein. In a case of primary sarcoma of the nose reported by the writer the entire heart wall was found to be infiltrated with sarcoma, while in the right ventricle there was a free sarcomatous mass of the size of a walnut.

Small tumors of the heart may produce no symptoms; larger growths may lead to cardiac hypertrophy, dilatation, valvular stenosis or insufficiency, rupture of the heart wall, secondary embolism, etc. An absolute diagnosis in the majority of cases is impossible. In suspected cases the Roentgen ray might reveal changes of size or form in the heart. If the pericardium is involved and a pericardial exudate present, some of the latter should be withdrawn for examination. The presence of a hemorrhagic exudate would be regarded as favoring the presence of a malignant tumor. Of greater diagnostic significance would be the character of the cells found in the exudate. The presence of numerous mitoses in these, particularly atypical mitotic figures, could be taken as almost positive evidence of the presence of malignancy. The treatment is wholly symptomatic.

Aldred Scott Warthin.

HEART DISEASES: NEUROSES.—THE NERVOUS MECHANISM OF THE HEART.—It has become known to physiologists that the power of pulsation of the heart is not engendered in, or derived from, the nervous system, but rests in the musculature of the organ itself. In the frog and other cold-blooded animals the heart continues for a short time to pulsate with a true rhythm after removal from the body and complete separation from nervous or other connection. The same is true in a minor degree in the higher animals, and while not actually verified by observation, will undoubtedly hold good in the case of man himself. Although striated the cardiac muscular structure is incompletely differentiated, and thus retains the power of spontaneous movement common to all primordial protoplasm. The nervous system, however, exercises a supreme influence over the cardiac movements. Two important sets of nerves derived from the cerebro-spinal and the sympathetic systems are concerned in the regulation and control of the circulatory centre. The scope of this article does not contemplate a complete and detailed description of the nervous supply of the heart and the phenomena of its mechanism. It is sufficient for our purpose to call attention in this place to the major facts relating to the functions of the two kinds of cardiac nerves which have been well established by physiological research.

1. Those derived from the vagus which are chiefly inhibitory or slowing to the action of the heart when subjected to a stimulation of either a direct or a reflex character. The vagus is thus known as the anabolic nerve of the heart. The pneumogastric trunk also conveys the depressor cardiac nerve which enables it to govern and regulate the arterioles in accordance with the demands of the heart.

2. The accelerator, or more properly the augmentor, nerves of the heart, derived chiefly from the first, second, and third cervical ganglia of the sympathetic system. The function of this cord, known also as the *katabolic* nerve of the heart, is to accelerate the frequency of the cardiac contractions and at the same time to augment their force. But when the question is asked, by virtue of what events produced in the heart itself do the impulses of one kind bring about inhibition and those of another augmentation of the impulses, we are met with difficulty. We may speak if we choose of an inhibitory mechanism placed within the cardiac structure, but we have no exact knowledge of the nature of such a mechanism, still less of an augmentor mechanism (Foster). It has been suggested that some of the intracardiac ganglia may serve as a medium for the distribution of these inhibitory or augmentor influences, but the evidence goes to show that the inhibitory impulses produce their effect by acting directly on the muscular fibres themselves. Nor are we in a position at the present time to assign the proper function of these ganglia, although it is believed that their influence is chiefly of a trophic or nutritional character. But, while the nervous system neither initiates nor controls the rhythmic movements of the heart, this function at once goes astray if removed from nervous governance. It is by the nervous system that the heart-beats and the calibre of the small arteries are brought into relation with each other and with almost every part of the body. It is by the nervous system acting either on the heart or on the small arteries that a change of circumstances affecting either the whole or a part of the body is met by compensatory or regulating changes in the flow of blood; that an organ has a more full supply of blood when at work than when at rest; that the tide of blood through the skin rises and ebbs with the rise and fall of the temperature of the air; that the work of the heart is tempered to meet the strain of overfed arteries, and that the arterial gates open and shut as the force of the central pump waxes and wanes. We have thus learned the seat of the automatic and rhythmic action of the heart, and are able to descry the part played by the nervous system in controlling the force, frequency, and rhythm of the muscular movements, and the tonicity or laxity of the vascular walls. But this knowledge does not aid us greatly in a definite appreciation of the pathogeny of the various disordered states of the organ which we designate as neuroses, nor does it quicken to any great extent our perception of the clinical phenomena, or our knowledge as to the therapeutic management of these conditions. The physiological relations existing between the vagus and sympathetic supplying cords on the one hand and the intracardiac ganglia and muscular structure on the other have not been sufficiently defined to enable us to agree upon any fixed or definite anatomical, pathological, or even clinical basis in our attempts to explain the cardiac neuroses.

NOMENCLATURE OF THE CARDIAC NEUROSES.—Until a very recent period the term palpitation was made to cover practically all of the nervous disturbances of the heart. With increased experience and additions to our clinical knowledge this restrictive appellation no longer serves its former purpose. It would appear indeed that we are in danger of going too far in the other direction. During the last decade or two there has developed a tendency to an embarrassing multiplication of terms in labelling the functional derangements of the heart. Furthermore, no two writers appear to agree exactly in classifying these disorders. It thus transpires that the nomenclature of the subject is at the present time in a most bewildering, it might almost be said chaotic, state. This is perhaps to some extent inevitable. Some of the conditions which we find it convenient to describe under distinctive titles so shade into each other that it is difficult to decide where one begins and another ends. For example, the condition described as palpitation may present at times the symptoms of neurasthenia cordis, or of arhythmia; while in tachycardia, the features of palpitation, or even of pseudo-angina, may obtrude themselves. Some of the terms employed do not constitute true symptom groups—they are mere symptoms themselves and not distinct diseases.

After much anxious thought and study of this subject, it has seemed to the author proper to present an account of these nervous manifestations, each under the head of the most prominent clinical features exhibited, noting the points of contact with other neurotic manifestations and such additional facts as our present state of knowledge would appear to warrant. It must be said that no perfectly satisfactory clinical classification of these disorders is possible until further light has been shed upon the physiological inter-relations existing between the supplying nerves, the cardiac ganglia, and the muscular structure of the organ itself. It has seemed to the writer, however, that all we know at the present time concerning the clinical and pathological features of the cardiac neuroses may be properly included under the following heads: (1) Palpitation; (2) tachycardia; (3) bradycardia; (4) the dyspeptic heart; (5) neurasthenia cordis; (6) the irritable heart; (7) arhythmia, including delirium cordis and tremor cordis; (8) the heart in Graves' disease; (9) angina pectoris and pseudo-angina. Of these terms it may be said that palpitation, tachycardia, neurasthenia, arhythmia, and angina are necessary and essential; the remainder might properly be omitted, but they are found in contemporaneous literature and may for the present be used provisionally as marking points of which we have no exact scientific conception.

PALPITATION.—According to Balfour all who suffer, or think they suffer, from disease of the heart are prone to palpitation. Under Laënnec's definition, any person whose heart's action obtruded itself upon the consciousness might be said to have cardiac palpitation. In accordance with the modern terminology, however, the name is used to cover a much more limited class of cases. One by one symptoms formerly referred to as falling under this term have been relegated to other forms of disorder, until at the present time palpitation has become quite unfashionable. Several writers mention it only as a symptom of other neuroses. In the author's opinion, however, it may still be regarded as a substantive affection covering a distinct symptom group.

Symptoms.—Probably some palpitation of the heart falls within the experience of every one. Being very near to our consciousness, eccentricities of the heart are usually attended by great perturbation of the nervous system. The attacks usually come on suddenly, independently of any mental or physical effort, and vary in severity from a mere sense of discomfort or uneasiness to a high degree of pain and distress. Some persons experience darting pains through the heart during the attacks, especially on attempting to take a deep inspiration. It is often brought on by a full meal and the belching of gas gives relief. The heart appears, as variously described by the patient, to jump, to roll, to throb, or to stand still. On physical examination the apex beat will probably be found to be increased in frequency and possibly in force during the attacks. It strikes the palpating hand with a quick throb which extends to the greater arteries. No murmur is present except in anæmic cases. Nor are there other signs of disturbance or lesion except possibly a slight intermittence or irregularity at times. The attacks may last for from a few moments to several hours, or at intervals for days together. One paroxysm generally implies a susceptibility to others.

Etiology.—The causes of this disorder are legion. Any sudden emotion—surprise, grief, fear, joy, or disappointment—may cause a transient palpitation in nervous persons. More severe and persistent forms are usually the result of some error or indiscretion on the part of the patient. Inordinate use of tobacco, tea, or coffee, dietary indiscretions, excessive venery, self-abuse, and late hours are fruitful causes. The condition is far more common among females than in males, and is especially frequent in the anæmic conditions of young girls. More or less palpitation is a common accompaniment of organic disease of the heart, brain, and spinal cord.

Like other pure neuroses, simple cardiac palpitation gives rise to no morbid structural changes which are tangible to our senses.

Prognosis.—The disorder is as a rule readily amenable to treatment, a withdrawal of the cause being usually sufficient to cause a speedy disappearance of the symptoms. At times, however, it is exceedingly obstinate and taxes the resources of the practitioner to the utmost. It may extend over years of time, but never *per se* endangers life.

Treatment.—This consists first in the removal of the cause, if it can be ascertained. It is quite useless to administer drugs with a view to relief of this disorder to a person consuming habitually excessive quantities of tea or tobacco. A careful mode of life is an important desideratum. Prudent and regular habits of eating and sleeping and moderate outdoor exercise are points to emphasize. A morning shower bath of moderately cold water followed by a vigorous friction of the skin with a coarse towel is a useful measure in lessening the liability to the attacks. In habitual cases the daily administration of three five-drop doses of the tincture of digitalis, combined with ten-grain doses of bromide of potassium, or sodium, has a valuable effect in warding off the paroxysms. It is important to give the patient full assurance that he is in no danger whatever as to his life. During the paroxysm the administration of some of the diffusible stimulants or antispasmodics to excite vagus inhibition is indicated. The old-fashioned combination of valerian, Hoffman's anodyne, and lavender is very serviceable. A good formula is as follows: ℞ Spiritus ætheris compos., Tinct. valerian., āā ʒ vi.; Spiritus lavandulæ compos., ʒ iv. M. et Sig.: ʒ ss. every half-hour until relief is obtained. The writer has found the application of some form of cutaneous irritant, in the shape of a small section of mustard leaf or thapsia plaster, to some section of the body remote from the heart so as to attract the patient's attention elsewhere, to serve a useful purpose. The administration of small quantities of brandy or ammonia may be useful in some cases, but it is seldom that morphine is required in simple palpitation. The application of a sinapism or a belladonna plaster to the heart is sometimes useful. It is said that certain mechanical means, such as holding the breath after a deep inspiration, pressure on the abdomen, etc., will sometimes abort an attack, but the author has discarded these measures after repeated futile trials. Compression of the vagus and sympathetic nerves in the neck and the use of faradism are worthy of a trial in obstinate cases.

Tachycardia.—Etymologically (*ταχύς*, quick, *καρδία*, heart) this word means a quick heart, but the name does not afford altogether an accurate conception of the disease. Tachycardia is characterized by an increased frequency of the cardiac pulsations, but not every person with a quick heart can be said to be a victim of the diseased condition which we now recognize under this appelation. Although the term has been subjected to great abuse, tachycardia properly embraces a fairly constant symptom group, and as such is entitled to be regarded as a separate and distinct morbid entity, and not a mere symptom. Many persons have normally a heart's action of 100 or more, but this does not constitute tachycardia, nor does the rapidly acting heart of emotional disturbance, or that associated with tuberculosis, fevers, organic disease, or Graves' disease. Many theories have been proposed in explanation of this strange affection, but none of them is fully satisfactory. In the present state of our knowledge we can do little more than guess whether the immediate causes lie in the augmentors of the heart, the vagus, the ganglia, or the musculature, or whether it be of centric origin. Possibly it is due at times to some eccentric irritation, such, for example, as a diseased ovary, a floating kidney, or a neuritis of distant cords. It seems rational to attribute the trouble in most cases to overstimulation of the accelerators or paralysis of the inhibitory nerves; probably in extreme cases both factors are operative.

Morbid Anatomy.—This condition is essentially a neurosis. It follows therefore that in the few autopsies which have been made in the case of persons who suffered from tachycardia during life no constant primary changes have been found, although there have been as a rule some marks of cardiac decadence in the shape of secondary degeneration of the muscular structure. Examinations of the vagus, the sympathetic, and the intracardiac ganglia have been negative.

Causation.—The etiology of tachycardia is in many cases past finding out. It is most likely to occur in persons of a neurotic or hysterical temperament, and in some cases it appears to be hereditary. Possibly such factors as worry, overexertion, frequent excitement of the emotions, and the abuse of alcohol and tobacco are concerned in the causation. Dyspepsia and diseases of the uterus and ovaries form a basis for many cases. Probably onanism and sexual excess or repression have some bearing on the causation. In a recent case, under the writer's observation, of convalescence from typhoid fever the pulse would quickly rise from 80 to 150 without apparent cause. The disease occurs with about equal frequency in the two sexes. It is rare under twenty, but no age is exempt. Perhaps a majority of cases are seen in persons in middle life.

Symptomatology.—The following clinical features are fairly uniform. The patient may have felt in an average state of health for a variable period, when a peculiar sensation of lassitude or restlessness steals over him. His apprehensions may be aroused and slight vertigo experienced. Perhaps the extremities become cold and numb, and a shivering feeling creeps up and down the spine. The face may become ashy or mottled. A sensation of oppression or tightness, but not of palpitation, is felt about the heart. This may occasionally amount to actual pain. During a marked attack the patient is quite helpless. He can neither stand, nor sit, nor lie with comfort. He is irritable and generally miserable. An examination of the heart will now show a pulse rate of 120 to 140 or 160. Sometimes it is so frequent as to be counted only with the use of the sphygmograph. A case was reported by Dr. Bristowe of 308 per minute! The use of the stethoscope shows no murmur or other evidence of organic disease of the heart. The pulsations have a tick-tack sound and not all of them are propagated as far as the radial artery. In most cases the urine is scanty, but nervous polyuria may exist. The attacks may last for a period ranging from a few minutes to several hours or even days. In a case reported by Bouveret the patient suffered for thirteen days (Allbutt). Permanent tachycardia is an expression of organic disease, usually in the course of the vagus or medulla, or an evidence of pontine softening with paralysis. The paroxysm generally ends suddenly with a few parting twinges of pain or twitching. During some attacks, especially in long-standing cases, signs of cardiac dilatation with œdema of the lungs, swelling of the ankles, and albuminuria may supervene. Death may possibly occur from asystole or syncope, probably nearly always from the latter. During the intervals patients recover their ordinary health but the substratum remains.

Prognosis.—This has to some extent been foreshadowed in the preceding paragraph. The ultimate termination in individual cases is always doubtful, but the immediate prospect, especially during the early years, is hopeful. Patients sometimes tolerate the affection for many years, dying eventually of old age.

Treatment.—We cannot with certainty arrest a paroxysm of tachycardia when it is under way, but we can lessen the tendency to recurrence by prudent and regular habits of life, by the avoidance of excess in every direction, and by the cautious administration of such tonics as strychnine and arsenic combined with a little digitalis or caffeine. During the attacks the exhibition of two or three half-ounce doses of brandy combined with five or ten drops of tincture of digitalis may be found useful in mitigating their severity. Strong coffee internally and the application of the ice-bag to the præcordium may have the effect of inhibiting the vagus, as may also electrization of the vagus, placing the positive pole over the inner border of the sterno-mastoid muscle and the negative up and down the lower part of the sternum. According to Whittaker, morphine is of little value in pure vagus tachycardia. Nitrite of amyl and nitroglycerin are likewise useless. Compression of the chest has been recommended by several well-known observers. The patient lying on his back thrusts his feet as hard as possible against the foot of the bed, then pressing his arm closely to his sides he takes a long inspiration. Now closing the glottis he makes a strong expiratory effort, thrusting hard at the same time against the walls of the chest with the upper arms and clasping them with the forearms. By this means it is stated that the rate of the heart may be controlled and the organ even caused to intermit in its action. A morning shower bath and the graduated douche or cold pack has been employed with advantage. When tachycardia is due to recent strains of the myocardium, the best treatment seems to be absolute rest, the full action of belladonna or atropine as indicated by slight dilatation of the pupil, being maintained at the same time.

Bradycardia—(from βραδύς, slow, and καρδία, heart), otherwise known as araiocardia, oligocardia, pulsus rarus, pulsus tardus, etc. This condition cannot in our present state of knowledge be identified as a distinct affection. The name connotes nothing and signifies nothing more than a phenomenon common to many definite groups. There is not, as in tachycardia, a particular symptom group of which bradycardia itself is the centre. Several cases of what was supposed to be essential paroxysmal bradycardia have been reported, but a closer and more continued observation has shown that these cases were always secondary. A description of the condition therefore can consist only in detailing the various diseases or disorders of which it is one of the clinical features. The phenomenon is no doubt partly due to direct or reflex irritation of the vagus centre, or the vagus trunk, and partly to increase of arterial pressure by vasomotor or purely muscular contraction of the peripheral arteries. It may also be brought about by diminution of pressure due to loss of blood, to direct influence on the heart muscle of substances circulating in the blood, and finally to anatomical changes occurring in the musculature of the heart or of the endocardium. Some persons have naturally a slowly acting heart, without apparent detriment to their vital functions. The well-known case of the first Napoleon is a familiar example. According to his physician, Corvisart, the apex beat of this by no means slow individual averaged only 40 per minute. While bradycardia is undoubtedly produced through some form of defective innervation, it cannot be accurately defined as a neurosis. It is an incident of organic disease of the brain and its meninges and of the spinal cord. During the progress of a case of pachymeningitis in a little boy, aged five years, lately under the writer's care, the heart beats fell as low as 48 per minute for several days before death. It may occur as a result of fracture of the vertebræ with compression of the cord, usually in the region of the fifth or sixth cervical vertebra. It occurs in epilepsy and is an incident of many infections, including typhoid fever, pneumonia, erysipelas, and rheumatism. Slow heart is often observed in puerperal women, and it may result from the presence of bile in the blood, of anæmia, of diabetes, or it may be due to many of the disorders of the intestinal tract. It is probably not often caused by alcohol or tobacco, nor is it an incident of organic disease of the heart, except when the myocardium is involved. It is occasionally seen in aortic stenosis and may result from occlusion of the coronary arteries.

The condition calls for no special form of treatment, its management being involved in the general treatment of the associated disease or disorder. It is usually advisable, however, to administer digitalis in moderate doses so as to maintain the metabolism of the myocardium and enable it to withstand the great strain produced by the conditions under which the circulation is carried on.

The Dyspeptic Heart.—Here we have another name applied to certain neurotic states of the heart. The term has not acquired extensive vogue as yet, but its use appears to be increasing. Is there a symptom group referable to the heart as its centre occurring with sufficient frequency or uniformity to warrant the addition of the term dyspeptic heart to our nomenclature as a separate and distinct affection? After much careful thought and observation the writer is led to answer this question in the negative. Aberrations of the digestive functions lead to all kinds of disturbances of the heart's action, whether it take the form of palpitation or of tachycardia, of neurasthænia cordis or of pseudo-angina; but they present nothing peculiar or distinctive. The neurotic cardiac manifestations due to digestive trouble are quite similar to those resulting from other causes, plus the presence of clinical features referable to the stomach or intestines. The association of gastric and cardiac trouble is one of extreme frequency, so much so that it is important to investigate every case of functional cardiac disorder for a possible digestive origin. These disturbances are of two kinds: first, reflex, giving rise usually to simple nervous palpitation, but not infrequently to tachycardia, to bradycardia, and even to pseudo-angina. It is probable that almost every case of so-called *tremor cordis* is of gastric origin. Second, the most severe and even dangerous symptoms of mechanical disturbance of the heart arise from the presence of an overloaded or tympanitic stomach. Some of these cases closely resemble in their manifestations organic disease of the heart itself, and it is not to be doubted that not a few sudden deaths attributed to heart disease might more justly have been credited to an abused and rebellious stomach. These cases of mechanical interference with the action of the heart are not, however, strictly speaking, neuroses, and do not properly fall within the domain of our present subject. It need only be added that in all cases of cardiac trouble of gastric origin therapeutic measures are to be addressed to the stomach and not to the heart.

Neurasthenia Cordis; The Weak Heart.—This condition is very similar in its manifestations to the irritable heart of some authors. It is practically identical with the not infrequent class of cases somewhat loosely denominated weak heart. The condition denotes aberration or insufficiency of the heart, the result of defects of innervation. It is clearly a neurosis, and in our present state of knowledge excludes all organic disease, although the time is probably close by when keen observers will be able to distinguish pathological departures in the intimate structure of the cardiac ganglia or nerve trunks, or perhaps in the muscular substance of the myocardium. Patients suffering from this affection usually belong to the neuropathic type, which may or may not be the result of defective endowment, hereditary or otherwise. It is brought on by overstudy, by sexual excess, or possibly by coitus reservatus, by long continued depressing emotions, failure in business, frequent excitements, long marches, and exhausting efforts of all kinds. Onanism and unrequited love have been cited as fruitful causes. It is frequently seen after recovery from long attacks of prostrating diseases, more especially the essential fevers. Being to some extent an occupation neurosis, it is far more frequent in males than in females. It seems to occur with unusual frequency among ironworkers engaged in high-building operations.

Symptoms.—By what means are we able to identify the condition of neurasthenia cordis? The cardiac features predominate, although general nervous manifestations are usually prominent. The patient as a rule is fretful, irritable, and fidgety. He is easily startled on sudden excitement and is apt to be more or less hypochondriacal in his tendencies. The cardiac attack itself is liable to begin with some quickening, possibly more or less irregularity or intermittence of the heart. The first cardiac sound is short and lacking in volume; the second sound is not accentuated. Palpitation is not common, but there may be a feeling of more or less uneasiness about the heart. The patient is apt to show vasomotor disturbances in the shape of frequent changes of color in the face and sudden coldness, followed by burning heat of the hands and feet. There are no œdema of the feet or ankles and no dyspnœa, but in severe cases there may be sufficient local distress to resemble pseudo-angina. The sleep is liable to be restless and the patient wakes with a sudden jump of the heart. After the stage of irritability the patient falls into a state of more or less depression, marked by defective nutrition. Insomnia is a constant symptom. In some cases the patients are unable to be up and must remain in bed. The pulse continues to be weak and excitable and the sphygmograph shows marked dicrotism.

Diagnosis.—The diagnosis of neurasthenia cordis is to be reached by discriminating consideration of the symptoms, as above outlined, and by exclusion. The term weak heart is too often used as a cloak. This condition is not one of palpitation on the one hand, nor of tachycardia on the other. The patient's general long-continued neurasthenic state, coupled with the cardiac symptoms and with the absence of any signs or symptoms of organic trouble, of Addison's disease, diabetes, carcinoma, or tuberculosis, renders the existence of neurasthenia cordis a practical certainty.

Prognosis.—Neurasthenia cordis seldom destroys life directly, but it forms a bad accompaniment for acute prostrating diseases. Patients succumb much more readily to typhoid or other intercurrent affections. The condition is essentially chronic and a long duration may usually be predicted.

Treatment.—This should consist chiefly of cheerful surroundings, agreeable society, and pleasant occupation. The food should be simple, abundant, and easily digested. Daily systematic outdoor exercise, particularly walking at a slow or moderate pace, should be advised. A morning shower bath as cold as the patient can endure and react from with comfort is a useful habit to inculcate. Da Costa allows alcohol in liberal quantities to patients of this type, but it seems to the writer that this remedy should be used as discriminatingly in these cases as elsewhere. One of the lighter wines may be allowed with meals, but in most cases the extract of malt will answer all purposes to be gained from alcohol and with less likelihood of unpleasant results. A very useful stomachic tonic and reconstructive is as follows: ℞ Acid. hydrochlor. dil., Tr. nucis vomicæ āā fl. ʒ iv.; Elixir lactopeptin q.s. ad fl. ℥ iij. M. et Sig.: A teaspoonful in half a wineglassful of water before each meal. Cascara, rhubarb, and Kutnow's improved sprudel salt used alternately are to be preferred for the constipation of these sufferers. The bromides, valerian, and even opium may be required at times. Digitalis and nitroglcyerin are useless.

The Irritable Heart.—Under this name a form of cardiac neurosis is described in various ways by different writers. The term was originally used by Da Costa in describing a peculiar cardiac excitability which he found to exist among soldiers in the field. The condition is much more frequent among men than among the gentler sex, and is usually seen prior to the thirtieth year of life. The patient complains that he is never free from a tired feeling about his heart, sometimes a sharp pain is felt. The organ is liable to throb and jump and is never entirely outside of consciousness. Even when the patient is lying quietly in bed it makes itself a nuisance, banging away at the time when he should be asleep, while exercise or exertion brings on a violent beating (Allbutt). In most cases there is a history of overexertion. The trouble frequently remains among college men as a reminder of the rush and crush and indiscretions and untamed passions of youth. Spasmodic bouts of study, overdoses of alcohol and tobacco, late suppers, overwork in the gymnasium, and other incidents of an irrational and irregular life in a nervous or dyspeptic young person usually go to form the groundwork of the irritable heart. A physical examination may show a slight degree of hypertrophy, but dilatation is most frequently present. The peripheral arteries are lax and the pulse is dicrotic; its slackness is in marked contrast with the excitable state of the heart itself. The rhythm of the cardiac contractions is often a little uneven and the second sound at the apex too loud. The action of the heart may seem labored and heavy under the palpating hand. A murmur may possibly be heard, but more often simply an impurity of the first sound, as though it were dimmed by a distant murmur.

Treatment.—Prevention of this trouble during the early years of young adult life is of the utmost importance. Young men especially should be warned of the dangers of an unsteady method of life. Violent and irregular exercise, drinking and smoking to excess, late hours and sexual indiscretions should be guarded against. Adolescent youths are prone to err in all of these directions, and it is the function of older and wiser persons to inculcate correct and uniform habits. If the condition which we know as the irritable heart has actually become established, the medical adviser of the patient must set himself to the task of repairing the mischief without delay. The patient's daily habits must be carefully investigated, and his life made as tranquil and as free from sources of irritation or excitement as possible. His good health cannot possibly be recovered by any other means. It is useless to give digitalis or other cardiac tonics or stimulants, though at times a systematic exhibition of bromides in small doses may serve a useful purpose. In many cases a complete change of scenery and surroundings is required. A temporary removal to a quiet rural locality absolutely free from temptations to indiscretions or excess is usually followed by good results.

Arrhythmia (*a*, privative, and ρυθμός, rhythm), known also as the pulsus inæqualis or pulsus irregularis, is a disturbance of the rhythmic contractions or regularity of the heart. The rhythm of the heart may be normally intermittent or irregular in some persons, and slight deviations of this kind are not incompatible with the complete and proper performance of the cardiac functions. It is not uncommon to notice certain disturbances of the rhythm in childhood, especially during sleep, which disappear after the child wakes and runs about. This has no pathological significance, but the irregularities which are increased by exercise or excitement, especially if accompanied by pain or palpitation, are always a sign of gravity. Irregularities of the heart may be due to direct, reflex, or toxic causes, or a combination of any or all of these. According to Roy and Adami, they are brought about by the failure of the auricles to respond to some of the contractile influences which reach them from the sinus (venosus), or by the interference of the sinus and ventricular rhythm with each other. Ultimately the cause of all irregularity may be traced back to inhibition of the heart through, but not by the vagus. Simple intermittence is always an indication of cardiac failure due to anæmia, overwork, or worry. It may be associated with valvular lesions, but has only an incidental connection with them. Intermittence may be true or false. In true intermittence the heart itself actually omits a contraction, while in false intermittence the organ contracts but the pulse wave is not transmitted to the wrist. These insufficient waves are known as "frustrate" contractions and sometimes observe a form of regularity themselves, *e.g.*, the second, third, or even up to the tenth or fifteenth contraction may be a frustrate, or two frustrates may appear together successively, or they may be irregular for some time and then show themselves in rapid succession. In some instances these frustrate contractions are simply due to a slight nervous disturbance and have no real significance. Among the writer's patients is a man of sixty, usually in the best of health, whose heart has shown these intermissions for the last fifteen years. Sometimes strong and weak beats alternate with each other regularly, giving rise to what is termed the *pulsus alternans.* Two strokes in quick succession followed by a longer pause constitute the *pulsus bigeminus*, three strokes the *pulsus trigeminus.* A combination may occur constituting the *pulsus bigeminus alternans.*

ALLORRHYTHMIA (ἄλλος, another) is a condition in which a distinct method is observed, the irregularity being always the same. When, in addition to this state, the heart is tumultuous, it is known as *delirium cordis.* The writer has at the present time a case under observation in which acceleration, intermittence, and irregularity are combined, the pulse rate never being less than 160 per minute, and complete allorrhythmia being present. The *pulsus paradoxus* is more a disturbance of the pulse than of the heart, the pulse being weaker instead of stronger during inspiration. The rhythm of the heart may be in no wise disturbed, but its contractions are not strong enough to propel the blood through the vessels of the thorax against the inspiratory suction force which arrests or holds back the blood wave.

Causes.—Arhythmia is found occasionally in all of the other cardiac neuroses and the causes which originate those conditions likewise bring about irregularity of the cardiac rhythm. Disease of the brain and spinal cord and pressure upon the nerve trunks by tumors or inflammatory products are among the direct causes. In leucocythæmia and progressive pernicious anæmia, conditions interfering with the nutrition of the heart, arhythmia is a frequent accompaniment. It is sometimes due to the pressure on the heart of a large pleuritic or pericardial effusion, or a flatulent or distended stomach. Among the reflex causes may be included diseases or disorders of distant organs or parts, viz., an inflamed ovary or uterus, the passage of a gall-stone, a blow on the stomach, a sharp attack of intestinal colic, or an operation on the pelvic or abdominal viscera. The toxic causes embrace certain drugs, notably muscarin, alcohol, digitalis, strophanthus, tobacco, chloral hydrate, and aconite, all of which may cause interference with the cardiac rhythm. Certain infections, like those of typhoid fever, scarlatina, diphtheria, etc., produce this result. In a severe case of scarlatina under the writer's care in a little girl aged six years, the heart remained intermittent during sleep for some weeks after the passage of the fever.

Symptoms.—The symptoms of arhythmia are referable chiefly to the heart and pulse and are of an objective character. Many persons have an irregular or an intermittent heart for years without becoming aware of it. In many cases there are no subjective symptoms whatever, while in others there may be a feeling of anxiety about the præcordium or even severe palpitation or anginal symptoms. In grave cases there may be signs of pulmonary œdema, cyanosis, or dropsy. The condition is to be recognized only by a careful observation or actual count of the heart's pulsations.

Prognosis.—This depends entirely upon the cause. It may possess no evil significance whatever, or it may be a harbinger of approaching dissolution. As a rule arhythmia may be looked upon as a graver symptom than palpitation. If it disappears under excitement or exercise, it may be disregarded as of little consequence, but if increased under these circumstances it is a sign of gravity. The intermittence or irregularity resulting from the abuse of alcohol, tobacco, and bad habits at the table generally disappears on removal of the offending cause.

Treatment.—The systematic treatment of arhythmia is closely involved in that of the associated conditions, although the symptoms of irregularity and intermittence will at times require direct attention. If there be present a flatulent or an irritable stomach, measures directed to its relief should not be delayed. If the uterus is displaced, it should be restored to its proper position; if an ovary is diseased or a kidney loose from its anchorage attention must be given to these matters. The arhythmia following acute febrile states generally disappears with the lapse of a few weeks more or less. In most cases of persistent arhythmia the daily administration of strychnine, in doses of not less than one-thirtieth of a grain before each meal, is indicated; with this may be combined one-half to one grain of digitalis or caffeine, or two or three minims of the tincture of strophanthus. In cases of high arterial tension, as shown by a hard, incompressible pulse, the use of nitroglycerin is required. If the action of the heart be heaving and tumultuous a warm bath (96° to 100° F.) may be of service, provided there is no atheroma or other organic trouble with the heart or arteries. Mild cases are often benefited by the systematic use of cold baths. Icebags to the præcordial region have been recommended by some excellent authorities. The use of massage is frequently productive of good results. Moderate exercise, regular habits, and proper food should be insisted upon.

TREMOR CORDIS.—This term savors somewhat of pedantry. It should never be understood as being applicable to a morbid entity, but to a symptom sometimes met with in neurotic persons, especially those of a dyspeptic tendency. It is a peculiar form of irregularity of the heart which seizes the sufferer without a moment's warning. The symptom is exceedingly alarming to the patient but is devoid of danger. "Like a bolt from the blue, and with as little warning, a quiet, steady heart is suddenly seized with a rapid fluttering and the ordinary full pulse of health suddenly drops to a mere tremulous thread" (Balfour). The attacks may vary in duration from three or four to a series of short, rapid, incomplete systoles extending over several seconds. On laying the hand over the heart a delicate, tremulous sensation is felt and the radial pulse is scarcely perceptible. The paroxysm ends suddenly with an unusually forcible beat and is never attended by faintness or vertigo. There is no doubt some weakness of the myocardium and cardiac tonics are required, but all direct medication must be subordinated to careful dieting and promoting the general health.

DELIRIUM CORDIS denotes an extreme degree of irregularity accompanied by intermittence and a rolling or staggering sensation conveyed to the palpating hand. It is usually classified as a neurosis, although, as it seems to the writer, improperly so, as true examples of the condition are found only in cases of dilatation and, very rarely, in mitral stenosis. Delirium cordis is not very amenable to treatment, but large and frequently repeated doses of digitalis sometimes give temporary relief.

THE HEART IN GRAVES' DISEASE.—Graves' or Basedow's disease, more recently known as the thyroid cachexia, is classified by numerous authors among the cardiac neuroses. This, it seems to the writer, is not fully warranted. The clinical triad which constitutes the basis of a typical case of Graves' disease are, first, a rapidly acting heart; second, enlargement of the thyroid gland; and, third, protuberance of the eyeballs. All of these symptoms are not invariably present. It often happens that the bulging eyes, or hypertrophied thyroid, are not in evidence. The rapid heart is the most constant symptom, but the writer has seen more than one case presenting all the active signs and symptoms of

Graves' disease, with a heart's action little or not at all accelerated. In a well-marked case of thyroid cachexia, however, the action of the heart is very rapid, amounting to 120 or more beats to the minute. This is often accompanied by a violent throbbing, which extends even to the small arteries. The sounds of the heart are also greatly augmented in volume, being audible in some instances at a distance of several inches from the chest. This peculiar action of the heart differs from simple palpitation by its continuity and by its embracing the small arteries as well as the heart itself in the throbbing. At first there is no structural change in the heart, but the rapid and perturbed action is associated with a falling-off in the ventricular output, and this ultimately leads to residual dilatation with its attendant train of evils. The treatment of the thyroid cachexia is to be directed to the general condition and not to the heart, although a little digitalis combined with Hoffman's anodyne or valerian may be exhibited to mitigate severe throbbing. General tonics, outdoor air, and good food, supplemented by the use of the thyroid or thymus extract, are recognized at the present time as offering the best hope for a modification of the course of this prolonged and obstinate affection.

Angina Pectoris.—This name was introduced by Heberden in 1768. It was intended to denote a strangulation (*angere*, to bind, to strangle). The affection has been known as stenocardia, sternalgia, and breast-pang. There are two varieties, the true, or angina pectoris proper, and the false, or pseudo-angina. True angina is always attended by structural changes and is no more a neurosis than is atheroma or endocarditis. It is usually treated as a neurosis, however, and this is at least partially justified by the fact that the most formidable and striking manifestation of the trouble undoubtedly has its origin in some of the nerve structures communicating with, or located within, the heart. Many authorities have regarded it as a neuralgia. Pseudo-angina is not attended by organic change and is unequivocally a neurosis. The features of false angina are not usually so severe as those of angina vera, but it is not always possible to separate the two. A fatal issue has undoubtedly resulted from pseudo-angina pectoris in some instances.

Causation.—The structural changes which constitute the basis of true angina pectoris do not occur in early life. Thus the affection seldom makes its appearance before the fortieth year of age. All influences which give rise to sclerosis or atheroma of the arterial coats tend to lay the foundation of this dreadful disease. These are notably alcoholic excess, high living, syphilis, gout, lead-poisoning, and overwork, especially of a mental or sedentary character. Probably ninety per cent. of cases occur in males. It is especially prone to appear in persons in the upper walks of life, those of an intellectual occupation being most liable to it. Physicians, clergymen, lawyers, and writers supply the greater number of victims. Heredity plays a rôle in some instances. The paroxysms may be precipitated by exhaustive work or sudden excitement, anger, fright, etc. A patient under the writer's observation suffering from a double aortic lesion developed attacks of unmistakable angina on two successive occasions when taken before a class of students.

Morbid Changes in True Angina Pectoris.—Atheroma of the coronary arteries is the most constant lesion present. Welch found this change in every one of six fatal cases. Embolism of these vessels may also be present, as pointed out by Cohnheim and Virchow many years ago. The process is apt to begin in the ascending aorta at the point of origin of the left coronary artery. The calibre of this vessel may become entirely occluded, or so contracted that a bristle cannot be passed into it. Various other organic lesions have been observed, notably fatty degeneration of the heart, calcification of the aortic valves, aneurism of the aortic arch, pericarditis, and endocarditis. Not every case of coronary sclerosis is accompanied by angina pectoris. The lumina of the vessels are sometimes left sufficiently patent to admit of enough blood, and in other cases the cardiac circulation is carried on by supplemental coronaries which remain unaffected. It will thus be seen that an imperfect metabolism of the myocardium furnishes the groundwork for angina pectoris. No one has ever seen the heart during a paroxysm of angina, but reasoning from analogy it seems probable that the seizures are precipitated by a sudden ischæmia of the cardiac muscles, the blood supply of the coronaries being for the moment totally, or almost totally, arrested. Pseudo-angina may be produced by any of the causes which have been enumerated as producing other cardiac neuroses. It is in greater or less degree an occasional concomitant of those affections. Probably "angina dyspeptica," a mere gaseous dilatation of the stomach, constitutes a majority of the cases of pseudo-angina pectoris in nervous subjects.

Symptoms.—The paroxysm may set in suddenly without previous warning, although the marks of arterio-sclerosis and general failure of the health and strength may have shown themselves for some years. Cardiac palpitation, arhythmia, etc., may also have been experienced. The attack may come on when the patient is sitting quietly in bed, but is most likely to appear during some exertion, such as climbing a hill, breasting the wind, or straining at stool, or when laboring under some form of excitement. In true angina the seizure is of overwhelming suddenness and of unspeakable intensity. The pain begins in the præcordial region, usually about the midsternum, and radiates as a rule upward into the left shoulder and down the left arm, perhaps as far as the finger ends. Sometimes it is propagated in the direction of the right shoulder, or possibly downward toward the leg or the lumbar region. The nervous system is acutely alert. One of the most characteristic features is the feeling of imminent death. Some patients state that the heart feels as though it were being tightly squeezed in the grasp of a gigantic hand. Probably no condition in the entire range of our knowledge entails more dreadful agony than that of a typical attack of true angina. In some cases a sense of coldness, numbness, deadness, creeping, or other vaso-motor disturbance is felt. In others the pain may not be so acute, but takes the form of a dull ache (angina sine dolore) and is overshadowed by the intense anxiety. During the attacks of angina the features are haggard and the face is blanched; the forehead is bedewed with a cold sweat. The respiration, as a rule, is in nowise affected but may be hurried and superficial. The patient is well able to take a deep breath, but is afraid to attempt it. He usually prefers to keep perfectly quiet in a sitting or upright posture for fear of increasing the severity of the paroxysm. A physical examination may or may not show the signs of organic heart disease; the most frequent lesion is aortic stenosis. During the attack the heart's action may be increased or diminished in frequency. In one of the writer's patients it sank below 40 per minute. The blood pressure is always raised at the beginning of the attack. The seizures may last for from a few moments to an hour or more, probably five or ten minutes being about the average. After the attack, which may cease as suddenly as it set in, the patient feels weak and exhausted for a short time. A sensation of numbness and formication in the arms may be experienced. There may be a considerable belching of gas and voiding of a large quantity of urine.

Diagnosis.—This is usually not difficult. No other condition presents the same complex of symptoms—sudden irradiating pain, squeezing, tightening, constriction, overwhelming sense of impending death, etc. As distinguishing between true and false angina, Huchard's aphorisms, while not infallible, are very important: (1) Every angina produced by effort is a true angina. (2) Every angina which occurs spontaneously, without effort, is a false angina. (3) But an angina occurring at night, though independent of effort, is a true angina. Disturbance of the special senses, hysterical manifestations, etc., are far more characteristic of false than of true angina. The absence or presence of signs of organic heart disease is important in the diagnosis. The hysterical pseudo-angina of young women is excluded by the sex and age of the patient, the ability to scream and throw herself about, and the probable presence of anæmia or menstrual disorders. The pseudo-angina of alcohol and tobacco occurs as a rule in young persons and can generally be recognized by the history of the case. The pain here is of subordinate severity. In cardiac asthma dyspnœa is a marked symptom, but is entirely absent in angina pectoris. Then in cardiac asthma are superadded the symptoms of blood stasis in the extremities, cold hands and feet, hyperæmia of the liver, and occasionally the expectoration of blood-stained sputum.

Prognosis.—In true angina the prognosis for complete recovery is hopeless, the anatomical lesions not admitting of restoration. The patient is in constant danger. He may die in the first attack, or after several attacks. Unexpected prolongation of life occurs in some cases. The patient may not have a repetition of the early attacks and may possibly die of other troubles. A case reported by Murrell lasted forty years, and the elder Austin Flint believed that he had seen a case of actual recovery.

Treatment.—This resolves itself into the management, first, of the paroxysm, second, of the interval. When called to see a case during an attack the practitioner should always feel the pulse; this will generally but not invariably be found hard and tense, denoting high arterial pressure, which condition is usually present at the beginning of an attack. The first object of treatment is to lower the blood tension and relieve the strain on the heart. For this purpose the nitrite of amyl is still our most prompt and efficient weapon. This drug may be administered by inhalation, a few drops being placed on a handkerchief and held to the nose, increasing the dose carefully if necessary. Small pearls or capsules may be supplied to the patient with instruction to break and inhale in the event of an attack. Nitroglycerin acts in a similar manner to nitrite of amyl but is much slower. Its effects, however, are more lasting, usually extending over a period of from four to six hours. It is very useful in mild cases of vaso-motor angina and in pseudo-angina. The nitrite of sodium has an effect quite similar to that of nitroglycerin. If the arterial tension be found low and the pain still severe it is better to try the administration of a little chloroform or ether by inhalation, the former being, in the writer's opinion, most trustworthy. These agents must always be used by the physician or a trained attendant. A hypodermic injection of morphine is sometimes demanded. Yeo recommends the continuous current at the inception of a paroxysm. Mild cases may be relieved by antispasmodics and diffusible stimulants such as Hoffman's anodyne, musk, valerian, and assafœtida. Sinapisms or hot-water bags to the surface are sometimes helpful, and the same may be said of the quick application of the ice bag or cold cloths. During the intervals the underlying pathological state—arterio-sclerosis—should be combated by every available means. The iodide of potassium, strychnine, and arsenic form our main reliance. According to Balfour, arsenic is indicated in all heart diseases attended with pain. A most careful and discriminating mode of life is to be observed. All undue exposure and excitement should be avoided and the strictest self-control practised. *James K. Crook.*

HEART DISEASES: SYPHILIS.—Syphilis of the myocardium manifests itself in the form of a local or diffuse fibroid myocarditis or as a gummatous myocarditis. The interstitial induration is by far the more common process; it may be the result of the direct action of the syphilitic poison or secondary to a syphilitic endarteritis. It occurs in both acquired and congenital syphilis, in the former case as a tertiary lesion. In its earliest stages the interstitial change is found as a cellular infiltration along the small vessels of the intermuscular connective tissue. Fibroblastic proliferation occurs in the latter, leading gradually to the formation of small scattered nodules of granulation tissue, which soon become converted into scar tissue. In the fibroid areas thus formed remains of degenerated muscle, pigment, fat droplets, etc., are found. The newly formed fibrous tissue may undergo caseation or become calcified. The neighboring muscle shows extensive atrophy and fatty degeneration. In other cases the cellular infiltration is in the form of bands or sheets running parallel with the axis of the muscle bundles. These may or may not be sharply defined; usually the new tissue sends out fine prolongations into the neighboring muscle. As the cellular infiltration develops it becomes gradually changed into a coarse hyaline variety of fibrous tissue containing few nuclei. Through atrophy of the intervening muscle the bands of connective tissue gradually coalesce and may come to make up the entire thickness of the heart wall from pericardium to endocardium. The left ventricle, the anterior wall, the apex, and the septum ventriculorum are most commonly affected, the papillary muscles and the walls of the auricles only rarely. In the congenital form the wall of the right ventricle is much more frequently affected than that of the left.

In the majority of cases the fibroid change is directly dependent upon the presence of an obliterating endarteritis in the coronary arteries. Complete occlusion of a terminal branch produces anæmic infarction, the necrosed muscle being replaced by scar tissue; slowly progressive obliteration of the vessels leads to degenerative changes in the muscle with secondary inflammation and proliferation of the interstitial tissue. To the naked eye the fibroid areas appear as white, glistening, tendon-like bands or masses. The weakening of the heart wall, due to the inability of the new connective tissue to contract against the intracardiac pressure, often leads to an aneurismal dilatation at the point of greatest change.

The gummatous form of myocarditis is of much less common occurrence. It is usually associated with a more or less diffuse interstitial change. It is probable that in many cases the fibroid myocarditis found at autopsy is the result of antecedent gummatous processes. Gummata may be found in any part of the heart wall, in the myocardium, or beneath the peri- or endocardium. To the naked eye they appear as yellowish or grayish cheesy nodules, varying in size from a mustard seed to a walnut, and are usually surrounded by a dense fibrous capsule. Fresh gummata are red or pink in color and of a soft homogeneous structure. They do not possess a fibrous capsule and are not sharply outlined from the surrounding tissue. Usually the heart gummata are solitary, but in many cases multiple caseous nodules are found scattered throughout the cardiac wall. When the gumma is located just beneath the peri- or endocardium chronic adhesive pericarditis and sclerosis of the endocardium are usually present. Hypertrophy and dilatation of the heart are frequent secondary changes dependent upon the myocardial condition. On microscopical examination the gummata of the heart are distinguished from those in other regions of the body by the cellular nature of the process, the rarity of giant cells, and the relatively slight degree of caseation. Obliterating endarteritis of the coronary arteries may or may not be associated with gummatous myocarditis.

Slight degrees of interstitial myocarditis and gummata of small size may give rise either to circulatory disturbances or to general symptoms. In the majority of cases the onset is slow and insidious, the symptoms of serious myocarditis developing only when extensive involvement of the heart muscle has occurred. Consequently sudden death from acute cardiac insufficiency is very common, occurring in two-thirds of the cases. In those cases which are observed for some time before death dyspnœa, venous stasis, ascites, and general œdema gradually developed without the presence of the physical signs of valvular disease. Extensive fibroid change or gummata of large size may lead to aneurismal dilatation of the heart wall, general hypertrophy, or dilatation accompanied by the gradually developing symptoms of cardiac insufficiency. Rupture of a softened gumma into the blood stream very frequently leads to thrombosis and embolism. In the reported cases the emboli were found in the vessels of the retina and choroid, and in the coronary and pulmonary arteries. A form of syphilitic angina pectoris has been described by some writers who have attributed it to a specific action of the syphilitic poison upon the neuro-muscular apparatus of the heart wall or upon the sympathetic nerves. The progress of cardiac syphilis is usually very slow, periods of apparently good health may alternate with extended attacks of cardiac insufficiency. In either period slight accidents may cause sudden death. This may be due to rupture of the heart or to occlusion of the coronary arteries, either through fibroid changes, or through thrombosis or embolism.

The diagnosis of syphilitic disease of the heart rests upon the exclusion of other causal factors and the establishment of the existence of a syphilitic infection, either past or present. In doubtful cases the therapeutic test should be employed. The prognosis in undoubted cases of syphilitic myocarditis is very unfavorable if the condition is well advanced. Only in the earliest stages, before much structural change of the heart wall has occurred, is there hope of a cure. The treatment is that pursued in cases of syphilis in general, with special treatment directed to the myocardial condition. It is very probable that systematic treatment of all cases of syphilis, if continued faithfully for four or five years, would greatly diminish the number of cases of myocardial syphilis. *Aldred Scott Warthin.*

HEART DISEASES: TUBERCULOSIS.—Tuberculosis of the myocardium is very rare. The first recorded case is that of Townsend in 1832. In 1894 Valentin collected thirty-six cases from the literature, and estimated that the condition occurred but once in one thousand tuberculous bodies. Hand, in 1898, collected forty-two cases, and in 1899 Thiry was able to gather sixty-three cases from the literature up to that year. With the exception of a few cases the condition was secondary to tuberculous disease elsewhere in the body. Demme and Knopf have reported cases thought to be primary. The majority of the cases occurred before the fifteenth year, several in infants. The ventricles are more often affected, the wall of the right auricle next in frequency. In the majority of cases the lesions are characterized by the scarcity of tubercle bacilli found in them.

The infection of the myocardium occurs either by direct extension from the pericardium or endocardium, or by hæmatogenous or lymphogenous metastasis. According to some writers a retrograde lymphogenous metastasis from the bronchial lymph glands forms the most common means of infection. This is denied by others, inasmuch as the lack of collateral anastomosis of the cardiac lymph vessels does not favor retrograde metastasis. In the miliary cases the avenue of infection is usually through the veins.

The disease may manifest itself in several forms: (1) Scattered miliary nodules through the muscle; (2) large caseous nodules varying in size from a pea to a hen's egg, usually multiple, but occasionally single; (3) diffuse tuberculous myocarditis in the form of a fibroid change with scattered caseous nodules of small size; (4) fibroid myocarditis with small non-caseating tubercles. The third and fourth forms are very rare; and are with difficulty distinguished from syphilitic processes, as the bacilli are found in such scanty numbers as to be very difficult of demonstration. The miliary tubercles are usually most numerous just beneath the epicardium, occasionally beneath the endocardium. They rarely extend far into the muscle. The large caseous tubercles represent a more chronic infection; they may be encapsulated or show extensive signs of healing. In these cases the pericardium is almost always involved, the endocardium only rarely when the lesion is in the ventricles. In the case of a tubercle of large size developing in the auricular wall both peri- and endocardium are soon involved. Perforation into the auricular cavity may take place and give rise to a general miliary tuberculosis. In a case reported by Püschmann there was an acute miliary tuberculosis which seemed to have taken its origin from a thrombus containing numerous tubercle bacilli which was attached to a caseating tubercle in the auricular wall.

With slowly developing tubercles there is always associated an interstitial myocarditis. In the case of the large caseous tubercle this process is confined to its immediate vicinity. This form of interstitial myocarditis is much less important than the diffuse form associated with scattered tubercles of slow growth and showing little tendency to caseate. In spite of the weakening of the cardiac wall through replacement of the muscle by connective tissue and through caseation of the tubercle, a rupture or aneurism of the wall is not likely to occur in these cases because of the diminished blood pressure. In none of the recorded cases of myocardial tuberculosis has this event been observed. Further, there is usually extensive fatty degeneration of the heart muscle in the neighborhood of the tuberculous process, and this diminishes to a still greater degree the efficiency of the heart's action. Calcification or encapsulation of the caseous tubercles may occur here as elsewhere. Complete healing may result, the tubercle being wholly replaced by connective tissue.

Within very recent years the presence of tubercle bacilli in parietal thrombi and endocardial vegetations has been many times demonstrated, and it is very probable that tuberculous endocarditis is of much more frequent occurrence than is usually supposed. The great frequency of cardiac thrombi in pulmonary tuberculosis suggests the possibility of their formation by the lodgment of bacilli upon the endocardium. Secondary involvement of the myocardium may follow the development of such endocardial tubercles.

Tuberculosis of the myocardium presents no characteristic symptom complex, and in the great majority of cases cannot be diagnosed. The symptoms depending directly upon the condition would be those of a myocarditis. Involvement of the pericardium may give rise to such definite signs and symptoms as to permit of the diagnosis being made. In case of pericardial effusion a bacteriological examination of fluid obtained by puncture could be made. The termination of the cases is by death, due usually to the general tuberculosis rather than to the condition of the heart. Rarely solitary tubercles of small size and slow growth may heal. For the great majority of the cases there is no treatment beyond that of a purely symptomatic nature. *Aldred Scott Warthin.*

HEART DISEASES: VALVULAR LESIONS.—GENERAL ETIOLOGY.—The great majority of cases of chronic valvular lesions originate in acute or chronic endocarditis. A single attack of acute rheumatism may leave the valves in a seriously damaged condition, but more frequently contraction and thickening of the valvular apparatus continue after the acute stage has passed off, and the leaflets gradually become deformed and defective in function. Recurring attacks of endocarditis are liable to occur in valves once damaged by this cause, and slight defects may thus terminate in serious and irreparable injury.

Valvular deformity may also originate in a chronic sclerotic process, comparable to the changes which take place in sclerosis of the vessels. Although this chronic process may originate from rheumatic influences, yet there are a number of causes which, when taken collectively, exert a more frequent influence.

That high arterial pressure is capable of producing valvular lesions is shown very clearly by the experiments of Roy and Adami. These observers narrowed the aorta of the dog by clamping and thus induced a fringe of swollen tissue at the free edge of the valve, due to infiltration of cells and œdema.

Clinically it is well recognized that long-continued high arterial pressure may result in sclerosis and thickening of the valves. More particularly is this noticed in the aortic segments which have to bear the brunt of increased strain in the arterial system; the mitral cusps often suffer as well, and thickening of their free borders is very frequent in cardiac hypertrophy, a condition in which they are subjected to increased strain.

The proportion of cases originating in acute and in chronic endocarditis, has been variously estimated. It is more common to trace an origin in acute endocarditis, resulting from rheumatism or other infectious processes, in the mitral than in the aortic segments. In aortic lesions the process is frequently chronic from the outset.

Guttmann regards three-fourths of all valvular cases as beginning in a chronic fashion, and Worobjew's (*Deut. Arch. f. klin. Med.*, 69, 466) analysis of 180 cases also confirms this view. Most writers have, however, regarded the rheumatic cases as the most frequent; Schott attributes 54 per cent., and Gibson 63 per cent. of cases to a rheumatic origin.

AORTIC INCOMPETENCE.—*Etiology.*—Although occurring at all ages and in both sexes, it is far more commonly met in males about the middle period of life. Under the age of twenty-five most cases are due to a rheumatic origin, and in these it is usual to find the mitral valve also affected. Anatomically, a large majority of cases originate in a chronic fibrosis of the segments of the valve with resulting retraction and deformity. All conditions leading to continued or even intermittent high pressure tend to the development of fibroid thickening. Incompetence is consequently often seen in arterio-sclerosis, chronic Bright's disease, gout, plumbism, and in chronic alcoholism. Those engaged in laborious physical work constitute the greater number of cases. It is consequently frequent in laborers, and is occasionally seen in athletes. Old soldiers often suffer from the disease, owing partly to laborious physical exertion, partly to chronic alcoholism and to specific infection, which has a well-marked but obscure relation to the disease. Tabetics are not infrequently attacked by aortic insufficiency, a fact attributed by Gowers to a common origin in syphilis. Owing to the frequent involvement of the coronary vessels in the sclerotic processes at the root of the aorta, the arterial cases are usually more serious than those due to stationary rheumatic endocarditis.

Morbid Anatomy.—In the great majority of cases aortic incompetence is due to a chronic sclerotic process in the valves. Their free edges become thickened and retracted, and the cusps fail to support a column of water when poured into the aorta. Their edges frequently adhere to each other, causing more or less obstruction. Patches of atheroma are often present on the valves, and in old-standing cases there may be an abundant deposit of lime salts, giving a hard bony feel to the margins of the orifice. When extreme adhesions and stenosis are present, a transverse bar is sometimes seen running from the united cusps to the wall of the aorta, and represents the margins of the original segments. The mitral valve is frequently involved in the sclerotic process, particularly in the rheumatic cases. The root of the aorta often presents atheromatous and calcareous plates and in many instances it is dilated. Freshly raised atheromatous plaques in the aorta, involving one or more of the aortic segments, are occasionally met with. Fresh endocarditis is frequently added on to older lesions, and it is not uncommon to find a row of warty granulations along the edge of the valve. Vegetations are found in the course of acute rheumatism and in malignant endocarditis. They may interfere mechanically with the closure of the valves, or in the latter instance cause incompetence from rupture of one of the segments.

Dilatation of the root of the aorta, the result of atheromatous changes, is a rare cause of aortic insufficiency. A series of cases has been recorded by Pitt (Trans. Path. Soc., 1898) in which incompetence was induced in this way, without marked changes in the valve. In aneurism it is very common to find aortic regurgitation, but in such cases it is usually due to a coexisting sclerotic change in the valve. With advancing age the aortic orifice becomes wider, but the comparative rarity of aortic incompetence in old people would seem to indicate that the dilatation is insufficient to allow of regurgitation.

Osler (Trans. Am. Phys.) has pointed out the frequency with which sclerosis and insufficiency occur in those cases of malformation in which two, instead of three cusps, exist.

Rupture of the aortic cusps occurring spontaneously, or more commonly from violent efforts, or as the result of severe direct injury to the chest has been recorded in a number of instances, and is a rare cause of aortic incompetence. Barié has shown that rupture may be produced experimentally, and that the aortic cusps suffer more readily than other valves. Although perfectly healthy valves may suffer in this way, yet in most instances there is evidence of previous sclerotic change. The average age at which rupture occurs is thirty-nine, a period of life at which degenerative changes are common, and is suggestive of previous disease.

Important secondary changes take place in the cardiac chambers as the result of aortic incompetence. The left ventricle is obliged to accommodate not only the usual amount of blood from the auricle, but also that which regurgitates during diastole of the ventricle. The consequence is that this chamber becomes dilated to an extent corresponding with the volume of blood passing from the aorta, and the degree to which dilatation takes place is thus an index to the extent of regurgitation. In the severer types of the disease dilatation is extreme, and the heart reaches a size seldom attained under other circumstances, *the cor bovinum.* Although dilatation is primary and the cavity remains greatly enlarged, some hypertrophy of the ventricular wall also results, and thus balances or compensates for the diseased valve. Owing to the difficulty it experiences in propelling blood into a ventricle already distended, the auricle in turn dilates and hypertrophies, and eventually the right heart becomes involved as in mitral disease.

Symptoms.—This lesion is most frequently discovered during the routine examination of patients in apparent health, or in the subjects of other maladies. Compensation is often well maintained for years, and during this period there are few or no subjective symptoms, and indeed there is usually much less discomfort than in mitral lesions. Dizziness, palpitation, and precordial pain are sometimes noticed, and dyspnœa on exertion is often an early symptom of failing compensation. The facies presents in many instances a pale and anxious aspect, contrasting with the cyanosis of mitral affections.

An exception to the insidious onset is seen in cases of ruptured valve. Here the abrupt onset with severe precordial pain and dyspnœa, the development of a diastolic murmur, sometimes so loud as to be perceptible to the patient himself, the occurrence immediately or shortly after some unusual strain or external violence to the chest, form a clinical picture which is very striking. The severer cases may terminate fatally in a few weeks, but for the most part they survive for a longer period. Two of Barié's cases lived for eleven and thirteen years respectively.

Failing compensation is marked by dyspnœa, palpitation, and swelling of the feet. Dyspnœa, as in other forms of cardiac disease, comes on from exertion, especially in mounting a hill or climbing a stair. As the malady advances there are often attacks of paroxysmal dyspnœa, coming on especially at night, and known as cardiac asthma. Loss of sleep and a moderate loss of flesh give the patient a worn and anxious aspect. Œdema, if present, is usually moderate in extent, except in advanced cases in which there is secondary mitral incompetence, when it may attain a high grade.

Pain is more commonly present in aortic than in other valvular lesions. It varies much in intensity, from a sense of weight and uneasiness to acute pain, often radiating to the left arm and shoulder, seldom to the right. In arterio-sclerotic cases, in which the coronary arteries are involved, all the characters of true angina may be present.

In advanced stages of the disease orthopnœa and Cheyne-Stokes breathing, either with or without general anasarca and the visceral congestion of mitral lesions, may be present.

Mental disturbance develops more commonly in aortic than in other valvular affections, and shows itself in restlessness and change of temper. In some instances delusions are prominent and the patient may require restraint.

The symptoms in many instances are dominated by those of arterio-sclerosis or chronic renal disease, in which the incompetent valve is merely an incident. Sudden death is an accident which may ensue even in apparent health. Such an occurrence is more liable to happen when there is disease of the coronary vessels. Death occasionally comes rather unexpectedly after the symptoms of ruptured compensation have lasted for some time, but the more common termination is by gradual failure, dropsy, and asystole.

Physical Signs.—Visible pulsation in the arteries often suggests the existence of aortic incompetence. Throbbing of the carotids, visible pulsation in the radial and temporal arteries, and, in severe cases, even in the digital branches of the hands and feet are distinctly seen. Pulsation of the palate and uvula has been observed, and the pulse may be counted in the retinal arteries with the ophthalmoscope. Capillary pulsation is seen in the finger nails, and is also readily observed in the lips when a glass slide is pressed on them. The pulse has certain characters which at once reveal the nature of the affection to the practised finger. The wave is large, it strikes the finger suddenly and as rapidly recedes, these characters being more marked when the arm is raised. Since the appearance of Corrigan's paper, this pulse has gone by his name, and is also known as the water-hammer or collapsing pulse. It is regular in volume and rhythm except in the later stages, when slight irregularity may develop. The arteries are frequently thickened and this feature is seen even in young people suffering from the rheumatic form of the disease.

Examination of the heart shows the presence of very distinctive signs, the more important being the increased size of the organ and the diastolic murmur at the base. These signs, taken in conjunction with the arterial phenomena, render the affection one of the easiest of cardiac lesions to recognize.

Inspection often shows a slight degree of fulness in the cardiac region, particularly in children and young adults, in whom the chest wall is more elastic. Visible pulsation is seen below and outside the normal apex site, and retraction may be seen in the third and fourth spaces due to atmospheric pressure during systole.

On palpation the cardiac impulse is forcible and heaving, and the apex is felt in the nipple line or as far out as the mid-axilla, in the fifth, sixth, or even the seventh space. The increased area of the heart is also shown by percussion, the dulness extending down and to the left side.

The most characteristic sign is found on auscultation in a diastolic murmur, due to the reflux of blood to the ventricle. It is usually a soft prolonged souffle, beginning with the second sound, and occupying the greater part of the diastolic interval; it is sometimes shorter or its character may be harsh. Although sometimes having its site of maximum intensity at the aortic cartilage, it is usually best heard about the pulmonary region. It is transmitted down the sternum, especially to its left side, and is occasionally heard only at the lower sternal region. It is frequently transmitted to the apex, and when loud is heard all over the front and back of the chest. The diastolic murmur in question is one of the most persistent of cardiac murmurs. It occasionally disappears during periods of asystole, to reappear with increasing cardiac power. Instances have been reported in which the murmur disappeared from closure of the orifice by a vegetation, and Musser has recorded a remarkable case in which the leak ceased owing to wearing down of the thickened corpora Arantii. A systolic murmur commonly precedes the diastolic sound, and with it gives the well-known to-and-fro murmur.

The second sound is often dull and indistinct and may be entirely lost. When absent it indicates serious deformity of the valve segments and is usually a sign of extensive regurgitation. The sound should be listened for in the arteries of the neck, as it may be present, but obscured by murmurs at the base of the heart.

The gradual development of aortic incompetence may sometimes be traced from an accentuated second sound in arterial sclerosis to the diastolic murmur of the incompetent valves.

A presystolic murmur at the apex was first described by Flint in cases of aortic incompetence, and commonly goes by his name. It exactly resembles the rumbling murmur heard in many cases of mitral stenosis. Thayer in a recent study of this murmur states that it was present in sixty per cent. of his cases, and that thrill, snapping first sound, and the tapping impulse of mitral stenosis were also occasionally noticed. The pulse characters form the best guide in distinguishing the two conditions, but when they are combined it is often difficult or impossible to state whether the murmur is associated with mitral stenosis or is due to aortic incompetence.

The temperature in cardiac disease is usually subnormal. Elevation of temperature is sometimes the first evidence of a fresh endocarditis. It may, however, signify some rheumatic or other inflammatory complication. In the advanced stage of cardiac disease it is most often due to a broncho-pneumonia, and is frequently seen a few days preceding death.

Diagnosis.—The physical signs of a well-marked case of aortic incompetence are unmistakable. The diastolic murmur is a very constant feature, only seldom disappearing in advanced cases with asystole. Temporary diastolic murmurs are occasionally heard in arterio-sclerosis, the valve probably yielding to the increased blood pressure. Allbutt regards such cases as the early stage of the affection. A diastolic murmur is sometimes heard in mitral stenosis at the pulmonary area, and represents a temporary incompetence of the pulmonary leaflets from increased pressure in this vessel. Such a murmur is distinguished by the small pulse of mitral disease, instead of the large collapsing pulse of aortic incompetence.

The degree of regurgitation is estimated by the size of the ventricle and the character of the pulse. Disappearance of the second sound at the base and in the arteries of the neck also indicates free regurgitation.

AORTIC STENOSIS.—*Etiology.*—Although occurring at all ages, and sometimes as the result of changes in early life, aortic stenosis is most common in old men with calcareous arteries.

In high degrees of the affection the valves are thickened and calcareous and the orifice may become so narrowed as hardly to admit a probe. In rare cases the obstruction is subvalvular and the result of an attack of fœtal endocarditis. Stenosis, apart from the slighter grades of the affection, and unassociated with aortic incompetence, is a rather rare condition.

The symptoms are similar to those found in aortic regurgitation, and depend rather on associated conditions, such as generalized arterio-sclerosis, sclerosis of the root of the aorta, disease of the coronary vessels, and myocarditis, than on the aortic lesion itself.

The onset of the affection is insidious, and there is a long period of latency. Uneasiness or pain in the cardiac region, sometimes assuming the characters of true angina, cardiac oppression, palpitation and dizziness, dyspnœa and syncopal or even epileptic attacks, may be amongst the earlier symptoms. In the later stages dilatation of the left ventricle takes place and relative mitral insufficiency ensues. Dropsy and the usual evidence of venous stasis set in, and the clinical picture assumes the type seen in the more advanced stages of mitral disease.

The diagnosis rests on the physical signs. The peripheral arteries are usually thickened and calcareous, whilst the characters of the pulse afford valuable evidence of the nature of the lesion. It is small, often of high tension, the upstroke is slow and gradual, the wave is well sustained and it falls away slowly. These features are well shown in a sphygmographic tracing; the upstroke is oblique and is sometimes interrupted by an anacrotic notch, like the dicrotic notch in the down stroke. This notch has been regarded as a double effort on the part of the ventricle during systole, but it occurs in other conditions and has no special diagnostic significance; the apex of the curve is rounded and the downstroke gradual. The pulse rate is often infrequent, falling to 60 or below. (*Vide* Clin. Soc. Trans., 1897.)

Evidence of hypertrophy of the ventricle is present, but the enlargement does not reach the degree seen in aortic incompetence. Inspection and palpation reveal an apex beat below and outside the normal site, with a strong heaving character. Emphysema of the lungs, however, is frequently present and prevents the apex site from being determined, rendering it weak and indistinct. Under these circumstances cardiac dulness is often lessened. A systolic thrill about the aortic cartilage is commonly present; it is often well marked and of great intensity, and is sometimes transmitted to the vessels of the neck, or felt in the episternal notch. With failing cardiac power the thrill may lessen or disappear. On auscultation a rough harsh murmur is heard in the aortic region, occasionally having a musical character. It is prolonged through the whole of systole, often completely obscuring both sounds of the heart, the second being lost from the rigid character of the valves. It is best heard about the aortic cartilage and transmitted to the vessels at the root of the neck. It is heard over the cardiac area with diminishing intensity toward the apex, and in many cases it is so loud that it is heard all over the chest and even at a short distance from the patient. In the terminal stages of the malady, with failing cardiac action, the murmur may lose something of its intensity and roughness.

Diagnosis.—A common error is to regard all aortic systolic murmurs as due to stenosis. Murmurs in this region are most frequently due to atheroma of the root of the aorta, to slight sclerotic changes in the valves, or they are of a functional character. They are then often less loud and rough than in cases of stenosis. Coarse atheromatous changes in the aorta may, however, cause both a rough murmur and a thrill, and it may prove difficult or impossible to distinguish such a condition from true stenosis. An accentuated second sound is common in atheromatous states, and is not likely to be present in stenosis, owing to the rigid state of the valves.

The peculiar characters of the pulse, the marked characters of the murmur, and the presence of thrill form a combination of signs which are highly characteristic, and, when distinct, are unmistakable.

Mitral Incompetence.—This may result from acute or chronic endocarditis, from rupture of the chordæ tendineæ, or from dilatation of the ventricle preventing the apposition of the valve segments.

In young people a large proportion of cases originate in acute endocarditis; hence the frequency with which a history of acute rheumatism occurs in the clinical history. It is by no means infrequent to obtain no history of rheumatic conditions, even in children and young people, whilst in older individuals a chronic sclerotic process is often the primary change.

The mitral valve is much more liable to rheumatic inflammation than the aortic, and in fact the latter valve seldom suffers from this cause without involvement of the former.

In malignant endocarditis, rapid ulceration or necrosis of the valves, or rupture of the chordæ, is occasionally responsible for serious destruction of the valve. Rupture of the chordæ also occurs, apart from acute endocarditis, as a result of strain or external violence, although such cases are very unusual. Cardiac dilatation, resulting from strain or from myocardial changes, often produces relative mitral incompetence, even with perfectly healthy valves. This condition is frequent as a temporary manifestation in the acute dilatation of infectious disease and in anæmia. In aortic lesions and in chronic dilatation or myocarditis, incompetence occurs owing to this mechanism.

Morbid Anatomy.—The changes in old-standing cases consist in thickening and rigidity of the valvular segments. In cases due to endocarditis, there is almost invariably some degree of narrowing. The orifice is naturally wider than normal when relative incompetence is present.

Secondary changes of a compensatory character take place in the various cardiac cavities. The left auricle dilates to accommodate the extra current of blood passing through the leaking valve, and also hypertrophies to cope with the increased work thrown upon it. The ventricle undergoes similar changes, being stimulated by the increased flow from the left auricle. The circulation in the pulmonary circuit is impeded by the overfilled auricle, and in consequence the right ventricle, and ultimately the right auricle, dilate and hypertrophy.

The tricuspid orifice, owing to dilatation, may become incompetent, a feature which accounts for certain clinical phenomena in the advanced stage of the affection. Sclerotic changes occasionally occur both in the trunk and in the smaller branches of the pulmonary artery, owing to the increased blood pressure.

A deposit of fibrin amongst the musculi pectinati or chordæ tendineæ is seen in the dilated cardiac chambers, and forms the usual source of emboli.

Venous stasis in the various organs is frequent in mitral lesions. The lungs are affected earliest, and undergo the change known as brown induration. The capillaries are overfilled and consequently thrown into loops, whilst blood pigment passes to the alveolar walls, and a slight increase of interstitial tissue, the result of chronic congestion, takes place. The epithelial lining in the alveoli is somewhat swollen, and contains specks of pigment.

Hemorrhagic infarcts are common in the advanced stages. They are often attended by hæmoptysis and a localized pleuritis. Œdema of the lungs and hydrothorax are frequent as manifestations of part of a general dropsy, and a terminal broncho-pneumonia is a common cause of death.

The liver shows dilatation of the radicles of the hepatic veins in the centres of the lobules, with an exudation of pigment in the surrounding cells, whilst the periphery of the lobule undergoes fatty changes owing to deficient oxygenation. To the naked eye the cut surface presents a mottled appearance, the dark-colored centres contrasting with the pale peripheral portions of the lobules, and giving the organ the name of the nutmeg liver. When congested it is enlarged and extends below the costal border, and in the later stages fibroid changes may supervene, the organ becoming indurated and uneven on the surface, a condition known as cardiac cirrhosis.

Somewhat similar changes take place in the kidneys; these organs are enlarged and congested in the earlier stages, and eventually may terminate in cirrhosis and contraction.

Œdema and congestion of the gastro-intestinal tract, and subcutaneous œdema with effusion into the serous sacs, are also present in the advanced stages of the affection.

Symptoms.—These vary greatly according to the character and stage of the disease.

In acute endocarditis the development of a mitral incompetence is revealed only by the physical signs; dropsy and dyspnœa are only exceptionally present even in the graver forms of endocarditis, and the clinical picture is that of the primary infectious process. In chronic cases compensation may be maintained for a long period, even when the serious nature of the lesion is shown by a greatly enlarged heart and an apex murmur. Although some individuals pass through a long life with little or no discomfort, it is more usual to find some dyspnœa on exertion. The facial appearance is often suggestive. The lips and cheeks may be of a deeper tinge than usual, the veins of the neck are distended, and there is stellate enlargement of the veinules of the cheeks, and occasionally clubbing of the finger nails. Attacks of palpitation are often induced by exertion, but they may also result from flatulence. A dry hacking cough or recurring attacks of bronchitis are frequently found.

Amongst the graver symptoms are a weak, irregular pulse, dropsy, and increasing dyspnœa. Breathlessness is brought on by even slight exertion, ultimately becoming constant even at rest. The respirations are deep and labored, accompanied by contractions of the extraordinary muscles of respiration, and the patient rests propped up by pillows, or leaning forward in an armchair. Attacks of Cheyne-Stokes breathing are often seen, or again paroxysms of dyspnœa, often occurring at night and interfering with rest.

Accompanying the dyspnœa is œdema, which begins about the feet and ankles, noticed first after being up, and disappearing with a night's rest. Unless checked by suitable treatment it gradually increases, and extends to the thighs, scrotum, and serous sacs. The face remains free, but the upper extremities sometimes share in the progressing œdema. The œdema is firm and hard, and is accompanied by coldness and cyanosis of the extremities, and lividity of the face. When the abdomen becomes distended with fluid it still further embarrasses the breathing.

Hydrothorax is usually bilateral, but in some instances occurs chiefly on one side. In some cases the dropsical effusion affects principally the serous sacs, particularly the peritoneum, and requires periodic removal. It sometimes collects with extraordinary rapidity, after a period of absence.

Sleeplessness, starting from sleep, and bad dreams occasionally occur, even apart from the severer symptoms of failure of compensation.

Of the various organs the liver is enlarged and somewhat tender, frequently reaching as low as the umbilicus. A slight tinge of jaundice is very common, and bile may be detected in the urine. The secretion of urine is greatly diminished, sometimes falling to three or four ounces, or even being suppressed. It is of high specific gravity, it deposits a sediment of urates, and shows albumin in small or moderate quantities, and often granular and hyaline casts. With the disappearance of dropsy diuresis sets in, and the urine may run up to two or three times its normal quantity, with disappearance of albumin, and later of casts. Gastric symptoms such as flatulence, and sometimes nausea and vomiting, are not uncommon.

With appropriate treatment dyspnœa and œdema may disappear, and the patient be restored to comparative health. Sooner or later, however, the same symptoms recur, particularly in individuals who are unable to obtain the necessary rest. It is frequent to find several such attacks before the fatal issue.

Eventually a period is reached when the heart, either in consequence of extreme dilatation or of myocardial degeneration, fails to respond to treatment. The terminal illness is frequently very prolonged, and for several months the unfortunate individual struggles with dyspnœa and dropsy, and eventually succumbs to exhaustion.

Physical Signs.—The most characteristic sign is a systolic murmur, heard best at the apex. It is variable in character, being sometimes loud and bellows-like, sometimes having a musical character, or again being extremely soft and distant. Faint systolic murmurs at the apex also occur with slight defects in the valve, and in conditions of temporary dilatation, whilst a loud bellows or a musical murmur usually indicate more definite changes in the valve. The murmur of incompetence may, if faint, be localized at the apex, but it is usually transmitted to the axilla, or heard in the back at or above the angle of the scapula; it is often heard up to the pulmonary cartilage and near to the ensiform, and it may even have its site of maximum intensity at the pulmonary area. The first sound is often obscured or replaced by the murmur, whilst the second sound is accentuated at the pulmonary area. With failing power of the right ventricle accentuation disappears, and is thus of unfavorable omen.

A thrill is of the rarest occurrence in mitral incompetence. When there is any considerable degree of regurgitation there is enlargement of the left ventricle. The impulse is strong and heaving, and lies in a line with, or outside the nipple; a well-marked epigastric pulsation is often present owing to hypertrophy of the right ventricle. As dilatation or weakness supervenes, the impulse becomes weak and diffuse. Fulness and distention are sometimes seen, particularly in the yielding chest walls of children. Percussion shows an increase in dulness to the left and often to the right, reaching the right sternal border or even the parasternal line. Upward, dulness often begins a space higher than normal.

Diagnosis.—It is not uncommon to find a systolic murmur at the apex in the absence of any other sign of cardiac disease. Its chief importance is the mental disquietude it may cause in nervous patients, and the unfavorable light in which it is usually regarded by life insurance companies. Such murmurs are sometimes evidence of slight valvular damage, but in the absence of symptoms and of other signs of disease, such as enlargement and pulmonary accentuation, they may be disregarded. A murmur heard toward the end of inspiration, and attributed to the entry of air into the pulmonary vesicles during systole, is not uncommon, and is known as the cardio-respiratory murmur. It has usually no cardiac significance. It is not always possible to distinguish regurgitation due to a valvular lesion from that of muscular dilatation. In elderly individuals, in Bright's disease or arterial sclerosis, or in anæmia, the latter condition may be suspected. A history of rheumatism, on the other hand, suggests endocarditis. In some instances, as in anæmia and in acute dilatation from strain or infectious fevers, any doubt is often cleared up by the gradual disappearance of the morbid signs.

Mitral Stenosis.—Narrowing of the mitral valve is for the most part a disease of the first half of adult life, often starting from an acute endocarditis in childhood. It is much more common in females, owing doubtless to the greater frequency of rheumatism in young girls than in males of the same age. Although the lesion is often regarded as of purely rheumatic origin, it is remarkable how often a history of acute rheumatism is absent. In children, however, rheumatism, as pointed out by Cheadle, is frequently an ill-marked condition, the articular manifestations being slight, or replaced by such symptoms as tonsillitis, growing pains, or erythema, and yet in these apparently slight cases severe forms of endocarditis may develop.

Cases of mitral stenosis are occasionally found in a first attack of acute rheumatism, a fact strongly suggestive of an old-standing latent rheumatic influence. An absence of a history of acute rheumatism is therefore no evidence of a non-rheumatic origin.

Mitral stenosis is occasionally found in arterio-sclerotic cases and in interstitial nephritis, a fact which has suggested an arterial origin for some of the cases. In 542 autopsies, in cases of interstitial nephritis, Pitt found mitral stenosis 33 times, and other writers have recorded the association of the two conditions.

In most if not all instances of rheumatic endocarditis, there is some narrowing of the mitral orifice, but it is only when this is considerable that the signs become distinct.

Anatomically the valve curtains are rigid, thickened, and adherent; and form a diaphragm perforated by the mitral orifice, which is reduced to a narrow slit-like opening, often termed the "button-hole" orifice. Less commonly the valves project in a funnel-shaped fashion toward the ventricle. The chordæ tendineæ are thickened and adherent, whilst a deposit of calcareous salts is frequent in the valve and even in the chordæ themselves.

The secondary changes are seen first in the left auricle which becomes hypertrophied and often dilated. According to Samway's observations hypertrophy is the primary change, dilatation occurring later. He found that cases of stenosis dying from cardiac failure presented, in addition to hypertrophy, a marked degree of dilatation, whereas those dying from surgical diseases or affections apart from the heart usually showed hypertrophy only.

The state of the left ventricle varies greatly. Theoretically it is argued that the diminished quantity of blood passing through the narrowed orifice cannot induce hypertrophy or dilatation, and that the ventricle remains of normal size or even undergoes a certain degree of atrophy. This view is certainly correct for some cases; at the same time hypertrophy is seen in a considerable proportion of cases, and according to Baumbach, who enters into this question very fully, a moderate degree of hypertrophy is present in almost all cases. Mitral regurgitation may be regarded as responsible for this hypertrophy in some instances, whilst in others there are pericardial adhesions or arterio-sclerosis. The cavities of the right side undergo a marked degree of dilatation and hypertrophy, and the contrast between the enlarged right ventricle and the small left is sometimes very striking.

Symptoms.—Some degree of dyspnœa is almost always present on exertion, and this with palpitation may continue for years. When the disease dates from childhood there is frequently a stunted growth, the chest is ill-developed, and there is diminished physical and mental vigor. The lips are often of a deep blue tinge, and in old-standing cases there is sometimes clubbing of the nails of the fingers and even of the toes.

As compensation fails dyspnœa becomes more and more troublesome, and signs of venous stasis similar to those seen in mitral incompetence are found in the various organs. Pulmonary symptoms are common and these patients are very subject to recurring attacks of bronchitis.

Attacks of hæmoptysis occasionally occur, and, unless due to infarction, often have a beneficial effect, relieving pulmonary congestion and the embarrassed right heart. Other signs of venous congestion are observed in recurring attacks of epistaxis from which some patients suffer, whilst hemorrhoids or menorrhagia occur in others.

Dropsy of the extremities is seldom a prominent feature, and any œdema present is usually slight. Signs of a venous obstruction often fall chiefly or exclusively on the portal system, and hepatic enlargement or even cirrhosis may be present with ascites, in cases which show little or no œdema of the lower extremities.

Welch (Trans. Am. Phys., 1900) has recently called attention to venous thrombosis in cardiac disease, occurring in serious failure of compensation, and more particularly in mitral stenosis. The veins affected are most frequently those conveying blood from the neck and upper extremity, and more commonly on the left than the right side. The peculiar localization of the thrombosis is to be attributed to the greater length and obliquity of the left innominate vein, and to pressure, direct or indirect, on the left subclavian vein from the dilated left auricle and pulmonary veins.

Symptoms of ruptured compensation often first appear during pregnancy or labor, or follow parturition: alarming or even fatal attacks of pulmonary œdema sometimes appear, or persistently rapid action of the heart leading to asystole. Pregnancy is a complication in which there is always serious risk, although in favorable cases there is little or no disturbance. Subsequent pregnancies are sometimes passed without special difficulty, when earlier ones had caused great disturbance.

Hysterical manifestations are not uncommon in the course of mitral stenosis, both conditions being common in young women. Cardiac symptoms often predominate, and severe attacks of pseudo-angina, of palpitation, or of dyspnœa may occur in well-compensated cases. Without a correct appreciation of the neurotic element in such individuals these symptoms may lead to undue alarm.

Embolism is more common in this than in other forms of valvular lesions. If it occurs in the brain this accident shows itself in the form of hemiplegia, and if the embolus lodge on the left side, there will be aphasia.

The physical signs when well marked are extremely characteristic, but in the advanced stage of the disease they are often indefinite or equivocal. The more important are: the presystolic thrill and murmur, the snapping first sound, the accentuated pulmonary second, and evidence of enlargement of the right heart.

The pulse is small, somewhat increased in rate, and often of good tension; it is usually regular until a late stage of the malady, when extreme rapidity and arrhythmia may set in. The thrill, which is one of the most characteristic signs of the disease, is felt at the apex, and when the heart is not unduly rapid it is readily made out distinctly to precede the systolic impulse. It is sometimes prolonged, running through the whole diastolic interval, or it may immediately precede the impulse, and is then strictly pre-systolic. When present it is pathognomonic of stenosis. The cardiac impulse often gives the impression of a jet of liquid being projected against the hand. The murmur in typical cases is loud and rough, and is commonly compared to the sound "rrrb." It runs up to and terminates in a loud, abrupt, and snapping first sound. The murmur may be prolonged through the diastolic interval, but in the great majority of instances it occurs at the end of this period. In either case it is usually spoken of as the pre-systolic murmur. The murmur is in most instances localized at or about the apex, although, as pointed out by Griffiths, it is sometimes transmitted to the axilla or even heard in the back. The murmur is sometimes represented by a mere rumble, and in the absence of the snapping first sound is easily missed by the untrained ear. With advancing cardiac weakness both thrill and murmur often disappear. A systolic murmur is frequently present, due to associated incompetence. It may persist when the thrill and murmur have disappeared.

Hardly less characteristic than the murmur is the abrupt snapping first sound in which it terminates. It is often mistaken for the second sound, but the distinction can be made by noting that it is synchronous with the apex impulse. The second sound is often lost at the apex, and is sometimes reduplicated at this region; in the pulmonary area it is accentuated and even ringing, losing these characters with failing power in the right ventricle. With high tension in the pulmonary artery, a faint, whiffing, diastolic murmur is occasionally heard. This is regarded by Gibson and others as due to a temporary incompetence at the pulmonary orifice.

Evidence of enlargement of the right heart is often present, as shown by the increased impulse over the lower sternal region, and by an extension of dulness to the right border of the sternum or beyond, reaching in extreme cases as far as the right nipple line. With failing compensation and particularly in advanced stages of the disease the thrill and murmur often disappear, and the lesion is readily overlooked. A sharp first sound, evidence of enlargement of the right heart, sometimes a gallop rhythm, together with a small pulse should suggest stenosis, and with recovery the thrill and murmur often reappear.

Diagnosis.—A presystolic murmur is occasionally heard in conditions other than mitral stenosis.

The Flint murmur has already been referred to under aortic incompetence. In an adherent pericardium and in vegetative endocarditis of the mitral valve, a murmur of this character is sometimes found, usually of the low rumbling variety rather than of the loud and rough character. Ewart and Rutherford have recorded a case in which all the typical signs of stenosis were present and in which the autopsy showed a fibrinous polyp hanging from the auricle through the mitral orifice.

TRICUSPID REGURGITATION.—Regurgitation at this orifice is very generally admitted to occur in health, resulting from conditions, such as violent exercise, which temporarily raise the blood pressure in the pulmonary circuit. This is often spoken of as the safety-valve action, preventing the lungs from becoming unduly congested.

In the great majority of instances, tricuspid incompetence is the result of dilatation of the right ventricle, inducing relative incompetence at this orifice; in only a comparatively few cases does the lesion depend on organic changes in the valves.

Dilatation of the right ventricle is always a secondary process. It constantly occurs in old-standing mitral lesions, and as the result of obstruction in the pulmonary circuit, from emphysema or fibrosis of the lungs. In dilatation of the left ventricle, from whatever cause, the right ventricle is commonly included in the morbid process.

The valve may be affected by endocarditis, acute or chronic, or by degenerative changes. Under these circumstances the valves of the left heart are almost invariably involved by similar lesions. In malignant endocarditis, the valve is occasionally affected alone. In thirty-nine instances, Pitt found ten in which this valve was alone attacked.

Symptoms.—These are similar to those found in mitral disease, and consist in breathlessness, with evidence of obstruction in both the systemic and the portal venous systems.

Physical Signs.—A systolic bruit is sometimes heard in the lower sternal region, having its maximum intensity just to the right of the sternum about the fourth and fifth ribs, and occasionally transmitted to the right as far as the parasternal line. It is not heard at the apex, although it may be difficult to differentiate it from a coexisting mitral murmur. In some instances a difference in timbre may be noticed. Owing to a debilitated condition of the right ventricle the murmur may be absent even in well-marked cases, and again, it may disappear under the influence of rest and digitalis. The enlargement of the right ventricle causes increased pulsation in the epigastric and lower sternal regions. Dulness extends to the right border of the sternum or for two or three finger-breadths beyond, although it is frequently masked by emphysema.

Pulsation in the veins, accompanying each systole of the heart, forms important evidence of the condition under discussion. It depends on a reflux of blood in the dilated veins after their valves have become incompetent. It is seen in the external and internal jugulars, and sometimes even in more distant veins such as the brachial. Care must be taken not to confuse true venous, or, as it is sometimes termed, positive pulsation, with certain undulatory movements of these vessels. If the vein is emptied from below, positive pulsation continues.

Venous pulsation is also observed in the liver. The enlarged organ, grasped between the hands, presents a true expansile pulsation, and not merely a transmitted epigastric impulse from an enlarged right ventricle.

TRICUSPID STENOSIS.—This condition, although rare, is more frequent than are lesions at the pulmonary orifice. Pitt found it 87 times in 12,000 autopsies.

Congenital stenosis is not uncommon in still-born children, or in those who have lived a few days. It is frequently associated with other cardiac abnormalities or defects.

It has been asserted that almost all cases are of congenital origin, but this view is not borne out by statistics. In Pitt's series of 87 cases, only one patient died under ten, and in Herrick's tabulation of 40 cases the youngest patient was twelve years old, with a history of acute rheumatism two years previously, facts which strongly suggest an acquired origin. In the great majority of cases, tricuspid stenosis is associated with a similar process in the mitral, and often with disease of the aortic segments as well. In Leudet's series of 114 cases the tricuspid valve was affected alone in only one instance, and in Herrick's once in 40 cases. Females are affected about four times as often as males. A history of acute rheumatism was present in 10 or 25 per cent. of Herrick's series, chorea in 2, doubtful rheumatism in 4, no rheumatism in 9, and in 15 there was no record. In Pitt's cases, however, rheumatism played a predominant rôle in the etiology.

A fatal issue usually results in patients who are under thirty, and in only 12 cases out of 151 (Leudet's and Herrick's series) did the patient reach the age of fifty. The symptoms are those of mitral stenosis of the most pronounced form. Dyspnœa and cyanosis are often extreme, and Broadbent regards pronounced dropsy as evidence of the disease. The diagnosis has been made in a few instances during life, but in the great majority of cases it has been overlooked.

A presystolic murmur and snapping first sound heard at the ensiform cartilage or a little to the right, and fading off and again becoming marked at the mitral, has been correctly interpreted as indicating stenosis of both orifices, and in a few cases a thrill has been detected in the tricuspid region. The murmurs in the tricuspid and mitral regions have also been noted as having a different character, but the characters of the cardiac sounds are often rendered difficult of interpretation owing to rapid or irregular cardiac action. The heart is enlarged to the right as in mitral stenosis, whilst both the venous and the hepatic forms of pulsation are often present owing to associated tricuspid regurgitation.

PULMONARY ORIFICE.—Disease of the pulmonary valves is usually congenital, and is then commonly associated with other cardiac anomalies. Only a few of these cases reach adult life.

The majority of acquired cases are due to malignant endocarditis. Congenital absence of one of the cusps may lead to sclerotic processes in later years, as in aortic disease.

Acute rheumatism is not a frequent cause, being present in only seven of twenty-nine cases collected by Gerhardt.

Obstructive disease is difficult to recognize owing to the frequent occurrence of systolic murmurs in the pulmonary area from other causes. A distinct thrill, a harsh murmur, and evidence of enlargement of the right ventricle are the signs which may be found, but similar signs may be caused by the pressure of an aneurism or tumor on the trunk of the vessel.

Incompetence gives rise to a diastolic murmur in the pulmonary region, often louder during expiration, and transmitted down the left sternal border. It is not heard toward the apex or in the vessels of the neck.

Enlargement of the right ventricle is usually considerable and the apex is pushed to the left. There is an absence of the arterial phenomena of aortic disease, but Gerhardt has shown that graphic representations of the pulmonary pulsations show analogous changes. By introducing a manometer into one nostril, closing the opposite one by pressure, and directing the patient to cease breathing, he obtained a tracing showing larger excursions of the lever, and a more sudden rise and fall than is obtained either in health or in aortic incompetence.

Cyanosis, venous enlargement, and pulmonary embolism have also been noticed in disease of this orifice.

Tuberculosis is not an uncommon mode of death, and is attributed to the anæmic condition of the lungs.

Combined Valvular Lesions.—In a large proportion of cases more than one valve is affected, or there may be both incompetence and obstruction at one orifice. The general features and signs usually point to predominant disease of one valve. Aortic and mitral incompetence are often associated, whilst mitral stenosis is frequently accompanied by slight sclerosis of the aortic segments, having no clinical significance.

Prognosis of Valvular Disease.—The prognosis is based partly on an estimate of the extent and character of the valvular lesion, partly on the general health and habits of the patient.

Aortic incompetence is usually regarded as the most serious of valvular affections. The arterio-sclerotic cases, owing to the frequency with which the coronary vessels are involved, are more serious than stationary rheumatic conditions. Of the valvular affections, aortic incompetence is the one in which sudden death is most apt to occur. Favorable features are a moderate degree of cardiac enlargement, a pulse not showing the collapsing character to a high degree, a distinct second sound in the arteries of the neck, and an absence of cardiac symptoms. According to N. S. Davis the average duration of life after compensation begins to break down is 3.8 years, a period which closely corresponds to Balfour's estimate of four years.

Aortic stenosis is usually regarded as the least serious of valvular lesions. In moderate grades of the disease but little disturbance of function takes place. More serious, however, are the cases with evidence of a high degree of stenosis, as shown particularly by the pulse. Arterio-sclerosis always suggests the possibility of disease of the coronary arteries, and anginal attacks convert such a suggestion to a certainty.

Sudden death is rare, although it may occur from disease of the coronary vessels, and has also resulted from occlusion of an extremely narrowed orifice.

Mitral lesions are on the whole less serious than aortic regurgitation. Stenosis is usually regarded as a more serious affection than incompetence. Osler regards the latter as almost as serious as the former, whilst N. S. Davis reverses the opinion usually held.

In many cases in which a mitral systolic murmur is heard at the apex, this lesion shows no tendency to shorten life, and in the absence of cardiac symptoms, and of other signs of cardiac disease, its presence may be regarded with but slight apprehension. More serious are the cases in which a considerable degree of regurgitation is revealed by marked enlargement of the ventricle, but even here the patient may enjoy a long period of good health, provided that symptoms of cardiac disturbance are absent.

A cardio-pulmonary murmur is not uncommon at the apex, and is heard best or exclusively at the end of inspiration. It is frequent in pulmonary tuberculosis, and in the absence of other evidence of cardiac disease may be disregarded.

The mere loudness of a murmur is in itself no index to the severity of the lesion. Very soft murmurs are often heard in failing hearts, whilst loud rasping murmurs, although indicative of valvular damage, may be present with perfect compensation.

Mitral stenosis is not incompatible with longevity, but in most cases there is a marked shortening of life. Broadbent found the average age at death to be thirty-three years in males and thirty-eight in females, and other estimates agree closely with this. Of other influences affecting the duration of cardiac disease experience shows that children bear these lesions badly, and such cases frequently terminate fatally at or shortly after puberty. Females bear valvular disease better than males, a fact which is probably to be attributed to their less active habits and to their less frequent indulgence in alcoholic excess. An exception to this rule is sometimes seen as the result of pregnancy, in which the increased strain occasionally results in serious and even fatal cardiac failure. Laborious occupations are unfavorable, as are also sexual and alcoholic excess, and the free use of tobacco.

Finally poor general health, anæmia, recurring attacks of bronchitis, hepatic and renal engorgement, and pulmonary embolism are all unfavorable signs.

Recurring attacks of rheumatism often exert a most unfavorable influence owing to fresh attacks of endocarditis, and in children rheumatic inflammations occasionally progress to a fatal issue within a few weeks or months.

Acute disease, particularly pneumonia, is often ill borne, and if survived is sometimes followed by loss of compensation. I have known several cases of mitral stenosis date their symptoms from an attack of pneumonia.

Finally, poor general health, anæmia, hepatic or renal engorgement, and pulmonary embolism are all unfavorable symptoms.

Treatment.—During the period of compensation no very active treatment should be directed toward the heart.

It is important in this stage to keep the general health up to the best possible point. For this purpose the diet should be plain and nourishing, and the coarser vegetables should be avoided as tending toward flatulence. Alcohol is unnecessary in young people, and if used at all should be taken in strict moderation with food. Tobacco is injurious, whilst tea and coffee must be avoided should they cause any cardiac palpitation or uneasiness.

In rheumatic cases special care should be taken to see that the patient is suitably clad, and even with slight rheumatic manifestations he should be confined to bed or the house.

Exercise and athletics are beneficial provided they cause no undue fatigue or are not pushed to the point of inducing dyspnœa. The more violent forms of exercise such as football or even tennis should be forbidden, but golf, mild bicycling, or rowing and walking are safer, inasmuch as they throw much less strain on the heart. In cases in which for any reason it is judged unwise to allow even easy exercise, rest in the open air is beneficial.

Medicinally, an occasional aperient; tonic doses of iron or arsenic, particularly when anæmia is present, or strychnine are valuable. Small doses of digitalis (♏ v. to x.) may be administered should any tendency to dyspnœa or palpitation exist, and the use of this drug is sometimes continued for lengthened periods with decided benefit.

When compensation begins to fail, and dyspnœa, dropsy, and palpitation become marked, a more active plan of treatment is required.

In most instances of uncomplicated valve lesions failure of compensation is due to dilatation, brought about for the most part by excessive muscular work, although in some cases it is induced by severe mental strain. The first object is therefore to secure physical and sometimes mental rest. When the symptoms are at all severe, absolute rest in bed must be enjoined; and treatment by this method alone is sometimes sufficient to relieve dyspnœa and remove dropsy. It is, however, advisable in most instances to use medicinal or other agents, which hasten recovery and alleviate distress.

Of the cardiac stimulants by far the most valuable is digitalis. This remedy slows and strengthens the muscular contraction of the heart, whilst the pulse rate is reduced and becomes more regular, the peripheral arteries are contracted, the renal arteries relax, and a large volume of blood passes through the kidneys as shown by the free diuresis.

In aortic incompetence the objection to digitalis is sometimes raised that it prolongs diastole and hence allows of freer regurgitation. This objection is largely theoretical, and many cases receive a marked degree of benefit from the increased muscular action, dyspnœa is relieved, and in favorable cases compensation is completely restored. It is in mitral disease, particularly when dropsy and dyspnœa are present, that digitalis induces the most brilliant results. Dyspnœa is relieved, free diuresis is set up, and dropsy lessens and disappears.

In mitral incompetence, not only is the muscle stimulated, but the regurgitation is lessened owing to the more perfect closure of the auriculo-ventricular ring. In stenosis the lengthened diastolic period allows more time for blood to pass from the engorged auricle through the narrowed valve.

The action of digitalis is somewhat slow and it is not until the third day that the full effects of the drug are seen. When marked slowing of the pulse to 60 or under, or a fall in the quantity of urine occurs, the dose should be lessened or stopped, owing to the danger of toxic manifestations, which reveal themselves in the form of nausea and vomiting, weakness and irregularity of the pulse, or a double beat of the heart to one of the pulse.

The drug should be given freely for from forty-eight to seventy-two hours when the symptoms are at all urgent—say in doses of ♏ xv. of the tincture or ʒ iv. of the infusion every three or four hours. Smaller doses are usually sufficient (♏ x.–xv. t.i.d.) in the absence of severe symptoms. Nausea and vomiting are sometimes produced by even moderate doses, and in such cases rectal administration of one or more large doses of the fluid extract are often extremely beneficial. Five or ten minims (♏ i.–gr. i. digitalis) administered with starch in this way often act rapidly, and I have seen the pulse slowed and dyspnœa relieved in the course of a few hours. An old and reliable preparation is Guy's pill, consisting of gr. i. each of digitalis, squills, and pil. hydrarg.

Strophanthus is a valuable substitute for digitalis. It acts on the heart like digitalis, but has not the same tonic effects on the arteries. It is consequently sometimes preferred in arterio-sclerotic cases with increased arterial tension. It is inferior to digitalis in removing dropsy, but is sometimes of value in alleviating cardiac symptoms when this drug fails. Sparteine acts in a similar manner to strophanthus, but as a rule is inferior to it.

Caffeine is occasionally useful as a substitute for digitalis. It sometimes induces restlessness and insomnia.

Suprarenal extract has recently come into use as a cardiac tonic; it acts on the muscular substance of the heart. Some of the clinical reports are very encouraging and it seems worthy of further trial.

Strychnine is a valuable adjunct to digitalis and may be administered in doses of gr. $\frac{1}{80}$ three to six times daily.

Diffusible stimulants such as alcohol, ether, and ammonia are of value in emergencies, and until the more slowly acting stimulants affect the heart.

A dose of calomel, gr. v. with gr. x. of bicarbonate of soda, is often administered with benefit preceding the course of digitalis. It relieves portal congestion and engorgement of the right heart, and increases the efficacy of digitalis.

In arterio-sclerotic cases the long-continued administration of iodides often proves of much value in controlling palpitation and other symptoms, possibly by lowering peripheral resistance. Nitroglycerin is also a valuable agent in lessening peripheral resistance and is often advantageously given with digitalis in doses of ♏ i. of the one-per-cent. solution.

Obstinate or persistent symptoms often require special measures for their mitigation or relief.

Dyspnœa continuing after the use of digitalis, and especially when nocturnal in character, is usually relieved in a remarkable manner by a hypodermic injection of morphine, and in advanced cases this drug is invaluable.

Sleeplessness sometimes yields to paraldehyde, trional, or sulphonal, but, as it is often dependent on dyspnœa, these remedies are much inferior to morphine.

Pain over the cardiac region is often alleviated by the iodides, especially in arterial cases, or by nitroglycerin.

DROPSY.—Dropsy may be diminished by free purgation. For this purpose calomel, salines, and hydragogues, especially compound jalap powder, are most serviceable.

Needle puncture of the distended limb with strict aseptic precautions allows considerable quantities of the fluid to drain away. Southey's tubes are also very efficacious, but there is considerable danger of inflammatory changes taking place in the subcutaneous tissues.

Theobromine in doses of gr. lx. to gr. xc. daily may be used with occasional benefit as a diuretic when the urinary secretion is persistently small.

When considerable quantities of fluid collect in the abdominal or the pleural cavity paracentesis is necessary and may be repeated as often as required.

Palpitation is much relieved by an ice-bag over the precordial region. A diffusible stimulant, or strychnine in full doses often proves of signal service. If the attack is severe, a hypodermic injection of morphine may be given. Strict attention to diet together with quiet and rest is also essential.

Vomiting.—Food must sometimes be withheld for some hours, or replaced by sips of hot water, brandy, or champagne. After the vomiting has yielded or lessened, liquid food may be cautiously tried. Milk may be given freely diluted with lime water, Vichy or effervescing waters, or peptonized beef essences are often tolerated when other foods are rejected. In obstinate cases rectal alimentation may become requisite. The frequent action of digitalis in inducing vomiting must be remembered in this connection. It must often be withheld for a period, but should not be given up without good reason.

Venesection is occasionally required when marked cyanosis or dyspnœa is present, and ten, twenty, or even thirty ounces of blood may be abstracted from the arm. A valuable measure which has largely fallen into disuse is the application of a few leeches to the precordial region followed by hot fomentations to encourage bleeding.

During the past few years much has been written on the Nauheim methods, consisting in bathing in aerated water, and movements with resistance. The baths lessen the peripheral resistance, and the movements tend to empty the veins. Percussion and skiagraphs show a lessening of cardiac dilatation after application of these methods. They seem to be more successful at the natural springs than when applied in hospitals or other localities. *Frederick G. Finley.*

HEART, RUPTURES OF.—These are divided into two classes: *First,* Those due to degeneration of the myocardium, the so-called spontaneous ruptures; and *second,* those due to traumatism.

Instances of the first class, while not frequent, are more often observed than are those of traumatic origin.

MORBID ANATOMY.—Spontaneous rupture of the heart generally occurs in the substance of the left ventricle owing to the greater frequency of degenerative changes in this locality, and to the greater strain which this part of the heart has to bear in lifting the blood through the systemic circulation.

The anterior face of the ventricular wall somewhat above the apex is usually the site of the tear. Although it is said that the tear usually begins from within and proceeds to the outer face, the reverse may happen, and it is impossible to tell from inspection upon which surface the lesion originated. The sites of the rupture in 55 cases collected by Elleaume were as follows: 43 in the left ventricle, 7 in the right, 3 in the right auricle, and 2 in the left auricle.

The tear may be complete or incomplete, and may vary in extent from a centimetre to the length of the ventricle. It is usually single, but as many as five have been noted, sometimes intercommunicating. The rent is generally ragged, irregular, and sometimes ecchymosed at the edges. Its course through the ventricular wall may be tortuous so that the endocardial and epicardial openings do not correspond. Usually the fissure runs parallel to the course of the muscular fibres. Those ruptures which are due to an abscess of the heart wall or to hemorrhagic softening more frequently are in the form of an ulceration or perforation. The immediate result of this accident is the distention of the pericardial sac with blood which generally forms clots, leaving the serum in the pericardium.

Cases have been noted in which a plug of fibrin has more or less completely occluded the tear in the heart wall.

ETIOLOGY.—This form of rupture is always the result of disease of the myocardium, softening, fatty degeneration, fatty infiltration, etc., dependent generally upon occlusion or fibrosis of the coronary arteries. This degeneration may be local or general, and may result primarily in an aneurism of the heart or aorta, which may burst. Very rarely we have abscess of the heart wall, which bursts and leads to rupture. The *exciting* cause of the lesion may be a sudden and perhaps an unusual motion like stumbling or falling, lifting or straining. A comparatively frequent cause is running for a train. Anger, excitement, and mental or physical shock may determine the accident. Not infrequently it occurs while the patient is in perfect rest. He may be asleep in bed. The male sex is considerably more liable to this accident than the female. It seldom occurs before the fiftieth year, more often after the sixtieth.

SYMPTOMS.—Seldom are the premonitory signs of this disaster distinctive. There would naturally be signs of a diseased and feeble heart. Comparatively few diseased hearts, however, go on to rupture. On the occurrence of the lesion, death is usually instantaneous; the patient not infrequently being found dead in bed with the clothes not even disturbed. In case the rupture is oblique in direction and small in extent, the patient may survive several hours, or even days.

Dr. Langman has recently reported a case of a man who had two ruptures of the heart wall, one having happened two weeks before the other. He died four hours after the occurrence of the second, which was in the left ventricle, the first was in the right. The heart walls were thin, but not fatty.

The special symptoms denoting approaching dissolution are intense precordial pain, restlessness, dyspnœa, rapid, feeble, and fluttering pulse; vomiting, cyanosis, loss of consciousness, and convulsions.

Hampeln has observed that there is greater pain in rupture of the pericardial portion of the aorta than in that of the heart substance proper.

The physical signs, even when the patient's life is sufficiently prolonged, are more or less indefinite. The pulse is weak and intermittent. The heart sounds are muffled, distant, and imperfectly developed, with probably some increase of pericardial dulness.

DIAGNOSIS.—This is so uncertain that it cannot as a rule be relied upon, although in some cases the condition has been made out ante mortem. A diagnosis ought certainly to be made in those cases in which, in addition to the rational symptoms already detailed, percussion affords evidence that the pericardial area has recently undergone enlargement.

PROGNOSIS.—This is uniformly unfavorable; no case of spontaneous heart rupture having ever been known to recover, although life may be prolonged for several days and even weeks, by judicious treatment and nursing.

TREATMENT.—This is mainly palliative and can have no effect on the diseased condition of the heart. Cold applications, morphine hypodermatically, a strict maintenance of the recumbent posture, perfect quiet, and warmth to the extremities may prolong life for a limited period. Stimulants are contraindicated.

Traumatic Ruptures of the Heart are quite rare. This organ from its shape and position, its mobility and the protection afforded it by the elasticity of its walls, and by its overlying and surrounding structures, is seldom ruptured—except in cases in which the entire chest wall is crushed in. A certain number of cases of rupture of the heart walls have occurred with comparatively little injury to the chest wall, even without penetration of the pericardial sac. The writer was able, in 1899, to collect forty-five cases of heart rupture, not due to stab or gunshot wounds, and generally speaking caused by an injury from the effects of which the heart walls would be expected to escape scot free. In the majority of the cases there was evidence of disease or abnormality of the organ. But in a few cases the heart muscle was healthy.

The writer reported the case of a vigorous man of twenty-eight who was riding his bicycle rapidly, when the forward wheel struck a hose pipe which was filled with water and which lay across the road. As a result of this sudden strain the bicycle broke at the "head," and the rider was thrown to the ground with great violence, the detached handle-bar post interposing itself between his body and the hard road. This impact fractured the sixth costal cartilage somewhat to the left of the sternum and drove the distal end attached to the rib into the pericardial sac. The sac did not tear; but the force of the blow was so great that the right auricle was torn entirely through. A triangular flap (see accompanying photograph, Fig. 2596) of the heart wall had been lifted up, and when it was turned back the ventricular cavity was exposed. The heart weighed eleven and one-quarter ounces, and its valves and muscular substance were healthy and competent. The man lived for an hour and a half after the accident and partly recovered from shock. The cause of death was apparently the distention of the pericardium with blood, of which from eight to ten ounces, mostly coagulated, was found in the sac.

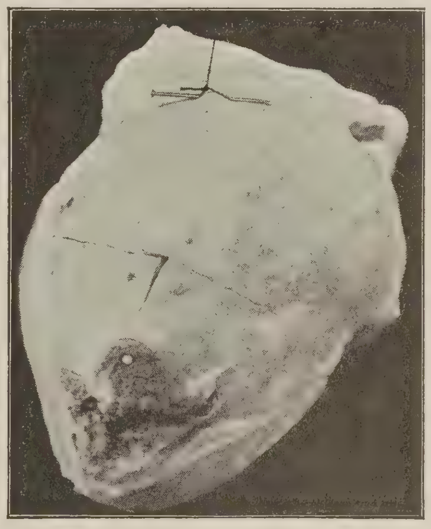

FIG. 2596.—Showing Traumatic Rupture of Heart at Apex of Right Ventricle.

Of traumatic ruptures a majority occur in the right ventricle near its apex. Of Gamgee's 28 cases, in 9 there was no fracture of ribs or sternum and either no bruise of the parietes or a very slight one. The pericardium was intact in at least one-half of the cases, and in 22 in which the principal seat of the injury was noted, the right ventricle was torn in 8; the left in 3. The left auricle was injured in 7 and the right in 4. The apex of the right ventricle is a favorite spot for traumatic rupture, first, on account of its exposed position as it comes in contact with the chest wall in systole, and second, because the myocardium is thinnest at this point. Ruptures of the muscular fibres most frequently occur in systole when they are tense and firm and offer the greatest resistance to the impact of the opposing force. If struck in diastole when the ventricles are filled with blood, their walls being flaccid, the seat of rupture will be in the resisting valves, or on the interventricular septum.

So far as ascertained the longest time that a person has survived after traumatic heart rupture is seventeen hours. The symptoms of intense pericardial pain, weak, fluttering or intermittent pulse, dyspnœa, lividity, cold extremities, sweating, and convulsions, are much the same as in cases of spontaneous rupture. With the history of a blow upon the chest, especially if the ribs or their cartilages are found fractured, the diagnosis of heart rupture might be made out and bold surgery might save a life. The technique of the operation would be the same as that laid down for wounds of the heart substance. No other treatment could be anything more than palliative.

Richard Cole Newton.

HEART STRAIN.—This may be defined as the untoward effects of overexertion on the previously normal heart.

While the metabolic changes during violent exercise doubtless produce toxins—"fatigue products"—affecting the nutrition of the heart, and causing relaxation of its tonus, the effects are largely mechanical. The heart is called upon to do more work than when at rest, to receive and send out more blood, and to do this under different conditions of blood pressure and nutrition.

The work done by the heart in a given interval of time depends on two factors—the amount of blood sent out and the resistance against which it is pumped. The heart's arterial output in turn is dependent upon its venous input,—that is, the heart normally sends out the same amount of blood per second as it receives. The resistance or aortic blood pressure depends on the balance between the output of the heart and that of the arteries—the heart endeavors to overcome the peripheral resistance. The output of the heart remaining the same, in other words, the resistance would depend upon the state of contraction or dilatation of the arterioles.

The peripheral blood pressure shows, during active exercise, a temporary increase, which is followed, even if the exercise continues, by a very marked decrease. In a recent examination of the contestants in a twenty-five-mile running race with which the writer was associated, this fall was invariably present in men examined at the finish and was shown by direct study of the blood pressure and by the sphygmograph. The temporary rise is due to increased output of the heart. The pressure of the muscles of the extremities on the large veins, the similar action of the muscles of the abdomen and diaphragm on the portal system, and the increased activity of the respiratory apparatus, all favor the flow of blood to the right auricle, and through the lungs to the left heart. For a while the increased output causes an increase in arterial tension and increased work for the left ventricle, but there is soon a dilatation of the peripheral vessels, especially in the muscles, and a consequent fall of pressure with relief to the left heart. According to Allbutt, when this adjustment is accomplished the phenomenon of "second wind" occurs.

Training.—When the heart is frequently called upon to do a large amount of work changes take place through which it is able to meet larger demands upon it. In trained athletes, especially in those engaged in sports requiring long-continued violent exertion, as in long-distance runners or oarsmen, the heart area shows marked and progressive enlargement. Inspection frequently shows visible bulging of the left chest and percussion shows more or less enlargement. The left border may be outside the nipple, and the right correspondingly changed. The impulse is often diffuse and powerful.

The explanation of these findings is doubtless that the heart muscle undergoes hypertrophy exactly like any other muscle. Perhaps there is some dilatation as well, the capacity of the organ as well as its strength being increased. The respiratory apparatus also becomes more efficient, but the changes here are less easily determined than in the heart. It cannot be too strongly insisted upon that these changes are physiological. More than that, it is probable that without more or less cardiac hypertrophy a man cannot with impunity engage in violent athletic contests, while with the heart properly trained he will rarely do himself any immediate damage.

What are the remote results of normal training? Are these hearts more subject in after years to functional disorders or degenerative conditions than others? Important as this question is in connection with modern college athletics there is much doubt about its answer. It is probable that a heart in which simple hypertrophy has occurred as a result of training, which has never suffered from any of the acute or chronic disorders presently to be described, which has, in short, enabled its owner to perform tasks beyond the power of other men without at any time causing any untoward symptoms—such a heart will, after the cessation of training, return quietly to its original size. The decrease is, however, slow. Darling found that after a year the Harvard rowers still had large hearts. But, as Darling remarks, hypertrophy of the heart from training is no more undesirable and gives the patient no more trouble than the corresponding hypertrophy of the biceps. Perhaps the most thorough investigation of this matter was that of Morgan (1873) who studied the after health of the 294 men who rowed in the Oxford-Cambridge races between 1829 and 1869. But seventeen claimed to have been injured, and in only two or three would the evidence convince us to-day that previously healthy men suffered permanent damage to the heart. The mortality was less than comparison with insurance statistics would lead one to expect, and Morgan concluded that in the majority of cases training does great and lasting good. On the other hand Stengel mentions cases in which trained men several years after the cessation of active athletics, with no intervening symptoms, began to complain of sensations of oppression and distention in the chest with "consciousness of the heart." Certainly, if in the course of training the heart has suffered any of the forms of strain, permanent damage may remain. Too little attention has been given the subject of training by medical men and the matter cannot be said to rest at present on very firm scientific foundations.

Acute Heart Strain; Acute Dilatation.—When the heart is examined immediately after an athletic contest it is common to find enlargement of the area of dulness over and above what was already present as a result of training. So commonly is this the case, and so rapidly does the temporary enlargement subside that some dilatation or relaxation would seem to be physiological after sufficient severe exercise.

Under constant conditions of intraventricular blood pressure the total stress on the walls of the ventricle varies with the size of the cavity, and the increase in total stress is as the cube of the radius of curvature, assuming that the ventricle is approximately spherical. It is evident that as dilatation advances the heart muscle has to bear a constantly increasing strain, and that should it continue a point would be reached where it could no longer contract at all (paralysis from overdistention.)

There are, however, certain things which limit this process: in the first place, up to a certain point the muscle fibres act to better advantage when stretched than when partly contracted; secondly, the chordæ tendineæ and trabeculæ tend to prevent excessive stretching; thirdly, the fall of blood pressure as exercise continues relieves the strain; finally, the auriculo-ventricular orifices share the dilatation, or the mitral and tricuspid sphincters relax and regurgitation occurs. In regard to this last point, the normal mitral and tricuspid valves are able to close an orifice considerably dilated, and the action of the so-called sphincters is not fully admitted by physiologists. According to Albutt sudden stress affects chiefly the aortic area, prolonged exertion the right heart.

Acute dilatation may result from severe exertion in any form, though it is said to be most frequent when the legs are used, as in running, rowing, forced marching, bicycling, and mountain climbing. It has resulted from fright and other emotional shocks, and from sudden peripheral vaso-motor contraction the result of cold bathing. It is much more apt to occur in untrained individuals, but even in the Harvard University crews each race is followed by temporary increase in the area of dulness. It is more easily produced in older persons, in those with beginning degenerative conditions, and after convalescence from acute diseases.

The symptoms due to severe physical exertion are familiar to every one—rapid pulse, pallor, and dyspnœa. In extreme cases these symptoms are severe and the skin is cyanosed or grayish. There may be a sense of severe oppression in the chest, dizziness, nausea, or nosebleed. The man may fall to the ground unconscious or even dead. But recovery is generally prompt, so that the athlete who falls exhausted at the finish of a hard-fought race may be well in an hour and ready to win another event.

But symptoms may persist for some days or weeks, during which there are dyspnœa on slight exertion, palpitations, præcordial oppression, pain or "side-ache," with vertigo, and albuminuria. The heart is rapid and irregular. Exacerbations of these symptoms may occur after a meal, without exciting cause or may even waken the patient at night. The patient may die in a few days, compensation not being established. Sometimes there is permanent damage and he remains "broken-winded" to the end of his days—unable to perform any unusual exertion without dyspnœa and cardiac irregularity.

The most important physical sign of pathological dilatation is sudden and persistent increase in the area of cardiac dulness. It must be remembered that the heart of the athlete is generally already enlarged from hypertrophy and that some further temporary dilatation is so common that it cannot alone constitute a disease. The impulse is often feeble and the rhythm irregular. There may be a murmur, usually systolic, at the base to the left of the sternum. The murmur is fugitive, generally disappearing within a few minutes. Its nature and position of maximum intensity are somewhat variable.

The explanation of this murmur which is frequently present in the normal cases of slight temporary dilatation is a question that has excited considerable discussion. Stengel believes that it is due to dilatation of the pulmonary conus arteriosus. In a study of the runners in the Boston Athletic Association's Marathon race (twenty-five miles) of 1899, Williams and Arnold found fugitive systolic murmurs at the base to the left of the sternum in eleven out of thirteen cases examined. In some it was transmitted along the left border of the heart to the apex and in some to the back. They consider that the heart shared in the general muscular exhaustion, and that the mitral sphincter and papillary muscles relaxed, giving a true regurgitation into the auricle. Darling found similar murmurs in the Harvard crew after racing and accepts Williams' and Arnold's explanation, which appears to be widely adopted.

The writer has assisted in examining the hearts of the Boston Marathon runners for the past two years, during which murmurs were not found with the same regularity as by Williams and Arnold. Some might be described as mere "murmurishness" of the first sound. In two cases murmurs were found at the right of the sternum. In some they were present both before and after the race, and in one or two they were present at the start and not at the finish. If any considerable mitral regurgitation had occurred, evidences of pulmonic engorgement would be expected. These were not present, nor were they reported by either of the other writers mentioned. Possibly some murmurs were cardio-respiratory, and certainly some—those that were present at the start only—were due to nervousness. Such murmurs from nervous excitement are matters of common observation. Further study of the matter is needed.

The diagnosis of acute dilatation is generally obvious. The enlargement and murmur which are the normal result of severe exertion will soon disappear, while in the serious dilatation they, together with the symptoms, will be more persistent. Persistence of the murmur with the other signs of mitral insufficiency after the disappearance of the symptoms will usually mean a pre-existing valvular lesion. If the heart is known to have been previously normal a permanent murmur with pain, œdema, and gradual recovery with hypertrophy may indicate a ruptured valve.

Treatment should be directed to relieving the heart from work as much as possible. Rest in bed is imperative in the severe cases. When cyanosis is extreme and the right heart distended, venesection may be called for, more often in older full-blooded men than in young athletes. For drugs, strychnine and alcohol may be used, with digitalis if the pulse is weak and rapid. The latter should be used cautiously especially in the early days; later it may be of the greatest value. During and after convalescence the patient must be very careful not to overexert himself. An athlete should return to active exercise, if at all, very gradually and under close medical supervision.

In prophylaxis the most important point is training, the object being to produce a hypertrophy of the heart comparable to the accompanying development of the peripheral muscles. This is illustrated by the cases of Williams and Arnold. The only two of their thirteen who failed to show enlargement dropped out of the race before reaching the finish. The avoidance of alcohol, tobacco, and other excesses is important.

The question as to what findings should exclude a man from participation in a race or game is difficult to answer. We are not justified in excluding a man because his heart does not show the requisite hypertrophy. If he has been under constant supervision there is no difficulty—persistent murmurs with dyspnœa and irregularity after preliminary trials should exclude him. But a murmur just before the start is of no significance.

Rupture of a Valve is a rare result of overexertion in the normal organ. The aortic and mitral valves are most frequently involved. There is generally severe pain at the time of the accident, often with a sense of something giving way in the chest. The usual signs of regurgitation are present. Immediate death may occur or recovery, according to the severity of the lesion.

Rupture of the Heart is even more rare and probably never occurs in the normal organ. A number of cases have occurred in degenerative conditions as a result of sudden strain. Death is usually instantaneous.

CHRONIC HEART STRAIN.—By this is meant those forms of cardiac disturbance which result from frequently repeated exertion—the functional condition known as "irritable heart" and the hypertrophied or dilated organ with symptoms of overaction. The pathology of these conditions and their relation to one another are obscure. J. M. Da Costa, who studied soldiers in the War of the Rebellion, considered that irritable heart was an early stage whose continuance resulted in hypertrophy and overaction. Treadwell studied the same class of men seven years after the war and concluded that the symptoms were due to dilatation when compensatory hypertrophy had failed.

While repeated overexertion is the chief element in the production of many of these cases it is certain that, especially in the functional cases, syphilis, and excesses of alcohol, tobacco, tea and coffee, play an important part. They often commence after convalescence from acute diseases—diarrhœa, digestive troubles, typhoid, or malaria. Improper food, insufficient sleep, and exposure or sexual excesses are occasional factors. In athletes worry over an approaching contest and in soldiers the excitement of an active campaign may have a direct or indirect influence. Constriction of the chest by heavy and improperly adjusted accoutrements has been given a prominent place.

Most of the "soldier's hearts" occur in men under twenty-five, of tall, lanky build. In civil life it is commoner in pedestrians, mountain climbers, and bicyclists. It may result from excessive dancing. J. Burney Yeo describes similar conditions in girls at puberty as a result of rapid growth and educational strains. In college athletes who are kept in the best physical condition and whose training is carefully managed it is apparently uncommon. Still, the cause of "staleness" or overtraining is very obscure and probably the heart (Darling) is a factor.

The symptoms and course of "soldier's heart" are thus summarized by Da Costa: "A man who had been for some months or longer in active service would be seized with diarrhœa, annoying, yet not enough to keep him out of the field; or, attacked with diarrhœa or fever, he rejoined his command and again underwent the exertions of a soldier's life. He soon noticed that he could not bear them as formerly; he got out of breath, could not keep up with his comrades, was annoyed with dizziness and palpitations; his accoutrements oppressed him, and all this though he appeared well and healthy. Seeking advice from the surgeon of the regiment, it was decided that he was unfit for duty and he was sent to the hospital, where his persistently quick-acting heart confirmed his story, though he looked like a man in sound condition. Any digestive disturbances which might have existed gradually passed away, but the irritability of the heart remained, and only very slowly did the excited organ return to its natural condition. Or it failed to do so, notwithstanding the use of remedies which control the circulation: thus the case might go on for a long time, and the patient, after having been the round of the hospitals, would be discharged, or, as unfit for active service, be placed in the Invalid Corps."

The important symptoms are precordial pain, usually paroxysmal; palpitations, tachycardia, the heart being characteristically more rapid in the upright position or after slight exertion; dyspnœa; and nervous disturbances—headache, dizziness, and sleeplessness. The symptoms may be absent except during exercise or they may come on paroxysmally during rest or sleep.

Examination in the functional cases shows little or no enlargement, the chief physical signs being irregularity or rapidity of action on slight exertion or on suddenly assuming the erect posture. Systolic murmurs may be present, but they are inconstant and variable. The first sound is described as short and valvular. In the cases with permanent dilatation the area is large, the impulse labored and diffuse, the first sound dull and prolonged. Constant murmurs may be present; due to regurgitation from relatively insufficient valves.

In the differential diagnosis it must be remembered that a true valvular lesion from endocarditis may exist without causing a murmur, especially in the case of mitral stenosis, and that the patient with such a lesion may correctly date the onset of symptoms to a period of over-exercise. Renal, pulmonary, and vascular degenerations must be borne in mind. Some of the cases are clinically identical with myocarditis.

The prognosis is uncertain. Complete recovery may occur, but as a rule more or less irritability remains. The quotation from Da Costa given above indicates what seems to be the common result in military cases. It is probable that many cases become virtually ones of valvular disease—relative insufficiency—or of myocarditis. Some go from bad to worse and die within a few years.

For prophylactic treatment training is again of great importance, or at least occupations requiring severe exertion should be entered into gradually so that hypertrophy of the heart muscle may occur before the full strain is put on the organ. Active exercise should be resumed with great care after recovery from acute disease. Excesses, especially of tobacco and alcohol, should be avoided permanently by those whose occupations call for a large amount of work on the part of the heart.

When the condition of irritable or dilated heart is once established prolonged rest is imperative with gradual return to active life after recovery. Among drugs digitalis will be of greatest use. The bromides will also be of service. Iron and other tonics may be called for.

In conclusion the statement must be reiterated that the danger from over-exercise in healthy hearts is not great, especially if the subject be well-trained. Indeed, Darling mentions one oarsman in whom, at the beginning of the season, the heart showed obvious signs of mitral regurgitation from previous organic disease of the valve. As the season advanced the symptoms and signs entirely disappeared, and the man did valuable work in the final hard-fought intercollegiate boat race. Such instances may be rare, but the heart certainly has a vast reserve power.

HEART, THROMBOSIS OF.—The blood clots found within the heart cavities may be divided into three classes: *post-mortem clots, ante-mortem* or *agonal clots,* and *true thrombi.* The post-mortem clot is formed after the heart has ceased to beat; it is a soft, dark-red, jelly clot filling up the cavity of the auricle or ventricle and not adherent to the heart wall. It is commonly known as cruor or the currant-jelly clot. Such coagula are found usually in the right auricle and ventricle, but may be present in all four of the cavities. When coagulation occurs rapidly after death the clot is uniformly red throughout; but if coagulation is delayed the uppermost portion of the clot may be light-colored or yellowish from the sinking of the red cells. In themselves the post-mortem clots are of significance only in so far as the character of the blood and its coagulability are concerned. If coagulation takes place while the ventricles are contracted in rigor mortis the clots will be found in the auricles only, but, if coagulation be delayed until the contraction of the ventricles has passed, the ventricular cavities may again become filled with blood which later coagulates.

The ante-mortem or agonal clot is a white or mixed clot found in the periphery of the large veins, right and left auricles, and right ventricle, but rarely in the left ventricle. Such clots consist of fibrin with few or many leucocytes, while that part of the clot toward the axial stream may contain red blood cells. They develop during the slowing of the blood stream in cases of slow death, and are formed only in the peripheral stream where there are no red cells. As the current becomes slower red cells are caught in that portion of the clot toward the central stream. As soon as death occurs and the current comes to a standstill, the blood in the central stream coagulates forming a post-mortem currant-jelly clot. Combinations of agonal and post-mortem clots are thus formed and are distinguished by the presence of a central red clot surrounded by a peripheral layer of white clot. The agonal clot is soft, but much firmer than the currant-jelly clot. It is not attached to the endocardium and is easily removed from between the trabeculæ of the ventricular wall. It is further distinguished from true cardiac thrombi in its moistness, translucency, and greater elasticity. On microscopical examination the agonal clot is found to consist almost entirely of a coarse reticulum of fibrin; on the other hand the fibrin in the post-mortem jelly clot is in the form of fine fibrillæ. The significance of the agonal clot is only that of a slowly progressive heart failure; in cases of sudden death without previous impairment of cardiac efficiency the white peripheral clots are either very small or absent, while in cases of slow death in chronic valvular disease, cachexias, etc., they may be very large. Care should be taken to differentiate between these and the true heart thrombi for which they are frequently mistaken.

The true heart thrombi are yellowish, reddish, or reddish-gray or brown, opaque, dry, inelastic, brittle, and in the great majority of cases more or less adherent to the endocardium. The conditions under which they are formed are practically the same as those of thrombosis of the blood-vessels, the chief factors being lesions of the endocardium, disturbances of the circulation, and changes in the chemical composition of the blood. Of these the endocardial changes are by far the most important. At the point of lesion blood plates are first deposited, followed by the processes of conglutination and coagulation as in the formation of thrombi in the vessels. The resulting thrombus is usually a mixed clot, very frequently laminated. When formed in the peripheral stream with rapid circulation it may be entirely white; if the current is very much slowed it may be red throughout. In old red thrombi the diffusion of the hæmoglobin from the red cells may give a washed-out reddish or brown color. The latter color is also the result of the formation of blood pigment from the disintegration of the red cells. The surface of the thrombus is not infrequently ribbed; this appearance has been explained as being due to wave-like movements in the blood, the process being analogous to the formation of wave marks on sandy bottoms. The general external appearances of cardiac thrombi are dependent upon the manner of formation, rapidity of development, and the local conditions of the circulation. The size and shape of cardiac thrombi show great variation. They may be so small as to be hidden between the muscle columns, or so large as completely to fill one of the heart cavities. They may appear as small globular masses projecting from between the muscle trabeculæ (globular vegetations); or as flat, circumscribed masses firmly attached to the heart wall. On the valves they may form bead-like excrescences or vegetations. Not infrequently the thrombus is attached to the endocardium by a pedicle (heart polyp); as the result of the tearing of such attachment free globular thrombi may be formed (ball thrombi). In rare cases the thrombus may be spread over the endocardium like a false membrane.

The thrombus when cut into may be found to be made up of dry and brittle laminations, in some instances the central portion of the thrombus is under slight pressure easily crumbled to dust. In other cases the central portion may be cystic, the cavity filled with a thick reddish-brown or pus-like substance. Such secondary degenerations are of frequent occurrence. The most common is a simple softening or liquefaction; when many leucocytes are present a grayish pus-like fluid may be formed; if the degenerating portion is made up of red cells alone a grumous reddish-brown fluid results. Calcification of the thrombus may also take place, resulting in the formation of a cardiolith. As a more favorable sequela of cardiac thrombosis organization of the thrombus may occur, the latter becoming ultimately converted into a nodular or diffuse fibrous thickening of the endocardium. In some cases both the degenerating and the organized thrombi have been mistaken for cardiac neoplasms, cysts, and fibroma respectively. It is also not improbable that some of the growths on the endocardial surface described as myxoma were recently organized thrombi.

The microscopical examination shows the cardiac thrombi to be composed of fibrin, disintegrated blood cells, blood pigment, masses of calcification, etc. In case of simple softening of the central portion the cavity thus formed contains granular débris, blood pigment, etc. In recent thrombi the leucocytes present may still show traces of their nuclei. If organization has begun fibroblasts and new capillaries may be seen extending from the endocardium into the thrombus.

Thrombi are more frequently found in the right side of the heart than in the left. In the auricles the appendix, and in the ventricles the neighborhood of the apex are the favorite seats of location. The pedunculated thrombi (cardiac polyps) are of frequent occurrence in the right ventricle, while the free ball thrombi, in the majority of recorded cases, were found in the dilated left auricle in cases of mitral stenosis. Cardiac thrombi may be single or multiple, and may be found at any age. According to their location in the heart they are also designated as parietal and valvular.

Etiology.—The changes in the endocardium leading to thrombosis are either inflammatory, or degenerative, or necrotic in nature. These lesions may be the result of the local action of pathogenic bacteria or due to general intoxications, disturbances of nutrition, changes in the blood, etc. The pus-forming organisms, gonococcus, and tubercle bacillus have been found in cardiac thrombi under such conditions as to make it very probable that they were the exciting factors of the thrombosis. The valvular vegetations are in the majority of cases due to bacteria. In the acute infections fatty degeneration of the endocardial endothelium not infrequently leads to thrombosis. Local changes in the myocardium, such as anæmic infarction, myocarditis, etc., are usually associated with the formation of thrombi on the overlying endocardium. Aneurismal dilatations of the cardiac wall are very likely to be partly or wholly filled by a thrombus. In many chronic diseases in which there are general disturbances of nutrition, systemic intoxication, etc., as in chronic nephritis, pulmonary tuberculosis, chronic valvular disease, etc., heart thrombi are frequently found. In pulmonary tuberculosis they are of such frequent occurrence as to give rise to the suspicion that in many cases they may be due to the local action of tubercle bacilli which have lodged upon the endocardium. Cardiac thrombosis often occurs in cases of general cachexia (marasmic thrombi). In severe superficial burns of the skin the changes produced in the blood may lead to the formation of thrombi, both in the right side of the heart and in the pulmonary arteries. Small emboli coming from venous thrombi and lodging upon the valves or between the muscle trabeculæ of the right ventricle may give rise to secondary or induced thrombi. Sclerotic changes in the valves or mural endocardium followed by atheromatous degeneration or calcification may also become the seat of thrombosis. Dilatation of the heart and slowing of the blood stream are favoring factors in all of the conditions named above, but are probably not in themselves sufficient to cause thrombosis; the changes in the endocardium must be regarded as of prime importance.

Symptoms.—Thrombi of large size may exist indefinitely without serious impairment of cardiac efficiency. In the majority of cases the symptoms produced cannot be differentiated from cardiac insufficiency due to other causes. The physical signs are those of dilatation; in case of the blocking of a valvular orifice by the thrombus the heart's action is usually too weak to produce audible murmurs. The valvular vegetations may give rise to symptoms of stenosis or insufficiency. In the case of the ball thrombi so frequently formed in the left auricle in mitral stenosis sudden death or the most serious disturbances of circulation may be caused by the complete or partial blocking of the mitral orifice. The occurrence of embolism, either of the pulmonary or of the systemic arteries, is the symptom of greatest value in the diagnosis of cardiac thrombosis. Embolic abscesses may be produced throughout the body in the case of emboli arising from thrombi caused by pyogenic bacteria. In the case of a patent foramen ovale paradoxical embolism from thrombi in the right side of the heart may occur. In general it may be said that the diagnosis of cardiac thrombosis is usually impossible, having been made in but few cases. Aside from the occurrence of embolism the irregularity of the symptoms and physical signs may excite suspicion of a movable body within the heart.

The Prognosis is bad, not only because of the interference of the heart's action and the danger of embolism, but also because of the conditions which have led to the thrombosis. The treatment is directed chiefly to the latter and to the support of the heart.

Aldred Scott Warthin.

HEART, WOUNDS OF.—Wounds of the heart may be either non-penetrating or penetrating—injuring the cardiac wall or opening a cavity. The chief dangers from the former are shock and injury to a coronary artery. Ninety per cent. are penetrating, and of these only nineteen per cent. are immediately fatal. The right ventricle is most frequently injured, and the left auricle is least so. Auricular wounds are more fatal than ventricular, and injuries to the apex are less dangerous than either. A needle puncture will rarely cause hemorrhage from a ventricle, but excessive bleeding, which is mostly systolic, is liable to follow a like injury to an auricle. A wound inflicted during diastole is less dangerous than a similar injury during systole, perpendicular wounds are more fatal than diagonal, and those of the right heart bleed more profusely than those of the left. The presence of the foreign body in the heart, the size of the wound, the location of the wound, the number of wounds, the connecting cavities, the attending syncope, the involvement of Kronecker's co-ordination centre, are important factors in determining the outcome. Pericarditis, myocarditis, endocarditis, cerebral embolism, and empyema are frequent secondary complications. When the wound heals there is a possibility of cicatricial stretching, and subsequent rupture as in a case reported by Izzo of a man stabbed in the left ventricle, who was conveyed to the hospital from which he was discharged cured on the twenty-eighth day; a few hours afterward, while lifting a heavy body, he fell and quickly died. At the autopsy the cicatrix of the left ventricle was found ruptured. In addition to injuries of the heart caused by bullets, daggers, knives, needles, and various implements of war, it may be wounded by a fractured rib, by a foreign body that has perforated the œsophagus, or by blows upon the chest. Traumatic ruptures are more frequent after a full meal, as the distended stomach pushes the heart upward and forward, and causes a large area of the organ to be in contact with the thoracic wall and receive the impact.

Newton and Gamgee have collected forty-five cases in which traumatisms caused rupture of the heart without opening the pericardium. All were fatal. Only one of Gamgee's cases survived the injury fourteen hours. The fatality is easily understood, for, there being no exit, as soon as the accumulation of blood exceeds the limit of pericardial distensibility, the cardiac movements are mechanically stopped. The surgeon not only would be justified, but it is his bounden duty to operate upon every one of these cases, for it is more important, if possible, to rescue a drowning heart than to relieve a strangulated hernia. It is possible for a foreign body, as a gun missile, to remain quiescent for years in the myocardium, as in the case of a British officer, reported by Stevenson, who carried a bullet encapsuled for eleven years, or the still more remarkable case of Beers (Cincinnati *Lancet Clinic*, 1898), of an American soldier who survived the lodgment of a bullet in the wall of the left ventricle for thirty-seven years.

Symptoms.—There is no certain cardinal sign by which an injury of the heart can be denoted, but when we consider the location of the external wound and the usually profuse hemorrhage from it, if it is large, in connection with other signs and symptoms, it can generally be recognized. The pulse is weak, irregular, and intermittent, and often imperceptible in the extremities. There are pain, pallor, restlessness, and generally dyspnœa. Frequent attacks of syncope are common. The mind is clear but the countenance depicts an anxiety and distress that seemingly would welcome death, with the wintry sterility of the grave, as a sympathizing friend. If there is much blood in the pericardium the heart sounds are indistinct and percussion elicits increased dulness. With the pulsation of the heart a foreign body, as a needle, may be seen to move under the skin, a sign centuries ago enshrined in the magnificence of indestructible verse:

> "He fell, the spear point quivering in his heart
> Which, with convulsive throbbing, shook the shaft."

Treatment.—I presume no one will question the propriety of immediate operative interference, as experience teaches that about thirty-nine per cent. of cases recovered in which the heart had been sutured as against ten per cent. of recoveries in which no operation had been performed. The patient must be kept absolutely quiet. A probe should never be employed, as it is liable to inflict an additional injury upon the myocardium. For temporary hæmostasis some operators have recommended Pean's forceps and various modifications of it, but they all more or less lacerate the myocardium and can never replace digital pressure. Interrupted sutures are preferable in closing a wound of the myocardium. They should not involve the endocardium, and as few as possible should be passed, commensurate with safety against leakage, as they cause a degeneration of the muscular fibre with its tendency to dilatation and rupture. Giordano, from his experiments upon rabbits, concludes that auricular wounds might be closed advantageously with Lembert's sutures. Silk is preferable to any other material. The needle should be the same as that used in suturing the intestines. The sutures should be passed and tied during diastole. If the wound in the heart is sufficiently large a finger should be introduced into it, as Parrozani did, for the double purpose of checking the hemorrhage and to facilitate the passage of the first suture which should be used to steady the heart for the passage of the others. If the pericardial sac is closed either interrupted or continuous sutures may be used. It hardly seems necessary to accentuate the fact of the necessity of perfect cleanliness in these operations whenever the urgency of the case does not require instant intervention, as in the patients of Longo and Ninni. The question of administering an anæsthetic is a mooted one. Ollier says general anæsthesia should not be thought of. Parrozani operated upon his two cases without an anæsthetic, and observed only slight movement when he cut the skin and in passing the sutures in the myocardium. Giordano made the same observation in his case, but thinks Ollier's statement is too sweeping; and if the pulse is strong and the general condition good, chloroform may be administered. Struggling from an anæsthetic is liable to produce detachment of a clot, and renew the hemorrhage, as occurred in Parlavecchio's case. No two operators have made similar external incisions for exposing the heart. Professor Rotter performed a number of experiments upon the cadaver, and concluded that the easiest way to expose the heart was by making an incision four inches in length along the lower border of the third rib, commencing three-fifths of an inch to the left of the sternum. A similar incision was made along the lower border of the fifth rib. The external ends of these incisions were joined by a third. The fourth and fifth ribs were divided and the musculo-osseous flap was turned inward. If more space should be required the third rib could be included. No arteries excepting the intercostal require ligation in this operation. In Parrozani's successful operation an incision through the soft parts one and one-fourth inches from the margin of the sternum, in the fourth intercostal space, was carried for a distance of five and one-half inches, then it descended vertically in the mid-axillary line as far as the superior margin of the ninth rib. The fifth, sixth, seventh, and eighth ribs were cut through, in the mid-axillary line, the incision extending through the pleura. The flap, or door, was raised with the cartilages of the ribs acting as hinges. Parrozani closed the pericardial sac and sutured the flap in position. As the uncleanliness of the weapon and often the urgency of the operation preclude the proper preparation of the patient, it is considered safer to drain the pericardial sac with iodoform gauze as was done in the successful cases of Rehn, Ramoni, and Rosa. There are on record eighteen cases of heart suture and one of ligation of the left coronary artery. Five of these eighteen cases were injuries to the right ventricle and were stab wounds. In two of the cases the surgeons stated that the wounds were one-fourth of an inch and three-fifths of an inch in length. In two cases three interrupted stitches, in two four interrupted stitches were taken, and in the fifth case the wound was closed with a continuous suture of five stitches. Two of the patients recovered. Of the three unsuccessful cases, broncho-pneumonia caused the death of one on the sixth day, and in the other two cases the operators were not explicit as to the cause of death.

In one patient the left auricle was opened to the extent of four-fifths of an inch. It was closed with four silk stitches. Death occurred on the nineteenth day from abscesses in the lungs.

In three cases the dagger entered the apex, and in two of these it extended into the left ventricle. In these two cases the wounds were respectively three-fourths of an inch and one and a half inches in length; both were closed with four interrupted sutures. The wound which did not enter a cavity was closed with one stitch. All ended in recovery.

There are seven cases of stab wounds of the left ventricle. The length of these wounds varied from three-fifths of an inch to one inch and two-fifths, and required from two to four stitches. Two patients recovered, one died on the operating table of hemorrhage, one in fifteen minutes after reaching the bed, one of pericarditis several days after the operation, and the other two within twenty-four hours, never having reacted.

In two of the cases no mention is made as to the location of the wound. One was a shot and the other a stab wound of the heart. The patient that was stabbed died of empyema on the twenty-second day after suturing.

The left coronary artery was cut and ligated two hours after the injury. The patient had pericarditis and died thirty minutes after the second operation, which was performed on the fifth day for the purpose of drainage. After most of these operations stimulating hypodermic injections were used and hypodermoclysis and autotransfusion practised.

Dr. John B. Roberts, of Philadelphia, in 1881, suggested heart suture, and Dr. Del Vecchio, of Naples, in 1894, demonstrated its feasibility before the Eleventh International Medical Congress in Rome, by his experiments on dogs. Two years later the human heart was sutured by Farrina and Cappelen. It is surprising to find the statistics collected by Fischer, of Breslau, in 1868, quoted as late as 1901 as authoritative in computing the prognosis in this class of injuries.

The successful suturing of the heart by Rehns, Parrozani, Parlavecchio, Pagenstecher, and others has revolutionized the treatment and changed the probable outcome. Fischer's statistics, though a monument to his untiring zeal and energy, are now like an antiquated signboard on a discarded highway; but

> "Faith, fanatic faith, once wedded fast
> To some dear falsehood, hugs it to the last."

HEAT, ANIMAL.—See *Calorimetry.*

HEAT-STROKE.—(Synonyms: Sunstroke, insolation, thermic fever, *siriasis, coup de soleil, coup de chaleur, Hitzschlag, Sonnenstich, ictus solis, insolatio.*)

Definition.—Insolation is a disease whose main features are, in its milder forms, intense exhaustion, with or without rise of temperature, and in its severer forms, with an enormous rise of temperature and coma probably caused by acute auto-intoxication due to the presence in the blood of toxic decomposition products or toxic substances produced at the unusually high temperature, the exact nature of these substances being at present unknown.

From the time when it is recorded that Elisha restored the Shunammite woman's son to life after a sunstroke the frequency of this affection has often been noted. Armies at times have been almost decimated by it, especially when operating in sub-tropical or tropical countries. Sunstroke occurs most frequently in the tropics, particularly where the climate is damp. In the United States it occurs during summer in the Mississippi Valley, around the southern shores of the Great Lakes, and especially along the Atlantic coast. In the Western and Southwestern States it is rare, owing to the dryness of the climate.

Any cause that diminishes the resistance of the body predisposes to sunstroke. Alcoholism is undoubtedly the most frequent predisposing cause, not only chronic alcoholism but even a single excess. All causes producing extreme fatigue, such as severe muscular exertion and sexual excesses, predispose to an attack. Elderly people suffering from chronic ailments and invalids of any age, even if taking no bodily exercise and remaining indoors, are sometimes overcome by the heat and suffer true attacks of heat-stroke. It is not so common amongst children as amongst adults. Men are more frequently attacked than women because their occupations more often subject them to different forms of exposure to heat and require of them greater physical exercise, and because men are more often given to alcoholic excess than women.

Exposure to the direct rays of the sun is usually the exciting cause, but this is not necessary; some of the worst epidemics in the tropics have occurred during the night. While soldiers on the march and laborers working in the sun have given the greatest number of victims to this disease, men working in superheated environment such as firemen, stokers, and laundrymen have often been attacked. The main factors in the weather which are specially prone to assist in the causation of insolation are high humidity with continuously high temperature and lack of motion of the air. Humidity and especially the absence of cooling breezes are as important factors as is high temperature, although the cause of sunstroke is usually attributed to the high temperature alone. It has long been noticed that a hot, sultry, lifeless atmosphere is the one in which most cases of sunstroke occur. Impurity of the atmosphere is not unimportant, as is shown by the fact that men sleeping in crowded barracks or small tents are more often victims than those in well-ventilated quarters.

Sunstroke occurs with greater frequency in the tropics amongst unacclimated individuals than amongst those of long residence, who have acquired a certain amount of immunity to the effects of heat. This immunity, however, is by no means absolute, as even the natives of India, Egypt, Arabia, and Africa are at times overcome. The light-skinned races are more susceptible than the dark-skinned.

Pathological Anatomy and Pathology.—The post-mortem appearances depend on the time that has elapsed since death occurred. When the post-mortem examination is made shortly after death the following conditions are usually present: When the ante-mortem temperature has been high the viscera feel noticeably hot; the lungs are congested, often extremely so; the liver is large, and the abdominal veins are filled with blood and there is intense congestion of the brain and meninges. The left ventricle of the heart is contracted and empty; the right ventricle is filled with semi-fluid blood, sometimes giving an acid reaction. Rigor mortis has set in early. When several hours have elapsed since death decomposition has rapidly set in. The heart, instead of being contracted, is then flabby and filled with grumous, semi-fluid blood. The spleen is slightly enlarged and soft. The meninges of the brain are congested, and there is more or less abundant subpial fluid. The brain itself is usually firm and not congested, with sometimes a little bloody fluid in the ventricles. The membranes of the spinal cord are congested, the cord being firm and about normal in appearance. Small hemorrhagic extravasations are sometimes found in the viscera, pleuræ, and pericardium. The most constant changes seem to be marked congestion of the meninges and viscera, the fluidity of the blood, and the unusual rapidity with which rigor mortis and decomposition supervene.

In the minute cellular structure of the brain we find changes which are much more constant and which are fairly characteristic. Dr. Ira Van Gieson, of New York, has described these lesions in the neurons of the brain and cord, as an acute parenchymatous degeneration of the ganglion cells best shown by the Nissl stain and counterstain with eosin. In the normal cell stained in this manner the chromophilic plaques, or Nissl bodies, appear to have a somewhat barrel-stave shape and to be somewhat thickly packed in the body of the cell. In insolation the appearances are strikingly different. In the early stages of degeneration the chromophilic plaques are divided into large and small segments, and in other places appear fused together in a confluent condition, and they show changes in form, having rounded ends or are oval or spherical, and are abnormally few in number. In other cells the chromophilic plaques show further disintegration, and have been converted into fine, dust-like particles strewn about over the cytoplasm, giving it a finely granular, almost homogeneous appearance. The outlines of these cells are much less distinct than normal. These appearances seem to be more often found in the anterior horns of the spinal cord, where the changes do not seem to have advanced so far as in the cerebral cortex and cerebellum. When the changes are further advanced the chromophilic plaques are not only converted into dust-like particles, but in some cells the particles have disappeared, giving to the cell body a pallid, shadowy outline. The changes in the nuclei may also be marked and radical. The nuclear membrane is uneven in outline, notched in places, and slightly crenated; the nuclear fluid is changed in consistence, so that it appropriates methylene-blue stain very freely. This is in distinct contrast to the normal. In some cells the nuclear contents appear homogeneous, while in others there is a fine granular content. In some cells the nucleus seems to have entirely disappeared. In none of the ganglion cells of the cerebral cortex, cerebellum, and spinal cord which have been examined, has there been any distinct evidence of destruction of the cells. There have been no vacuoles nor loss of substance in the cytoplasm. The cells preserved their form, with the exception of the various phases of dissolution of the chromophilic plaques. In the cerebral cortex these changes occurred in both motor and psychic cells.

The changes thus described are simply those produced by the operation of a great variety of poisons, as lead, alcohol, the microbic poisons, and auto-intoxications. It is therefore evident that a chemical reaction has occurred between the poison and the constituents of the cells. By the method of elimination and excluding other groups of poisons, these changes having been found in the nervous systems of patients in whom alcoholism can be positively excluded, it is justifiable to conclude that the lesions found in cases of insolation are from some kind of auto-intoxication. This toxic resolution of the ganglion cells may not necessarily go on to destruction of the cells.

Recently L. W. Sambon has brought forward the idea that sunstroke is due to microbic infection, basing his opinion on the fact that the cellular lesions cannot be distinguished from those of microbic infections, and upon the symptoms, relapses, its peculiar geographical distribution, epidemic outbreaks, condition of climate and soil under which it prevails, and the relative immunity by acclimatization. He has given the name of "*siriasis*" to this disease.

The explanations of these reasons, advanced by this author, do not seem to be sufficient to justify this opinion, and the history and circumstances under which the various epidemics have occurred point strongly against the microbic origin.

The changes in the cells of the other viscera also seem to be those of acute parenchymatous degeneration. These are especially noticeable in the liver and kidneys. The blood in sunstroke also undergoes certain marked changes. The number of red cells seems increased, but this is probably only apparently due to the condensation of the blood from loss of fluids through excessive sweating. The hæmoglobin in twelve cases gave from eighty-five to one hundred and twenty-five per cent., averaging one hundred per cent. The increase above the average normal was probably also due to blood condensation. There seems also to be destruction of the red cells, as the leucocytes are found to contain pigment. The pronounced anæmia following sunstroke also bears out the destruction of the red cells. These blood changes occur not only in patients who have suffered from hyperpyrexia, but also in those whose temperatures do not rise above 105° F. As the red cells do not disintegrate from heat until the temperature rises to 125–129° F., the destruction observed in insolation points definitely to some toxic elements in the blood. The blood serum of sun-stroke patients has also been shown to be exceedingly toxic to animals. Levene and Van Gieson found that 9 c.c. injected into the ear veins of rabbits killed the animals in less than an hour, normal human serum having no such effect.

The gases in the blood, however, seem to remain normal. Wood and other observers have reported that the alkalinity of the blood in individuals dying of sunstroke is greatly diminished, and in some instances the reaction is distinctly acid. Levene and Van Gieson have also found that the urotoxic coefficient was diminished in the urine of sunstroke patients, while it was increased in the urine of the same patients during the first twenty-four to forty-eight hours of recovery. This seems to point to failure of elimination of toxic substances during sunstroke. Arloing has found that the sweat during severe muscular exercise is two or three times more toxic than that of the same individuals at rest. When sweating ceases in sunstroke there would seem to be an accumulation of these toxic substances.

Based on the above lesions and experimental observations, the clinical symptoms of the various forms of sunstroke are more readily explained and understood than by the theory that heat alone within the body was the sole cause. The changes in the cytoplasm in the ganglion cells show the injury to the functional activity of the cell, while the changes in the nucleus show processes detrimental to cell life.

The prodromal symptoms of the severe forms of sunstroke are those of severe functional disturbance, while the later symptoms of the severe forms show a tendency to destruction of the neurons. Heat undoubtedly is the main contributing cause of sunstroke, as exposure to cold is of pneumonia. From whatever source the heat comes the action on the body is practicallly the same.

The even temperature of the normal body is maintained by the maintenance of the equilibrium between heat production and heat loss. Young persons with healthy eliminative organs will stand a high degree of temperature and long exposure to the effects of heat. Equilibrium is secured by the contraction and dilatation of the skin capillaries and increase and decrease of perspiration, with the consequent increase and diminution in radiation and conduction of heat over the body. There are also said to be nervous centres controlling the production of heat, but their exact location and action are not fully determined.

Heat is produced in the body by chemic metabolism constantly acting, especially during muscular exercise. Normally 2.6 per cent. of heat is lost from warming food and drink ingested; 2.6 per cent. by warming the inspired air; 14.7 per cent. by evaporation; and 80.1 per cent. by radiation and conduction through the skin.

Sunstroke occurs with greatest frequency among persons performing some form of bodily exercise in an intensely hot environment. The heat production of the body is thus at the maximum, while the heat loss from warming the inspired air is zero. The loss from radiation and conduction is also zero, the air being as warm as or warmer than the body. If sweating is excessive heat loss may be sufficient to maintain the equilibrium; but if sweating ceases, as it usually does in insolation, heat loss ceases and heat production continuing, the heat rapidly accumulates in the body, and thus an enormously high temperature is brought about.

Goldscheider and Flatau have shown that the neurons of the central nervous systems of animals whose temperatures have been artificially raised to 109.4° F. seem to show the same changes when stained by the Nissl method as those described above. The neurons of living animals whose temperatures have remained for three hours at 107–107.6° F. also began to show the same changes.

But when the animal had been previously killed and the temperature of the body raised to 112.3° F., the cells did not change. Heat alone, therefore, will not produce these changes, and the action must be one of chemical metabolism in the living cell protoplasm. In sunstroke patients at times die, the temperature never having gone above 106°. This temperature in other diseases of microbic origin is borne without causing death, hence the amount of heat *per se* in the body does not cause death in these cases of sunstroke.

Most authorities state that a temperature of 113° F. is necessarily fatal, but a patient suffering from sunstroke was admitted to the Presbyterian Hospital, in New York, with a temperature of 115° F., and recovered. The limit of temperature which can be borne by the body with recovery can, therefore, not be definitely stated. In infectious diseases it is the lesion produced by the causal agent and not the temperature which kills; in sunstroke it is the metabolic changes in the central neurons and not the heat.

As to the definite cause of death in sunstroke, many theories have been advanced. Sudden coagulation of the cardiac muscle due to heat does not seem a tenable theory. While it is true that on the battlefield men have been known to drop from sunstroke and become rigid, dying almost instantly, heat coagulation of the heart muscle does not occur below a temperature of 122° F. or higher, while many patients die long before such a temperature is even approached, and the highest temperature ever recorded in sunstroke is 117.8° F. Death is also not due to lack of conduction in the nerve fibres, as these do not lose their power of conduction to impulses until a temperature of 125.6° F. is reached. It would therefore seem to be due to some toxic action on the cardiac and respiratory centres at whatever temperature this action may occur. In the most accurately recorded experiments on animals respiration ceased before the heart. Clinically there seems to be simultaneous failure of heart and respiration, but at times first one ceases, then the other. As will be seen later, the prodromal symptoms of insolation are those of disturbance of the digestive tract and liver. Food is badly assimilated, there is indigestion in the stomach and in the intestines, and sometimes slight jaundice. Abnormal substances are thus produced in the digestive tract and liver. This causes headache and malaise. When severe muscular exercise adds its decomposition products to the circulation and at the unusual high temperature of the blood, abnormal chemic changes may take place.

The milder forms of sunstroke known as heat prostration, or exhaustion, are therefore due to a mild form of auto-intoxication, and are but the prodromal period of the severe forms, the neurons being but functionally disturbed. If the intoxication is more severe, syncope and unconsciousness occur. Heat loss due to great dilatation of the skin capillaries is sufficient to prevent accumulation of heat. Heat loss may be so pronounced and predominate over heat production that lessening of temperature may occur. When the intoxication is very severe unconsciousness may develop suddenly with or without prodromal symptoms, and the vaso-motor, cardiac, and respiratory centres are affected. Heat loss being abolished, and heat production and accumulation being at a maximum, an enormously high temperature is developed. The neurons are so severely poisoned that their functions are abolished and convulsions, delirium, coma, and death supervene.

Symptoms.—The mildest form of sunstroke is heat prostration or exhaustion. An unusual weakness following exertion in hot weather most often seen in feeble persons is probably the mildest form that occurs. In more vigorous individuals the symptoms of this form are more pronounced. Exhaustion may come on suddenly without prodromal symptoms, or there may be prodromal symptoms followed by complete exhaustion. There are usually headache, dizziness, pain in the back and legs and epigastrium, with sometimes tingling of the hands and feet. These symptoms may continue for a few hours or for three or four days, and are sometimes accompanied by anorexia, nausea, and vomiting, or there may be diarrhœa or constipation. Some patients show slight jaundice of the whites of the eyes. Uncommonly in this form of sunstroke perspiration may cease. While the patients are suffering from the prodromal symptoms they may be able to sleep and awake refreshed, but as soon as they attempt to go about their usual occupations after a varying length of time the prostration becomes so extreme that they are forced to give in to it. The headache is intense, either frontal or occipital, and the patient seems dazed; consciousness is retained. The respirations are slightly different from normal, 24 to 28 per minute. The pulse may remain normal in frequency, or, depending upon the intensity of the exhaustion, it not infrequently runs as high as 130 to 140 per minute. It is, however, of good force and tension. The temperature may be normal or even slightly subnormal, though as a rule there is a rise and the temperature may reach 104.8° F. Under proper treatment the temperature may become normal in a few hours, the other symptoms abate, and the patient rapidly recovers, or the symptoms may continue and there may be a slight thermic fever for two or three days, even a week, the temperature ranging from 99° to 103° F., gradually falling to normal. Cases have been observed in which a slightly elevated temperature has been maintained for fifteen days.

In moderately severe cases there is always loss of consciousness, but the temperature does not reach the hyperpyrexial level of 105° F. The same prodromal symptoms may be present as in the mild form, and at other times there is an intense feeling of burning and heat and "pins and needles" in the head. Sometimes there are alternating hot and cold flashes over the body with sweating. Vomiting and anorexia are often severe. Perspiration may cease a short time before unconsciousness occurs. Just before loss of consciousness there are noticed in some patients sudden dizziness and dyspnœa, sometimes with chromatopsia. In other patients there is no premonition of the attack.

These symptoms may occur while the patients are at work or they may be suddenly overcome while quietly walking in the street at night. Suicidal tendency is sometimes developed just prior to loss of consciousness; sailors have been known to try to throw themselves overboard, soldiers to attempt suicide with their rifles. This temporary mental aberration may continue for a week or two, and then be followed by complete recovery. In some cases of this class there are, with the loss of consciousness, symptoms of complete collapse. Wood reports a case with a temperature of 95° in the mouth. Temperatures of 96–97° are not uncommon. The majority of these patients, however, show a rise of temperature between 101–104°. Except in cases of collapse the pulse is full and of good force and tension, though it may be as high as 130 per minute. Respirations may be normal or as frequent as 40 a minute, being usually shallow, the stertorous breathing of the severer forms is not present.

Physical examination will show coated tongue, skin hot and dry or covered with profuse sweat, and the patient may be conscious or totally or partially unconscious. The pupils react to light slowly and are sometimes dilated. Slight convulsive movements may be present, or there may be a restless delirium with moaning and groaning. Not infrequently there is a peculiar dark-pink, petechial rash on the body, different from the ordinary prickly-heat rash.

The changes in the blood enumerated above occur in this form of sunstroke as well as in the hyperpyrexial form. Unconsciousness, delirium, and other symptoms may persist for a few hours after the cold bath; sometimes consciousness is not regained for twenty-four hours.

Thermic fever when present persists for several days or a week. Patients usually recover from this form of sunstroke. This degree of insolation seems to be the least common. In two hundred and twenty-four cases of different types of sunstroke coming under the writer's notice in Bellevue Hospital in 1896, there were but eighteen of this type.

The severest form of insolation is the hyperpyrexial type. In this class are included all patients whose temperature rises to 105° F. and over, with or without loss of consciousness. The prodromal symptoms when present are often more pronounced than in the lighter cases, though many cases of this severe form of sunstroke have no prodromal symptoms at all. Patients whose temperature rises above 108° are less likely to have prodromal symptoms than those in whom the temperature is not so high. The worst attacks of sunstroke, therefore, may apparently occur without warning. The same prodromal symptoms are often present as in the milder forms. Insomnia, however, is marked, and may be present four or five days before the attack culminates. There are often great irritability and restlessness and sometimes decided increase in micturition for several days. A feeling of intense heat throughout the body, with the sensation as if the head were bursting open and the eyes bulging outward, is often noticed just before loss of consciousness. Chromatopsia is not uncommon, external objects taking on different colors, blue being the most common, or the field of vision may be occupied by brilliantly colored flames. In other patients objects suddenly lose color and appear black. Previous to loss of consciousness there are sometimes hallucinations of hearing or sight. Suicidal mania may also develop. Some patients are able to continue work which requires intelligent action and perform complex acts working with machinery, or may leave work and go home, undress, bathe, and go on the street again before falling helplessly inert, and yet after consciousness is regained retain no memory of what they had done for several hours previous to the time when they were seen to fall. When consciousness is retained the patients suffer intensely with burning heat and intense headache, and may become stupid and dazed. Retention of consciousness in these severe forms of sunstroke is the exception. In patients with a temperature above 109° I have never seen consciousness retained. Most patients are comatose. The skin is dry, flushed, and hot; or it is livid, pale, and cyanotic, and covered with cold, clammy perspiration. The glazed, set eyes are suffused and half open, or may be wide open and staring. The pupils are at times normal, or may be dilated or contracted unevenly. They may or may not react to light. Respirations come in short gasps, often irregularly, with a noisy, gasping inspiration and quiet expiration, or with explosive expiration and quiet inspiration, often accompanied with a piteous moan. Some cyanotic patients lie absolutely limp and flaccid, not moving even an eyelid, while in others there may be convulsive twitchings or violent epileptiform convulsions. Other patients with dry, hot skin are wildly delirious and fight and struggle furiously. In the limp patients the pulse is usually soft and frequent or small. In the more sthenic cases it may be full, strong, with throbbing carotids. The worst cases are pulseless. Vomiting and involuntary defecation are very common. The urine is scant, sometimes albuminous, sometimes containing blood. The peculiar petechial rash is often present, being most abundant upon the arms and body.

These sunstroke patients emit a peculiar, characteristic, disagreeable odor, particularly strong in the fæces, though it is distinctly not a fæcal odor.

The cyanotic type of sunstroke occurs more often with temperatures above 109° F. than below this figure. The height to which the temperature can go is unknown. The highest reported temperature is 117.8°, in a patient brought to the New York Hospital in 1896. Another patient in the Presbyterian Hospital, New York, had a temperature of 115°. These temperatures were measured with special thermometers. Temperatures of from 112 to 113° are not uncommon, and those of 108–110° are exceedingly common.

There is no exact ratio between the frequency of the pulse and the height of the temperature in these severe forms of sunstroke. With a temperature of 110° the pulse may vary from 90–150. The same is true when the temperature is 105–106°. The number of respirations per minute may vary from 16 to 50, irrespective of the temperatures.

In the most severe cases death rarely occurs immediately, but is delayed for a few hours. It has been stated that when the temperature is reduced the patient is out of danger, although the elevation of temperature may persist for some days. This is by no means true. While it is true that consciousness returns in about half the cases within an hour after the reduction of the temperature to normal, and when once regained it is retained, others do not regain consciousness until after two or more baths are given to reduce the continually recurrent rise of temperature, and many patients may remain unconscious for twenty-four hours or even as long as ten days and yet recover. In the worst cases, even after the temperature has fallen, the patients do not react but die within twenty-four hours; some, however, will live longer and die without regaining consciousness at the end of a few days. Others, after they have regained consciousness and are apparently doing well, at the expiration of a few hours or one or two days may develop delirium and remain delirious for a few days or a week and recover, or they may die during the second period of delirium.

Patients with a temperature of 105–107° frequently recover without thermic fever or any secondary rise of temperature. This exceptionally occurs when the initial temperature has been 107–110°. With temperatures above 110° there are one or more secondary rises of temperature which usually require active interference, or there is a continued fever for some time.

The secondary rises of temperature are apt to occur from three to six hours after the temperature has been reduced, sometimes not until from twelve to eighteen hours after the first bath. In serious cases the secondary rise may come on within an hour. It is not uncommon to find these secondary rises occurring eight, twenty-four, or thirty-six hours after the first bath. Some patients may have as many as four or five or even more exacerbations of temperature requiring active treatment. It is not uncommon to have thermic fever lasting for several days or one or two weeks, the temperature ranging between 101 and 103° F.

In severe cases after the bath the pulse remains feeble and soft and frequent. In favorable cases it drops more slowly to normal than the temperature. Among markedly alcoholic patients there is an asthenic course of the disease requiring special mention. The initial temperatures in these cases which have come under the writer's notice have varied between 106 and 109°, and the patients were strong, well-nourished individuals. They reacted well after their baths and became conscious within four hours, remaining rational for twenty-four hours; they then became wildly delirious or sank into the low muttering form. Their skin became dry and harsh, there was incontinence of urine and fæces. During the wild delirium their temperatures rose, frequently equalling in height the initial temperature, with a pulse of 120–150. In the low stage of the delirium the temperature did not rise above 102°, with a pulse of 80–100. In some patients just before death there was an ante-mortem rise of temperature to 106–110°. These patients died within *from three to eighteen* days after the sunstroke.

The convulsions mentioned as occurring in severe cases are not dependent upon the height of the temperature. They occur with temperatures of 105–106°, as well as with those of 108–112°, though they are more frequent with the higher temperatures; and since they seem to depend on the toxic destruction of the central ganglion cells, they are always of serious import though by no means fatal. They may be of a general epileptiform type, or they may be confined to the head, neck, arms, and legs. They may be more severe on one side of the body than on the other and rarely are distinctly unilateral.

While they may occur with the acme of temperature, they may not develop until some hours after the temperature has fallen. When the patient is in convulsion before the first bath the convulsions are apt to continue for some time afterward, though they may cease when the temperature becomes normal. Sometimes a second bath of a few minutes will cause them to cease. After they have disappeared and the patient has been rational for hours, or even one or two days, convulsions may suddenly recur and the patient may die in one. This is not uncommon. Muscular twitchings which do not develop into the convulsions are exceedingly common. An intense rigidity of the muscles similar to tetanic spasms is of quite common occurrence. This usually relaxes as the patient sleeps. These spasms may involve the respiratory muscles, and when they come on suddenly there is great danger of suffocation. The rigidity is often so great that artificial respiration is impossible.

The skin, in these cases of hyperpyrexia, often becomes dry and harsh during the week after the sunstroke, and desquamation may occur, the skin pealing off in large scales or flakes. Ecchymoses which occur in patients from bruising during the delirium are much more extensive than those occurring from ordinary bruises, and hypodermic injections of any substance are not infrequently followed by large ecchymoses which may go on to suppuration.

Complications.—Meningitis and encephalitis are not uncommon complications of sunstroke. Delusional insanity, with ideas of persecution and hallucinations of various kinds, are frequently observed. Pneumonia sometimes develops and is usually fatal. Fayer mentions that cerebral hemorrhage may follow sunstroke. Patients with chronic nephritis are very apt to have acute exacerbations of the nephritis and develop acute uræmia.

The sequelæ of sunstroke, even after the mildest forms, are often very pronounced. Not infrequently headache, extreme weakness, malaise, and dizziness are persistent. There may be soreness in the muscles and bones, with numbness and tingling of the hands and feet. This tingling may last for days or weeks, or even months. Anæmia is usually very noticeable. Polyuria, glycosuria, or diabetes mellitus may develop shortly after sunstroke and be permanent. Chronic meningitis with intense headache and stiffening of the cervical muscles or encephalitis with inco-ordination of the extremities, so that the patients may be unable to feed themselves, have all been seen following sunstroke. The nervous and mental conditions may develop into permanent dementia. Various forms of insanity, such as paresis or mania or delusional insanity, are recorded. Multiple neuritis may develop. Sometimes atrophy of a certain group of muscles, as, for instance, the flexor muscles of the forearm, may occur. Patients may develop a change of disposition, and from good-natured change to an ugly irritable disposition. Sensitiveness to heat, dizziness, and headache are probably the most common sequelæ. Chromatopsia on hot days may occur. Epilepsy may arise, and when previously present the fits occur with increasing frequency. Loss of memory and inability to concentrate the mind forces some patients to give up their work.

DIAGNOSIS.—Heat exhaustion may be confounded with internal hemorrhage, cardiac failure, and alcoholism. The intense headache of which the patient complains will aid in diagnosticating heat prostration. The moderately severe forms of insolation, especially with subnormal temperatures, restless delirium, and collapse, must be differentiated from internal hemorrhage and cardiac failure. The intensity of the delirium and twitching of the muscles will aid in recognizing the condition.

When unconsciousness is present the diagnosis from apoplexy, with its slow, full pulse, stertorous breathing, normal temperature, and local paralysis, can easily be made. In sunstroke we have a soft, frequent pulse, shallow breathing, and rise of temperature, and often hot, dry, flushed skin and absence of local paralysis.

The hyperpyrexial form may be confounded with meningitis, typhoid fever, and abscess of the brain with extremely high temperature. The usual excessive height of the temperature with the peculiar respirations, convulsive movements or intense convulsions, or the absolute immobility of the patient and the cool, clammy skin and high temperature, with the history of previous environment, should render the diagnosis easy.

PROGNOSIS.—The prognosis of heat prostration is universally good. In the moderately severe forms of sunstroke it is also good. The prognosis of the severe forms depends on the previous habits and condition of the patient. In alcoholics and those weakened by disease the prognosis is worse than in those of abstemious habits. The height of the temperature usually serves as a good criterion. When the temperature reaches 111° F. or over, the prognosis is very unfavorable, though by no means hopeless. With a temperature between 110–111°, if proper treatment can be appled quickly, about 50 per cent. recover. If proper treatment is not applied, very few recover with a temperature above 108°. Temperatures between 108 and 110° under good treatment have 75 per cent. of recoveries. With temperatures of 105–108° about 90 per cent. recover. These statistics are based on the death rate in 1896 among 520 hyperpyrexial cases. The death rate in those treated by hydrotherapy in various ways was 25.12 per cent. In 805 cases of all forms the mortality was 16.39 per cent. The mortality is usually given as from 41 to 50 per cent. In 961 cases reported in Aiken's "System of Medicine," the mortality was given as from 56 to 62 per cent.

The mortality in sunstroke depends greatly upon the rapidity with which treatment is instituted and also on the kind of treatment employed.

TREATMENT.—In the milder forms of prostration, if the patient is overcome in the sun, he should be immediately taken into the shade and if possible to a cooler place. The clothing should be loosened and the head bathed with cold water. If possible, ice should be applied to the head; this gives great relief to the throbbing headache. Aromatic spirits of ammonia, Hoffman's anodyne, or liquor ammonii acetatis should be given for stimulation. A little alcohol, such as a small dose of whiskey, is sometimes of benefit, though it is by no means as good as the other forms of stimulants mentioned. Iced tea and coffee are also excellent remedies here. Sipping very cold water will also revive a patient overcome with a feeling of faintness. Some of the coal-tar products are also valuable here to relieve the headache, such as phenacetin, in gr. v. doses; antipyrin, gr. x. to xv.; antifebrin, gr. iv.; and ammonol, gr. v. to x. If these can be mixed with a little sodium bicarbonate or caffeine they are excellent. The patient should rest, preferably in bed, for some hours until the feelings of faintness and dizziness have passed; he can then be allowed to go about as usual, being careful not to overexert himself and taking especial care to eat only easily digestible foods.

In the moderately severe forms, when collapse and subnormal temperature occur, the patient should be covered with blankets and hot-water bottles packed around the outside. The same stimulants may be given, and if the patient is unconscious hypodermic medication is necessary, gr. $\frac{1}{30}$ to $\frac{1}{60}$ of strychnine, gr. $\frac{1}{100}$ of glonoin, gtt. i. to ij. of fluid extract of digitalis, or gr. i. to ij. of a mixture containing ten per cent. camphor and ether can be administered. If the temperature is 103–104° and the patient is unconscious with convulsive twitchings, he should be placed in a cold pack, as a sheet wrung out of cold water, or put in a cold bath and vigorously rubbed for a few minutes, then dried and covered with blankets. If the temperature is not above 107° and is not relieved quickly, sometimes an enema of ice water acts with great benefit. One or two quarts of ice water, in which salt has been dissolved (one teaspoonful to the pint), will often, when used as an enema, bring the temperature down within an hour. But this ice-water enema will not control a rising curve of temperature. Headache in these cases can be controlled by the coal-tar products, which also aid in reducing the temperature, and by the ice cap.

The hyperpyrexial cases demand the most active and immediate treatment. Various forms of cold baths have been used. An ice bath consists of a tub of water in which about half a bushel of cracked ice is floating. Just before the patient is lowered into the bath the ice should be removed, as sometimes the sudden contact with the ice causes intense rigidity of the patient which brings on suffocation. This is rare, but it does occur; therefore the ice should be taken out of the bath before the patient is put in, but if the patient is put in ordinary tap water and rubbed a few moments, the ice can be placed in the bath while the patient is in it. During his stay in the bath the patient should be rubbed vigorously with rough mittens or the bare hand; sponges do not afford sufficient irritation; and as long as the patient is in the bath the rubbing should not cease. His head should be supported and cold water continually poured upon it. A towel folded over the forehead will prevent the water running into his eyes. Such a bath in a few minutes will cause the cyanotic skin of the patient to appear flushed and rosy; an unconscious patient may come to in the bath and the temperature will quickly fall toward normal. A thermometer should be constantly kept in the rectum of the patient in the bath, and the temperature should not be allowed to fall below 103° F. When this is reached the patient should be quickly taken from the water, rubbed dry, and covered up warmly. Hypodermic stimulation will be required in these patients. The ordinary results of this stimulation do not seem to be observed while the temperature remains excessively high. This should be remembered, as over-stimulation can easily be brought about, and this will occur when the temperature falls to a point near normal. For cardiac stimulation a dose of morphine, gr. $\frac{1}{8}$ to $\frac{1}{4}$, with gr. $\frac{1}{250}$ atropine, will be most beneficial. It diminishes the convulsions which are apt to follow and produces a sleep from which the patient wakes refreshed. Strychnine increases the tendency to convulsions, although it does not cause all the convulsions following sunstroke, as has been stated. Convulsions will occur in patients who have never had strychnine, but they do not appear so frequently as when strychnine has been used.

The length of time necessary for the reduction of temperature by these cold baths cannot be stated. It depends upon the amount of heat being produced, and not at all upon the height to which the temperature has gone. It may take twenty minutes to reduce a temperature from 106° to 103°, while a temperature of 110° may drop to 103° in five minutes.

Another method of reducing temperature is to place the patient on a rubber sheet and rub with ice. This takes much longer, and it only allows friction of the upper surface of the body and it does not reduce temperature so quickly or so effectively.

Still another method is to place the patient on a cot on a rubber sheet and throw dipperfuls of cold water over him from a distance of several feet. The impact of the water causes the necessary friction, and it is not an ineffective method. While it takes longer to reduce temperature, the reactions following it are not so marked as in the case of the ice bath, and when ice cannot be obtained it is the quickest substitute. While the water is being dashed over the body of the patient, cold water should be poured upon the middle of his forehead from a pitcher held six or eight feet above his head; this is most beneficial in bringing the patient back to consciousness. A very excellent method, perhaps the best, is to place the patient in a tub or on a cot or simply lay him on the floor and play a hose on him through a fine needle-spray nozzle. Where the head of water is sufficiently strong this is a most excellent method. It causes the physical irritation to the skin which is so essential to overcome the stasis in the capillaries. This stasis, according to Winternitz, prevents ninety-four per cent. of radiation of heat from the skin.

Patients treated in this manner should be allowed to have their temperatures fall to 102° or 101°; then they should be taken up, dried, blanketed, and put to bed. In severe cases the reaction following this method does not seem to be so intense as with the ice baths, nor so apt to fall below the normal. When the reaction occurs and the temperature goes to 105° the treatment should be repeated; an ordinary tub bath at 65° will sometimes control it. Warm baths have not proved so successful as the cold ones for reducing the temperature.

No treatment seems to prevent the thermic fever. A useful method of controlling this fever is to place small bladders filled with ice in the axillæ and groins; this seems more effective in women than in men.

After the patients are in bed, liquor ammonii acetatis is a most excellent stimulant and produces both diaphoresis and diuresis. Digitalis, ether, and spirits of ammonia are also excellent for rapid stimulation.

Among alcoholics the question arises as to the desirability of giving alcohol. When delirium tremens seems about to develop, as it so often does, a mixture of half an ounce of whiskey with one or two drachms of paraldehyde, repeated in an hour if necessary, will often produce sleep from which the patient will wake much improved.

It is best for twenty-four or forty-eight hours to keep the patient on milk, or at least fluid diet, followed by eggs, cereals, milk, and broth. Where there is severe thirst an abundance of water can be given. The liquor ammonii acetatis is useful in this connection to allay thirst. The sequelæ or complications of sunstroke should be treated as the same diseases under ordinary circumstances. The nervousness, weakness, and loss of appetite can be overcome by a mixture of tincture of nux vomica and compound tincture of cinchona, five to ten drops each, in compound tincture of gentian as a menstruum. For alcoholics, one or two drops of capsicum and sometimes ginger can be added to this mixture. Meningitis following sunstroke may have to be treated by a merciless use of the actual cautery. Patients suffering from sunstroke in the tropics may have to go to a more temperate climate or they may become helpless invalids. Such patients may develop some form of insanity, and it is well to remember the possibility of suicidal tendencies and never allow them to travel alone. The anæmia and general lack of nerve force following sunstroke can often be treated with cod-liver oil and small doses of tincture of iron. Of the latter, three drops should be put in a tumblerful of water and sipped with meals. This does not derange digestion and is preferable to large doses. Blaud pills or any other form of iron may be used.

The numbness and tingling so often complained of can often be benefited by the Charcot douche to the spine.

It is remarkable how long the sequelæ of sun-stroke may persist, and they are often discouraging to deal with. It is often years before exposure to heat can be withstood without recurrent headache and prostration.

Alexander Lambert.

HEAT, THERAPEUTICS OF.—Although heat has always been recognized as one of the most valuable therapeutic agents, it has never been so widely used as at the present time. It is one of the safest and simplest remedies known. Its good effects are varied and the methods of applying it are numerous. The results of the therapeutic use of heat are dependent upon various conditions, chief among which are the manner of its application and the temperature used. A far higher temperature can be borne when the heat is dry than when it is moist. For example, hot water becomes painful at 115° F. Steam or vapor cannot be borne above 120°, while hot dry air can be used at a temperature of 300° and higher. The vaso-dilator nerves are stimulated by heat, while the vaso-constrictors are inhibited.* The cutaneous capillaries are

---

* This statement demands proper modification to express the facts as they appear. These are given in somewhat detailed manner in Armstrong's article on Baths in Foster's "Practical Therapeutics," and it is from this source that I have derived the information which is furnished in the following explanation:

In order that heat shall simultaneously cause stimulation of the dilated by a slow application of heat, but if the application is sudden the primary effect corresponds to that of cold, the skin is blanched and even wrinkled.

When the cutaneous capillaries are dilated the skin becomes reddened, and if the temperature is not higher than 104° F. cutaneous sensibility is increased. When, however, the temperature is increased to between 110° and 120°, sensibility is diminished or even abolished.

The nervous system is soothed by a moderate degree of heat, but untoward effects such as headache and vertigo are caused by a high degree if the air is not dry. The nerves to the sweat glands are excited by the application of heat, consequently the functional activity of these glands is increased and abundant perspiration is the result. The secretion of urine is proportionally decreased. The difference in the effects of dry and moist heat upon the perspiratory function depends upon the following facts. The body absorbs less heat from air than from water, and the skin perspires more freely in air than in water—the evaporation of the perspiration abstracting the heat—so that it is clear why it is possible to bear a higher degree of dry than of moist heat. The number of respirations is decreased by dry heat, but increased by a high degree of moist heat.

Although muscular activity is favored by a moderate degree of heat, a high temperature is depressing, and under its influence the muscular system becomes less able to support fatigue, especially if this is continued. A practical application of this fact is made in the treatment of the various muscular spasms, including chorea.

The effects of a hot climate depend upon the individual concerned and upon the various conditions of his life, such as diet, etc. It has been frequently noticed that debilitated persons are stimulated by a hot climate, becoming stronger and more able to ward off disease. Normal individuals are depressed, the effects being quickly seen in all of the functions of the body. In a temperature higher than that of the human body, body weight is diminished and in proportion to the degree of heat and the length of time of its application. This effect is less in dry heat than in moist heat. Hot applications to the abdomen cause constipation. This may be from two factors: from the decrease in intestinal secretions or from the decrease in peristaltic action of the intestinal musculature. Heat hastens eruptions.

There are many methods of applying heat, some of the appliances being as follows: bricks, water-bags, flat-irons, sand bags, Leiter's coils, and Paquelin's thermo-electric cautery. Moist heat may be applied by means of baths, both water and steam; douches, fomentations, and poultices; besides all of these methods there is the hot-air bath. The use of the hot flat-iron in such troubles as rheumatism gives astonishing results. The effects seem often magical, the relief afforded by this homely household remedy being greater than by many of the methods which are in more general use. The affected part should be protected by several layers of flannel, and in applying the iron it should be held carefully so that the weight is supported by the hand of the operator while the patient obtains the full benefit of the heat. The Paquelin cautery offers one of the best ways of applying counter-irritation. The hot bath produces various effects on the organism: by it the absorption of oxygen as well as the exhalation of carbonic acid is decreased; oxyhæmoglobin is reduced; so are the leucocytes; the excretion of nitrogenous products is increased. By means of hot baths interstitial combustion is diminished. In Bright's disease hot baths, on account of their weakening effect if often repeated, should not be employed unless dropsy or uræmia is present. When uræmia exists, however, the cerebral symptoms are often entirely relieved by the hot-water or vapor bath, for by this means not only the skin acts freely, but the effect on the whole organism is sedative, pain and irritability being allayed. Especially in childhood, various affections of the respiratory tract, such as bronchial catarrh, are relieved by this treatment. The sedative effect brings sleep and makes breathing less labored. The affected membranes are relieved of the surplus of blood, which is drawn to the periphery. The patient must be carefully watched and not be allowed to become weak from the treatment, as the secondary effects of a too long-continued hot bath are debilitating. However, continuous baths of moderate temperature are used in some affections, such as sloughing wounds and eczema; the patient eats and sleeps in the bath with the greatest comfort. For many years Kaposi, of Vienna, has employed the continuous bath in his wards with great success. Inhalation of warm vapor greatly relieves laryngismus stridulus. Diabetics should bathe in water of only a moderate temperature, and the bath must not be too long continued since this treatment may cause or increase glycosuria. One of the best methods of treating a strained joint, if seen early, is by the hot baths. Burns and phagedæna are much benefited by this method of treatment. Hot baths relieve the various forms of abdominal colic, as renal and hepatic; also inflammation of the urinary apparatus. In dysmenorrhœa, the hot foot bath is valuable. Heat applied to various regions of the spinal cord affects the organs which these nerves supply. This method is often successful in the treatment of metrorrhagia and menorrhagia. The Turkish and Russian baths are well known for their good effects in the treatment of many affections, such as coryza, gout, rheumatism, etc. But recently various new devices have been introduced by means of which the patient may be exposed with comfort to the beneficial effects of an extremely high temperature, for example 350° F., because the air is kept dry. Before apparatus was devised by means of which the air could be kept dry, the evaporated perspiration gradually rendered the surrounding atmosphere moist, and the perspiration on the skin actually scalded it. On this account the Turkish bath cannot practically be higher than about 170° F. The diseases that have of late years been treated with benefit by the new apparatus are the arthritic diseases—rheumatic arthritis, gout, rheumatism, etc.; joint affections, such as sprains; affections of the nerves, as neuralgia, sciatica, etc.; certain skin diseases; chronic ulcers, and flat foot.

There is other apparatus by means of which the body is subjected to the action of radiant heat. The diaphoretic effects of combined heat and light are said to be much greater than the same degree of non-luminous heat. The effect of the electric heat waves is invigorating and tonic. One result of these exposures to extremely high temperatures, one that is contradictory to former physiological teaching, is that the body temperature is raised several degrees. The following suggestion has been made in explanation of cases in which certain parts of the body are exposed to the heat: "It is probably due to imperfectly co-ordinated diaphoresis in parts of the body other than that exposed to the direct heat of the bath—that is to say, the blood as it flows through the heated area is not completely cooled down before it passes on to other areas, where the conditions are different, and where reflex, superficial, vascular dilatation, and consequent diaphoresis, are not correspondingly established." In the application of these new methods just mentioned, the apparatus is so arranged that the head of the patient remains free in the normal room temperature. Besides great local benefit, the general health is improved by these hot baths. In the radiant-heat bath the perspiration, as soon as it appears, is evaporated by the hot dry air. If this heat is applied locally, the circulation of the

---

vaso-dilator nerves and inhibition of the vaso-constrictors the temperature employed must not be above 104° F., for it must be remembered that it is a *moderate* degree of heat that stimulates the vaso-dilator nerves and inhibits the vaso-constrictors. The cutaneous sensibility is increased and the skin is reddened. When the temperature is increased from 110° to 120° F., sensibility is abolished or decreased. It is from the knowledge of this fact that certain diseases of the nervous system are treated by the application of great heat. The effects also vary according to whether the application is slow or sudden. In the first instance the capillaries are dilated; in the latter the vessels of the skin are contracted and the skin becomes pale as in the application of cold. This fact is taken advantage of in bathing, where *very* hot water applied for a very short space of time stimulates the cutaneous nerves but does not call for the same vigorous reaction as a cold bath demands.

part treated is increased and not only is extra nutrition supplied, but a greater amount of blood is carried away from the part; and it is probable that this blood takes away from the diseased area many morbid products in solution. When radiant heat is produced by electricity, the advantages can be clearly seen, as there is no combustion and the patient breathes perfectly pure air. Among the affections treated with benefit by this method are the following: rheumatoid arthritis, gout, chronic cramp, sciatica, fixed joints, inflammation of the veins, adhesions following fracture, chronic articular rheumatism, chronic alcoholism, rheumatic gout, stiffness following injury, gonorrhœal rheumatism, vaso-motor disease, epilepsy, chronic Bright's disease, asthma, bronchitis, strumous ulcers, fracture, spinal disease, chorea, and peripheral neuritis. The general effect of the radiant-heat and light bath is soothing, as it allays pain and imparts a feeling of well-being.

The douche is used chiefly in gynæcological, nasal, and aural troubles. For pelvic inflammations and congestion the hot douche is most valuable. The good effects are dependent upon the temperature used, and upon the length and the manner of application. The temperature of the irrigating fluid should be as hot as can be borne. The application should continue for at least twenty minutes and the patient should lie on the back with the hips elevated.

By fomentation or cataplasm is meant the application of cloths wet with whatever liquid is used and applied to the part. The heat may be maintained either by renewing the cloths or by applying a hot object, such as a water bag or a brick to the cloths.

Poultices are not used now nearly so extensively as they were formerly. If they remain on the part too long they will lower the vitality and produce vesication or pustulation.

Heat has many specific uses, some of the principal being as cardiac stimulant, counter-irritant, diaphoretic, general sedative, general stimulant, germicide, hæmostatic, hypnotic, local anæsthetic, and local sedative.

Some of these effects have already been touched upon. As a cardiac stimulant heat is used universally in cases of shock and collapse, in drowning, exhaustion, asphyxia or debility of the new-born, narcotic and other forms of poisoning, in chilling if the patient is not frozen, and in any condition of heart failure. It may be applied in the form of baths, enemata, drinks, cloths, bags, bricks, friction, etc. In the algid state of cholera, for example, it must be remembered that clothing does not supply heat, it simply prevents its dissipation, so that special measures should be taken to impart heat to the body, as surrounding it with hot-water bags and the like. Death from chloroform anæsthesia is nearly always in consequence of heart failure. In such a case hot applications should be made to the cardiac region. External heat draws the blood to the periphery and thus relieves the heart.

As counter-irritant, it promotes absorption and hastens repair; it also removes passive congestion. In this connection it is often applied in the form of the actual cautery. This treatment is more valuable in chronic than in acute inflammation. It is sometimes indicated in deep-seated inflammation of the joints. The superficial layers of the skin only should be irritated. The cautery should be brushed over the part lightly, and be used at a white heat when vigorous counter-irritation is desired, but at a cherry-red heat for hemorrhage. The relief from its use is often as great as it is sudden. It is indicated in neuralgia and rheumatism. Its action may be reflex through the nerves, producing a change in the nutrition of the part, with promotion of absorption.

The value of heat as a diaphoretic has already been spoken of.

It is a good general and local sedative. It draws the blood away from the great vessels to the periphery, dilating the vessels of this region and producing a feeling of general comfort. It is also used in the treatment of neuroses. Hot applications to the face in toothache are very soothing. This treatment also relieves itching.

Its general stimulating effects have been spoken of.

Heat is the most trustworthy germicide that we have. It may be used in the form of fire, dry heat, boiling, streaming or live steam, and steam under pressure. Fire is used only to destroy articles. All pathogenic organisms and their spores are destroyed in boiling water in five minutes. Streaming or live steam is utilized in the ordinary sterilizer or disinfector. Steam under pressure is used to disinfect bulky objects such as bales of goods.

Heat is used as a hæmostatic in the form of the actual cautery or of water raised to the temperature of 120° to 140° F. If the bleeding surface is large, the oozing should first be treated by compression with hot cloths to stop the capillary hemorrhage before the cautery is applied. The clamp and cautery method of treating hemorrhoids is well known.

Heat is hypnotic, hot baths being very beneficial in acute and chronic insomnia.

A high degree of heat may be used as a local anæsthetic, since it has the faculty of blunting the perception of different kinds of sensation at certain temperatures, as mentioned before.

Although the uses of heat are at present so varied and valuable, this field is probably yet but in its infancy, as new discoveries and improvements are constantly being made in this department of therapeutics.

Emma E. Walker.

HEDONAL, methyl-propyl-carbinol urethane, occurs as a white, crystalline powder insoluble in cold water, slightly soluble in warm water, and somewhat more so in alcohol. It has a persistent, rather unpleasant taste suggesting mint, and on boiling with an alkali decomposes, forming ammonia, carbon dioxide, and methyl-propyl-carbinol. There are many reports on the hypnotic properties of this substance, Goldmann, Nawrateski, Arndt, and others claiming for it valuable powers without any undesirable after-effects. Brownrigg, also Schüler, found it a feeble hypnotic, useful only in cases of moderate nervous irritability. In nine of Brownrigg's thirty-five cases, and in five of Schüler's twenty-one, no sleep resulted from its administration. Raimann found the lethal dose in a series of animals to be 1 gm. per kilogram of body weight. Moderately large doses were followed by depression of circulation, respiration, and temperature. Nawrateski and Arndt point out that the drug is so diuretic that it may cause such a desire to urinate as to arouse the patient. All things considered, this drug is of less value than its congener, ethyl-urethane. The dose is from 1 to 3 gm. (gr. xv.–xlv.) given dry on the tongue and washed down with aromatic water, or given in syrup, in capsule, or in cachet.

W. A. Bastedo.

HEILBRONN MINERAL SPRINGS.—Bradford County, Florida.

Post-Office.—Starke. Hotels and boarding-houses in Starke.

Access.—Viâ the main line of the fifth division of Seaboard Air-Line Railroad, forty-five miles from Jacksonville. Also viâ Suwannee River Division of the same system. Starke, the county seat of Bradford County, is located on the elevated backbone of the Florida peninsula at an elevation of 180 feet above the ocean level. The location is surrounded on all sides by an almost unbroken pine forest stretching to the Atlantic on the east and the Gulf on the west, about fifty miles in either direction. The waters to the west flow into the Suwannee River and thence into the Gulf, while those to the east find their way into the St. John's River and ultimately reach the Atlantic. The situation thus unites many of the advantages of a well-favored natural sanatorium and offers an attractive resting place for the winter tourist in search of a genial and balmy climate. The mean temperature for the months of December, January, and February during a recent winter was 52° F. The rainfall for this period was 10.22 inches. Starke has a population of about 1,200 and is well supplied with schools, churches, livery stables, banks, hotels, boarding-houses, etc. The springs are located about five and one-half miles northwest from Starke on a picturesque stream known as the Wateroak, from the presence of numerous trees which adorn its banks. They are reached by an excellent road. The springs are two in number, known as No. 1 and No. 2. No. 1 yields about one hundred and fifty gallons and No. 2, fifty gallons per minute. The following analyses were made by Prof. Henry Leffmann of Philadelphia:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Spring No. 1. Grains.	Spring No. 2. Grains.
Sodium chloride	2.08	1.42
Sodium carbonate	.40	.60
Potassium carbonate	.20	
Potassium sulphate	.17	
Calcium carbonate	5.13	5.83
Magnesium carbonate	.20	3.73
Ferrous carbonate	.33	
Silica	1.51	1.51
Nitrogen by permanganate	.20	Trace.
Iron oxide and alumina	....	.23
Total	10.22	13.32
Gases.		
Dissolved oxygen	.92	.67
Dissolved carbon dioxide	11.70	12.30

These are excellent waters of the light saline calcic type. No. 1 also possesses ferruginous properties. We have carefully examined the water of No. 1 and find it to be very palatable and well adapted to table uses. Though not heavily mineralized these waters have acquired an extensive reputation among Florida physicians in the treatment of dyspepsia, chronic skin diseases, and rheumatism. Many practitioners recommend their local use as a lotion in ill-conditioned sores and indolent ulcerations. The waters are now used commercially and are bottled and shipped to distant points.

James K. Crook.

HELLEBORE, AMERICAN. VERATRUM VIRIDE. *Indian Poke, Itch-weed.* ("Green hellebore," but not to be confused with *Helleborus viridis.*) The dried rhizome and roots of *Veratrum viride* Ait. (fam. *Melanthaceæ* ["*Liliaceæ,*" U. S. P.]). The plant is a large, conspicuous swamp herb, having a simple upright, leafy stem, from 50 to 150 cm. high (2 to 5 feet), and terminating in a large spicate panicle. Leaves, 3-ranked, large, ovate, or broadly oval, pointed, sessile, clasping at the base, from 15 to 40 cm. long. Flowers monœciously polygamous, regular, 1 or 2 cm. across, spreading. Perianth of six narrow, pointed segments; stamens six; anthers extrorse, opening transversely across the top; carpels three; fruit of three many-seeded follicles. The whole plant is slightly pubescent, and of a bright, light-green color, flowers and all. It grows abundantly in marshes and along brook-sides in the cooler parts of North America—the Northern United States, Canada, and Alaska. Its common neighbor, and a plant which might be mistaken for it, is the skunk cabbage, but that has subrotund leaves, at least as broad as long, and they lack the conspicuous plaits of veratrum. The hairs of veratrum are slightly irritating to the skin of many persons, whence the name "itch-weed." Varieties apparently identical with it are found in Alpine districts in Europe and in Eastern Asia. The type of the species, *V. album,* replaces it in Europe and Asia generally.

The poisonous properties of this plant are said to have been known to the aborigines, by some tribes of whom it was used as a sort of ordeal to test their strength and vigor. "He whose stomach made the most vigorous resistance, or soonest recovered from its effects, was considered the stoutest of the party and entitled to command the rest" (Bigelow, "Med. Bot.," quoting Josselyn). It was also one of the numerous things used by the early settlers to poison seed corn for protection against birds; it is still occasionally so used. In the early part of this century it was employed as a substitute for *V. album* in gout, rheumatism, etc., in the treatment of which that substance was then popular, and also as a parasiticide, for which purpose both have been superseded by veratrine and other things. Its modern use as a cardiac depressant is of the last half-century only.

The rhizome, which is the part used, is collected in the autumn and generally split longitudinally to facilitate drying, but it may be variously cut or left whole; the roots, to the length of 10 or 15 cm., are left attached, and dry in a skein around its lower end. The officinal description is as follows:

Rhizome upright, ovoid or obconical, 2.5 to 7 cm. (1 to 3 in.) long and two-thirds as broad, externally light- to dark-brown or blackish, frequently bearing at the summit some coarsely fibrous remains of leaf-bases, densely clothed at the sides with coarse roots; internally grayish- or yellowish-white, exhibiting numerous short, irregular wood-bundles; roots about 10 to 20 cm. (4 to 8 in.) long and about 1 or 2 mm. ($\frac{1}{25}$ to $\frac{1}{12}$ in.) thick, light yellowish-brown, much shrivelled, the surface somewhat reticulate-wrinkled; inodorous, but the powder highly sternutatory; taste bitterish, and very acrid.

It is very difficult to distinguish the *V. album* from this, and impossible when they are powdered. *V. album,* if fresh, is lighter-colored, and its roots are thicker, fewer, more spongy, and more reticulate-wrinkled. The properties are apparently identical.

Besides containing resin and starch, veratrum has a complex alkaloidal composition, regarding which authors are not agreed. The individual alkaloids are only of theoretical interest, as they are not used, only one of them (jervine) being listed, and that for experimental purposes.

Jervine ($C_{26}H_{37}NO_3 + 2H_2O$) is a whitish powder, soluble in alcohol.

Pseudojervine ($C_{29}H_{49}NO_{12}$) is very similar to it and slightly soluble in absolute alcohol, while *Veratroidine* ($C_{51}H_{78}N_2O_{16}$) is alcohol-soluble. There is a very little *rubijervine,* which strongly resembles the last.

ACTION AND USE.—The action has been studied with care by several Americans, especially by Dr. H. C. Wood, from whose "Therapeutics" this paragraph is largely condensed. His experiments were made with jervine and Bullock's "veratroidine."

The symptoms of poisoning with the former in animals are sluggishness, muscular weakness, and tremblings, followed shortly after by violent convulsions and great prostration. Sensation is affected only very late, and consciousness almost not at all. There is no purging or vomiting, but always profuse salivation. Death occurs from cessation of respiration. Jervine is an intense cardiac sedative, acting both directly upon the muscle of the heart or its local ganglia, and indirectly through the general vaso-motor system. It reduces the force of the heart beats and the arterial pressure to a very great degree. The rapidity of the heart is also diminished while the animal is quiet, but even slight exertion raises it to rapid and incoherent action. There is also in jervine poisoning a marked reduction of spinal reflex. It is not locally irritating. The other alkaloid, "veratroidine," resembles jervine in its general action, but is a local irritant like veratrine and produces generally vomiting and diarrhœa, which the other does not. It stimulates the pneumogastric, and for a while increases the arterial pressure. The crude drug has naturally the combined action of its two alkaloids, and within its medical limits produces in man weakening and infrequency of the pulse, lassitude, and increase of salivary and cutaneous secretions, lowering of temperature, and sometimes vomiting. None of these effects should be pressed beyond a moderate degree. Its utility is limited by conditions requiring these modifications—that is, quick, hard-bounding pulse, febrile excitement, high temperature, and dry skin—conditions found only in the early stages of acute febrile diseases in robust or plethoric patients—in the beginning of pneumonia, pleurisy, rheumatism, etc.; in the hypertrophic stage of cardiac disease it may be needed, but not often; in typhoid, septic, and other adynamic febrile conditions it should never be given, nor as an emetic.

In overdoses the vomiting, purging, and prostration are best combated by opium and stimulants, with a strictly enforced recumbent position.

ADMINISTRATION.—The dose of the substance itself is about a decigram (gr. iss.), repeated rather frequently and in increasing doses until the pulse is affected. During the administration the patient should be carefully watched. Once an hour is a good interval for the first few doses. The following good preparations are official: The fluid extract (*Extractum Veratri Viridis Fluidum*, U. S. P.), and a tincture (*Tinctura Veratri Viridis*, U. S. P.), strength 40 per cent., dose ♏ ij. to x.

W. P. Bolles.

HELLEBORE, BLACK.—HELLEBORUS NIGER. *Christmas Rose.* The dried rhizome of *Helleborus niger* L. (fam. *Ranunculaceæ*). This is a low perennial herb of Southern Europe, mostly in the mountains, and largely cultivated for its winter bloom.

The drug much resembles cimicifuga or black cohosh, but is rather smaller, blacker, and more tortuous, with fewer and broader wood-wedges in the rhizomes, and those of the roots less conspicuously stellate. It contains the two poisonous glucosides helleborin and helleborein, and has been used as a drastic. In overdoses it is an emetico-cathartic poison. It is now little used. The dose is 0.5 to 1.5 gm. (gr. viij.–xx.).

The rhizome of *H. viridis* L. or green hellebore (but not to be confused with *veratrum viride*, also so called), is very similar, and even more highly acrid and poisonous.

Henry H. Rusby.

HELLEBORE. (TOXICOLOGICAL.)—Green Hellebore (Veratrum viride), *American hellebore, Indian poke*, and White Hellebore (Veratrum album), the European species, owe their poisonous properties to several alkaloids which have been examined by a number of investigators. The results are not entirely accordant, and what is doubtless the same substance has received different names from the different writers. The researches of Wright and Luff and of Salzberger are of particular value. Wright and Luff found in veratrum viride, jervin, cevadin (crystalline veratrin), pseudojervin, with traces of rubijervin and veratralbin. Salzberger found in V. album, jervin, the pseudojervin and rubijervin of Wright and Luff, and two other bases, protoveratrin and protoveratridin, but no veratrin.

The official veratrin, obtained from sabadilla, and which melts at about 147° C., is a mixture of two isomeric alkaloids—the crystalline veratrin or cevadin of Wright, which melts at 205° C., and amorphous veratridin, melting at 143–148° C. Crystalline veratrin or cevadin crystallizes with difficulty, is readily soluble in alcohol, ether, and chloroform, and insoluble in cold water. It has a bitter, disagreeable taste and excites violent sneezing. It combines with acids to form salts, which are generally non-crystalline. The reactions for the official alkaloid and crystalline veratrin are substantially the same. Sulfuric acid gives a series of colors—yellow, orange red, carmine red. If heated, the latter appears at once. Hydrochloric acid produces no color in the cold, but on heating a fine red is obtained which is quite permanent. Sulfuric acid with sugar or with furfural gives a yellow, changing to an indistinct green, dark blue, and finally to violet. Nitric acid gives a transient rose pink; on evaporation and moistening with alcoholic potash a brown color is obtained.

Physiological Test: A minute quantity of veratrin injected hypodermically in a frog causes vomiting, slowing of heart beat, and contractions of the muscles, suggesting the tetanic convulsions of strychnine.

Jervin forms white crystals which melt at 238° C., and have a bitter, acrid taste. The alkaloid is non-sternutatory. It is readily soluble in alcohol and chloroform, less soluble in ether, and insoluble in cold water. Sulfuric acid gives a yellow, changing to greenish-yellow and greenish-brown with green at edges. On heating, a mahogany-brown appears at once. Sulfuric acid with sugar or with furfural gives a brownish color, changing to a deep blue and then to an indistinct violet. Hydrochloric acid gives no color in the cold; on heating, a yellow is obtained. Nitric acid, followed by alcoholic potash, gives the same reaction as does veratrin.

Experiments upon animals show that both hellebores first excite, then paralyze the sensory nerves of the skin and of the mucous membranes of the nose and alimentary tract. Both respiration and the action of the heart are first accelerated, then retarded, and finally paralyzed. The symptoms, which usually appear soon after taking, are burning in the mouth extending to the stomach, difficulty of swallowing, intense nausea, violent vomiting, and later purging, usually accompanied by tenesmus. Great prostration follows, headache and giddiness are frequently present, the pupils are slightly dilated, the pulse is feeble, respiration is difficult and sometimes fails entirely. Death may occur from heart failure or from exhaustion caused by vomiting.

Several homicidal cases have occurred in Europe, notably in France, but the only cases reported in this country are accidental. Thirty-six drops of the tincture of veratrum viride, taken in divided doses, caused the death of a child of one and one-half years. A teaspoonful of the tincture, seventy-five drops of Tilden's fluid extract, sixty drops of Norwood's tincture in divided doses, and an unknown quantity of the tincture, taken by mistake for whiskey, have caused the death of adults. Recovery has followed the taking of much larger quantities. On several occasions, a teaspoonful of the fluid extract (H. C. Wood) and a tumblerful of the tincture have been taken without fatal results. One-half ounce of powdered white hellebore has been taken with recovery. No death from veratrin is on record. The different preparations are evidently of greatly varying strength. One sixteenth of a grain nearly caused death, while recovery has occurred after taking three grains in a liniment and thirty grains of the crude alkaloid.

The treatment of a case of poisoning will vary with the nature of the symptoms. Vomiting, so commonly present, will have emptied the stomach; if it has not occurred, it should be induced until the object is reached, then restrained. Warm drinks and external warmth are used to raise the temperature and opiates to control pain. Alcohol and aromatic spirits of ammonia are useful in meeting the extreme prostration. The latter precipitates the insoluble alkaloids and thus retards absorption. Artificial respiration may be required.

Post-mortem examination discloses the intestinal tract usually congested and the viscera filled with blood, as occurs with many other poisons. There is an absence of characteristic appearances.

For the recovery of the poison, the contents of the stomach, or the tissues, after suitable comminution, are digested on the water bath with alcohol and acetic acid for some time, filtered, and the alcohol is removed by evaporation. The residue is extracted with water, filtered, and shaken with ether to remove fatty matters and extractives. It is then shaken with chloroform, rendered alkaline with sodium hydroxid, and after repeated shaking the chloroform layer is separated and evaporated. It is generally advisable to repeat this process to remove impurities, and on evaporation the veratrin will be found sufficiently pure for the application of the tests.

Brouardel isolated from a corpse of eighteen months, a ptomaïn which was extracted from alkaline solution with ether. It gave a violet color when heated with sulfuric acid and a cherry red on boiling with hydrochloric acid. This suggests the importance of confirming the chemical tests by the physiological test.

Curtis C. Howard.

HEMERALOPIA AND NYCTALOPIA, respectively, day-vision=*night-blindness*, and night-vision=*day blindness*, from ἡμέρα, day, νύξ, night, respectively, and ὤψ, eye, are names used by the older medical writers in opposite senses, to the great confusion of the literature of the subject. Following Hippocrates, Aristotle, and Galen, although in opposition to the usage of later Greek authors,[1] nyctalopia is a condition in which vision is comparatively good at night, or in a very feeble light, but is defective in strong daylight; and, conversely, hemeralopia (used, in contradistinction to nyctalopia, in a single passage in Galen[2]) is a condition in which vision is acute by daylight, but falls off disproportionately at night. If certain recorded observations are to be accepted as trustworthy, it would seem necessary to admit that hemeralopia may occur under two types, the one marked by a quasi-diurnal fluctuation in the perceptive power of the retina, the other directly dependent on changes in illumination. Thus, it has been stated that the acuteness of vision increases from early dawn to the middle of the day, and diminishes as the sun declines toward evening,[3] falling to its minimum as twilight deepens into night, or, according to some writers, not until midnight;[4] that the blindness is less marked in the early dawn than in twilight,[5] and that in aggravated cases the flame of a candle, the stars, and even the moon are either totally obscured or are seen as through a thick smoke or fog (Nachtnebel[6]). As a rule, however, luminous bodies are seen distinctly, while objects at a little distance from the lamp appear enveloped in deep gloom, so that the light of the full moon may be insufficient to enable the hemeralope to see his way.[7] By concentrating the light of a powerful lamp upon the book, the hemeralope may be able to read large print; in other cases reading by artificial light is impossible.[8] That the falling off in vision at night is closely related to the defective illumination is proved by the fact that it occurs in the daytime on entering a dark room, although with some persons, as it would seem, in a lesser degree than at night.[9] Experimental tests of the vision of hemeralopes, by varying degrees of illumination, have shown that it begins to fail under nearly the same conditions as with normal-seeing persons, but that on further diminishing the light the falling off in vision, as measured by the size of the test objects which can be discerned, is much more rapid.[10] The hemeralope requires also a relatively long time to attain his maximum of visual acuteness on going from full daylight into a darkened room;[11] on the other hand, some hemeralopes suffer from dazzling of the eyes on first going out into the sunlight.[12] The condition would appear, therefore, to be essentially one of dulled perceptive power (*torpor retinæ*), which may, in certain cases, be conjoined with some degree of retinal irritability. This view is, moreover, in accord with the seemingly well-attested fact that the same combination of causes may give rise to hemeralopia in certain persons, and to more or less distinctly marked nyctalopic symptoms in others.[13]

Hemeralopia is an almost constant symptom in certain affections of the retina, notably in retinal degeneration with stellate deposits of pigment (*retinitis pigmentosa*), in syphilitic retinitis, and in incipient detachment of the retina; and it is then associated with particular limitations of the visual field, characteristic of the special retinal disease, and very often also with marked falling off in the acuteness of vision in full daylight (see *Retina, Diseases of*). Rarely it is congenital, and it may then be an early symptom of pigmented retina, or perhaps of retinal degeneration in which the usually characteristic pigmentation may be absent.[14]

Idiopathic hemeralopia has been oftenest observed as an acute epidemic affection attacking large numbers of persons living under nearly identical abnormal conditions. De Sauvages mentions such an epidemic as having broken out among the soldiers in several garrison towns bordering on one of the smaller rivers in the south of France, not far from Montpellier.[15] Other extensive epidemics have been observed, occuring almost always in large bodies of men crowded together under unfavorable hygienic conditions conjoined with excessive exposure to the direct influence of strong sunlight. Thus soldiers in garrison, going habitually from crowded, and often very dark, quarters in casemates to drill for hours together on confined and unsheltered parade-grounds, seamen and marines on tropical stations, prisoners employed in stone-breaking or other outdoor work in courtyards enclosed by high whitewashed walls, also children in great public orphan-houses, have been especially subject to these visitations, while the officers, whose duties ordinarily involve much less exposure, and who are better nourished and lodged, also the inhabitants of garrison towns, have generally escaped. Hemeralopia has been described as endemic in certain localities in the East and West Indies, in Brazil, on rice plantations in China, in several provinces of France, in the countries bordering on the Mediterranean, in Podolia toward the end of winter, and also in midsummer among the harvesters of both sexes;[16] also in the Russian provinces bordering on the Baltic, at the period of the very strict Lenten fasts of the Greek Church.[17] An outbreak of hemeralopia, associated with cases described as nyctalopia, is reported by Carron du Villards as having been observed by his father, in 1793, in the Piedmontese army while encamped at a high elevation on the Mount Cenis and Little St. Bernard passes.[18]

From very early times both hemeralopia and nyctalopia have been attributed to "redundancy of humors in the system." Celsus repeats in connection with night-blindness[19] the observation made by Hippocrates regarding nyctalopia,[20] that it does not occur in women whose menses are regular. De Sauvages lays stress on the exposure incident to guard-mounting by day and night in a humid and nebulous atmosphere.[21] Demours particularly mentions exposure to the night air.[22] Hemeralopia is called moon-blindness by sailors, and is attributed by them to a morbific influence emanating from that planet, especially affecting such persons as commit the imprudence of sleeping on deck. In Brazil it has been described as endemic among the negroes;[23] it has also been said to affect especially persons with darkly pigmented eyes,[24] an observation which was made by Aristotle in connection with nyctalopia.[25] Stellwag observed numerous cases of night-blindness occurring in an asylum in Vienna, but almost exclusively in two pavilions which were exposed to the light on three sides,[26] and he cites this instance in support of the opinion that sleeping with the face turned toward the window may be an exciting cause of the affection. On shipboard it is often associated with scurvy, and the same connection was observed in the war in the Crimea.[27] In certain epidemics pregnant women have been especially affected.[28] As a rule, whether in epidemics of night-blindness or in the conditions prevailing in localities in which it has been observed as endemic at certain seasons of the year, also in most of the sporadic cases which have been reported, two principal factors are to be distinguished, namely, impaired nutrition and long-continued exposure to strong sunlight, often intensified by reflection from large bodies of water, snow, or sand; and it appears most rational to regard the former as a predisposing, and the latter as the chief exciting, cause of the affection. Simulation has doubtless often played a part in swelling the number of supposed cases in outbreaks which have occurred in garrisons, on ships, in workhouses, etc., and this probability must be considered in judging of some of the remarkably prompt cures which have followed very diverse plans of treatment.

Of the objective signs of hemeralopia, that upon which the most stress has been laid by military and naval surgeons is a considerable dilatation of the pupils, generally most conspicuous at night; also the sluggish response of the pupils to changes of illumination. Dryness of the scleral conjunctiva with formation of scaly patches, a dulled appearance of the corneal epithelium, even xerosis of the conjunctiva and cornea, also conjunctival hyperæmia with lachrymation and photophobia, a staring expression of the eyes, with the eyelids widely separated, have all been noticed, especially in endemic hemeralopia; but so far as organic changes have been remarked, they would seem to be connected rather with concomitant disturbances of nutrition than directly with the affection of vision.[29]

The duration of the affection in different cases, or as stated by different observers, has been variously reported as limited to a single day or to a few days, or as extending to several weeks or months. As a rule, recovery speedily follows any change which works an amelioration of the two conditions of impaired nutrition and undue exposure to strong light. Relapses are apt to occur on renewed exposure to conditions similar to those which have given rise to the first attack.[30]

The treatment of night-blindness, as also of day-blindness—in both of which conditions the name nyctalopia has been used with little or no discrimination—was, until well into the last century, chiefly depletive and derivative. Bleeding from the arm or from the angle of the eye,[31] cupping, purgation[32] by elaterium,[33] scammony,[34] etc.; the administration of emetics,[35] diuretics, and diaphoretics;[36] the application of blisters and other counter-irritants behind the ears[37] or to the back of the neck; errhines and masticatories;[38] baths, frictions, exercise, and gargles;[39] in extreme cases trepanning the skull;[40] various applications to the conjunctiva, especially of an ointment made from the juices exuding from roasting liver; also steaming the eyes with the vapor of water in which liver is boiling, to which is added the recommendation to eat the liver;[41] these are the therapeutic measures recommended by the earlier and later Greek and Roman authors, by the Arabian writers on medicine, and by their followers down to quite recent times. Seclusion from bright sunlight and amelioration of diet must have contributed incidentally to the cure, but upon these points little or no stress was laid. In modern times a short confinement to a more or less perfectly darkened room,[42] attention to any concomitant pathological conditions, improvement of the nutrition, and, above all, the removal of the patient from the sphere of operation of the combined causes of the affection, have taken the place of the heroic plans of treatment formerly in vogue.

Nyctalopia, in the sense of seeing exceptionally clearly in comparative darkness, has been observed in the case of prisoners confined for a considerable period in dark dungeons;[43] and such persons are said also to suffer from dazzling of the sight for a longer or shorter time after being set at liberty, or, in some instances, to have continued permanently day-blind.[44] Physiological or pathological variations in the size and in the dilatability of the pupils may be relatively favorable to night-seeing or to day-seeing, according as the pupils are habitually larger or smaller than normal. In ametropia—whether myopia, hypermetropia, or astigmatism—the requisite conditions for distinct vision are generally best in a strong light, owing to the incidental contraction of the pupils and the consequent partial suppression of disturbing circles of confusion on the retinæ; and this may be also the case in turbidity of the vitreous or in diffuse clouding of the crystalline lens, in which conditions the penetrating power of strong light may be required for fairly good vision. On the other hand, in certain cases of circumscribed central opacity of the cornea or crystalline lens, vision may be comparatively good when the pupils are widely dilated, as at night, and very bad when they are strongly contracted, as in bright sunlight. Normally pigmented eyes, as a rule, best fulfil the conditions for clear and undazzled vision in strong sunlight, whereas the sight of persons with very light blue eyes, and notably of albinos, is generally best in moderate light. Retinal irritation following prolonged exposure to direct or reflected sunlight (snow-blindness), and especially reflex irritability of the retina dependent on irritation of the terminal ramifications of the fifth nerve in the cornea and iris, are marked by excessive and often painful contraction of the pupils under the influence of strong light, with consequent inability to see well in the daytime (photophobia). It is a curious fact that nyctalopia (day-blindness) is mentioned by medical authors several centuries before the definite recognition of hemeralopia (night-blindness), and it is still more remarkable that the earlier teachings regarding the etiology and treatment, and also the name, of the former came later to be applied to the latter affection. Excluding cases of photophobia and of central opacity of the cornea or crystalline lens, the conditions to which the name nyctalopia is in any degree applicable are reduced to certain retinal affections attended with irritability, and to the few imperfectly reported instances of day-blindness following long confinement in the dark. A few brief notices exist of day-blindness of an endemic or epidemic type,[45] but no recent instance of the kind has been reported.

John Green.

HEMIANOPSIA is a condition of blindness limited to one-half of the visual field. *Hemiopia* is used as a synonym incorrectly, as it signifies vision (not blindness) in one-half of the visual field. This condition may be present in either the outer (temporal) or inner (nasal) half of the field of vision, and may affect one eye alone or both eyes. If both eyes are affected like-named halves of both may be involved—*e.g.*, the left half of both eyes, in which case the condition is called *homonymous hemianopsia;* or unlike-named halves of both eyes may be involved—*e.g.*, the left half of the left eye and the right half of the right eye, in which case the condition is known as *heteronymous hemianopsia.*

By means of Förster's perimeter the visual field of each eye has been determined (Fig. 2597). It is found to have an irregular outline, and to be divided into a large outer and a small inner portion by a line drawn vertically

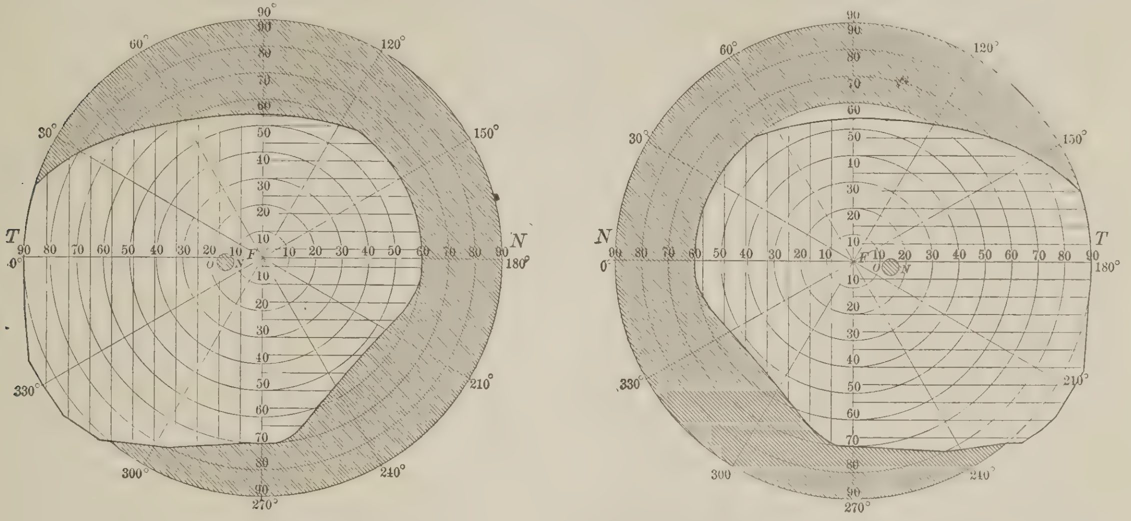

FIG. 2597.—Visual Field of Both Eyes, taken separately. The vertical lines represent the portion of the visual fields affected in left hemianopsia; the horizontal lines, in right hemianopsia.

through the point of fixation. This point corresponds with the macula lutea, and lies on the outer side of the entrance of the optic nerve. The two inner fields really overlap one another, so that the actual outline of the entire visual field of both eyes is that represented in Fig. 2598. It becomes evident from this figure that the loss of one nasal half of the visual field is not appreciated by any one unless the unaffected eye is closed. This fact is of importance, as it is evident that a nasal hemianopsia is a symptom which may not be noticed by a patient, and hence must be looked for by the physician. The unequal size of the two portions of each visual field is so marked that in an homonymous hemianopsia the patient usually ascribes the blindness wholly to a defect in the eye whose larger portion is affected, and a careful medical examination is necessary to establish the existence of a bilateral affection.

To determine a patient's visual field, each eye is to be tested separately. The patient holds a card before one eye and looks the examiner in the eye with the other. Any object, preferably a white one, is then moved about in the visual field of the eye which is uncovered, and the power and extent of indirect vision is thus determined. If hemianopsia exists the patient will be unable to see the object when it is within the field of vision which is defective, or when it is carried beyond the vertical line passing through the fixation point toward the defective side. More accurate measurements may be made by means of a perimeter, but the method described is sufficient to establish the existence of blindness in one-half of the visual field. In no case of hemianopsia is direct vision at the fixation point affected.

Since the lens of the eye reverses the image of the object seen upon the retina, each half of the visual field corresponds to the opposite half of the retinal expansion. A hemianopsia therefore indicates a suspension of function in the half of the retina opposite to the defective visual field. Such a functional derangement of one-half of the retina is rendered possible by the origin, course, and distribution of the nerve fibres in the optic nerves, as seen in Fig. 2599. Each optic nerve is seen to pass from the eyeball back to the optic chiasm, and there to divide into two parts. One of these turns outward and joins the optic tract of the same side. The other crosses the median line in the chiasm, decussating with its fellow from the opposite optic nerve, and joins the optic tract of the opposite side.

The anatomical separation of the fibres from one optic nerve renders it possible for a lesion situated in the chiasm, or in the optic tract, to affect a portion of the fibres coming from one eye, and consequently a part of the retina; while a lesion affecting the optic nerve itself involves necessarily the entire extent of the retina, producing amaurosis, not hemianopsia. It is found that the portion of the retina lying to the outer side of the fixation point is joined with the fibres of the optic nerve which pass directly into the optic tract of the same side; while the inner portion of the retina sends its fibres across the median line in the decussation (Fig. 2599). It has been already shown that the nasal portion of the retinal expansion, corresponding to the temporal half of the visual field, is larger than the other portion. The number of fibres in the optic nerve which decussate is greater than the number which do not cross the median line. The ratio of non-decussating to decussating fibres in the optic nerve, in any animal, is directly proportionate to the extent of the visual field common to both eyes. Thus in the horse, or the rabbit, in whom there is no part of the visual field which is common to both eyes, the decussa-

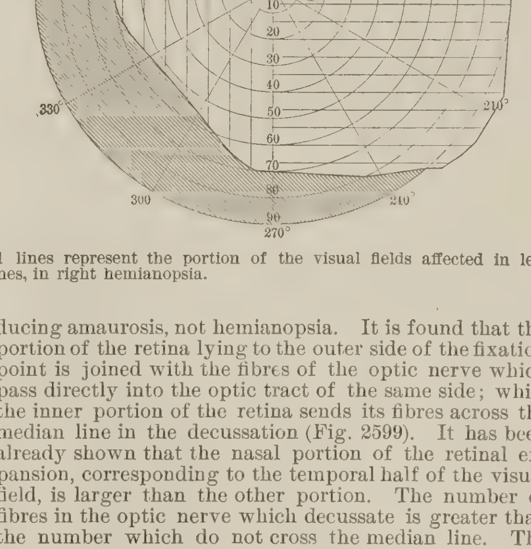

FIG. 2598.—Outline of the Entire Visual Field of Both Eyes.

tion of the optic fibres is total. In dogs, cats, monkeys, and man, in whom, to a less or greater degree, the eyes are directed in parallel lines, the decussation is partial. In a rabbit or horse hemianopsia is impossible. In the other animals named it is observed.

Unilateral hemianopsia is produced by lesions affecting the optic chiasm only. If the lesion lies on the outer side of the chiasm it produces nasal hemianopsia on the side of the lesion. Thus a tumor pressing upon point *N* in Fig. 2599 would produce blindness in the temporal half of the left retina, and hence nasal hemianopsia in the left visual field. If the tumor lies in front of or behind the chiasm, or presses upon it from above or below in such a manner as to involve the decussating strand of fibres either before or after they have crossed to the opposite side, it will cause a temporal hemianopsia (*T* in Fig. 2599). As it is impossible to determine whether the fibres are affected before or after decussation, no statement as to the side upon which the lesion lies can be made.

Bilateral hemianopsia is far more common than unilateral. It may be of several varieties. Bilateral nasal hemianopsia implies a destruction of the direct optic fibres on both sides, the decussating fibres being unaffected. Such a case has been observed by Knapp, in which a tumor surrounded the chiasm, pressing upon its sides, but not affecting its centre. Bilateral temporal hemianopsia is a rare condition, and is produced only by a lesion which divides the chiasm through its antero-posterior diameter without affecting its lateral halves, thus destroying both decussating strands. It has been observed in a few cases of tumor of the hypophysis.

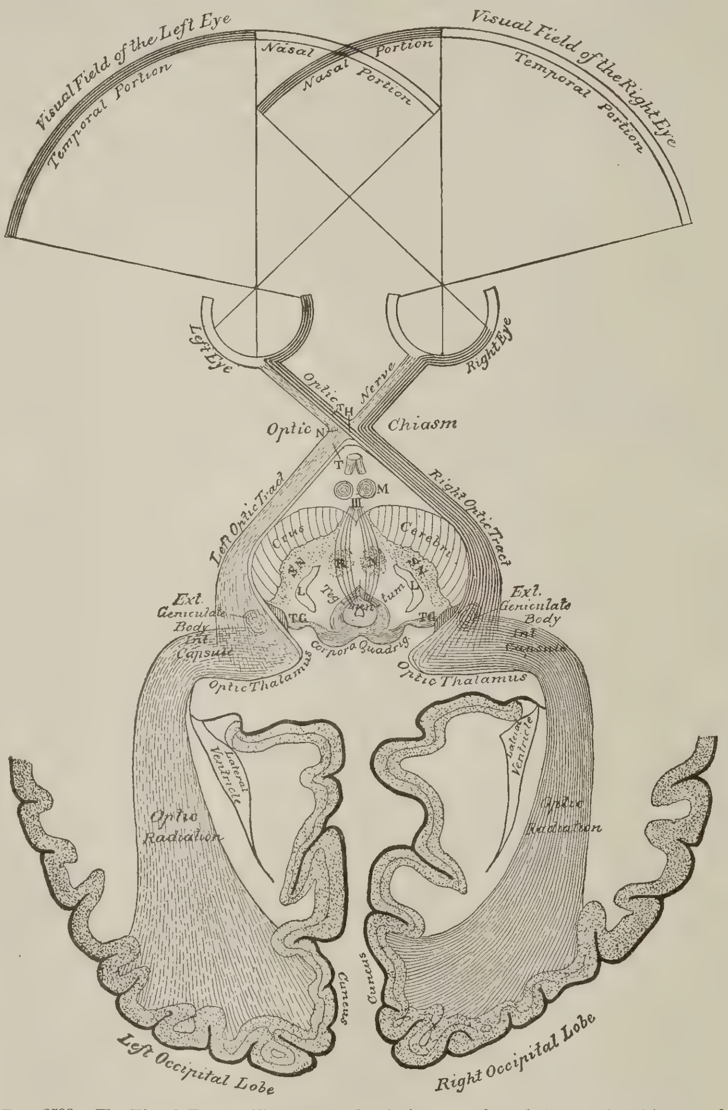

FIG. 2599.—The Visual Tract. The result of a lesion anywhere between the chiasm and cuneus is to cause homonymous hemianopsia. III. Third nerve; S. N., substantia nigra; R. N., red nucleus of tegmentum; L., lemniscus; T. G., fibres from optic tract to corpora quadrigemina.

Bilateral homonymous hemianopsia is a not uncommon condition, and may be produced by many causes, and by lesions situated in many various parts. This will be better understood after the course of the optic tracts has been followed to their terminations in the visual area of the cerebral cortex (Fig. 2599), since a lesion at any point in this course will produce the symptom named. Each optic tract, after leaving the chiasm, passes around the crus cerebri, lying directly upon the fibres which pass through the foot of the crus (pes pedunculi), and ends on the level of the tegmentum of the crus in the external geniculate body, in the pulvinar of the optic thalamus (*i.e.*, the eminence forming its posterior surface), and in the corpora quadrigemina anteriora, which latter it reaches by the brachium conjunctivum. The last-named fibres of the optic tract have probably nothing to do with conscious vision, and may therefore be excluded from consideration in studying hemianopsia. They form the sensory part of a reflex arc, whose motor part is made up of the motor nerves to the eyeballs. The functions of this reflex mechanism are to direct the motion of the eyeballs, and to regulate the process of accommodation and the size of the pupil. The primary visual centres are, therefore, the external geniculate body and optic thalamus. The fibres of the optic tract end in the cells of these ganglia, and from these cells new fibres arise which collect in a large tract and issue from the posterior external angle of the optic thalamus into the posterior third of the internal capsule. This visual tract turns upward and backward in the internal capsule, radiates into the centrum semi-ovale of the occipital lobe, and, passing around the outer border of the posterior horn of the lateral ventricle, terminates in the convolutions of the occipital cortex, including the cuneus. At no point in this course is any decussation found. The only decussation of fibres between the eye and the cortex is in the optic chiasm.[1]

Bilateral homonymous hemianopsia may be caused by a destructive lesion lying anywhere in the course of these fibres between the optic chiasm and the occipital cortex, or by a lesion in the cortex which destroys the perceptive centres in which the fibres end. Wherever the lesion, the character of the symptom will be the same. From the accompanying symptoms, it is in some cases possible to locate the lesion causing the hemianopsia. Thus, if the optic tract is involved as it curves around the crus cerebri, the same lesion which causes the hemianopsia will be likely to affect the motor tract in its passage through the pes, or to involve the third nerve in its exit from the pes. In this case hemianopsia and hemiplegia of one side, with oculo-motor paralysis of the other side, will be combined. Or, if the termination of the optic tract in the geniculate body and thalamus is involved the lesion, unless extremely limited, will affect the sensory tract from the opposite side of the body in its passage through the tegmentum of the crus, or in the posterior portion of the internal capsule; and in this case hemianæsthesia and hemiataxia will be associated with hemianopsia. Or, if the visual tract in its passage through the internal capsule is involved by disease in the basal ganglia or in the capsule, the proximity of both sensory and motor tracts in the capsule will render a combination of hemianopsia, hemianæsthesia, and hemiplegia quite probable. This is the seat of the lesion, and this is the combination of symptoms most frequently observed (see *Brain Diseases: Diagnosis of Local Lesions*).

Lesions in the centrum ovale involving the optic radiation may not produce any other symptom than that under discussion. If it is the left hemisphere, however, in which the disease is present, a condition of word-blindness (see *Aphasia*) is not infrequently associated with it; and in all the cases of word-blindness hitherto reported hemianopsia has been found. This is probably due to the destruction of association fibres between the occipital and temporal lobes which lie side by side with the visual tract.

Lesions in the cortex of the occipital lobe produce no other symptom than hemianopsia. It is impossible to limit the visual area of the brain to any one part of the lobe, since destruction of a portion of the convexity has produced the same result as destruction of its median surface.[2] Nor is it possible to project upon the cortex the retinal expansion, as has been attempted by Munk, since lesions in all parts of the occipital convolutions produce the same effect.

Lesions in the angular gyrus may produce hemianopsia, and it is well known that Ferrier has located in this convolution the visual centres. It is probable that such lesions have caused the symptom by affecting the visual tract as it passes beneath this gyrus in the centrum ovale. There is no reliable evidence that a unilateral lesion in the cortex can produce blindness of one eye alone.

Hemianopsia is, therefore, a local symptom of brain disease of great value in determining the situation of a lesion, when considered in connection with other symptoms. The symptom alone affords little evidence of the nature of the disease producing it, since it may be caused by any of the various forms of brain lesion (see *Brain*). It has been observed in cases of basilar meningitis, in tumors of the occipital lobe and basal ganglia, in hemorrhage and softening involving the internal capsule, and in embolism of the terminal branches of the posterior cerebral artery, and of the trunk and posterior branch of the middle cerebral artery, as well as in other rarer conditions.

The diagnosis of the symptom may be made by an examination such as has been described. The prognosis and treatment of it will depend entirely upon the nature of the disease producing it. *M. Allen Starr.*

HEMICRANIN is a mixture of phenacetin five parts, and one part each of caffeine and citric acid.

W. A. Bastedo.

HEMIDESMUS.—Hemidesmus Radix. *Indian Sarsaparilla.* "The dried root of *Hemidesmus indicus* R. Br." (B. P.) (Fam. *Asclepiadaceæ*). The plant is a slender, twining shrub, native of India. The description in the British Pharmacopœia, into which it is introduced apparently out of compliment to the Indian physicians, is as follows: "The root is long, rigid, nearly cylindrical, tortuous and longitudinally furrowed. It seldom exceeds ¼ of an inch (6 mm.) in thickness and is of a reddish-brown or dark-brown color. On one side of the root the cork is frequently separated from and raised above the cortex, and is transversely fissured. The transverse section exhibits numerous laticiferous cells in the cortex. The root has a fragrant odor and a somewhat sweet taste." A syrup, made from one ounce of hemidesmus to ten and one-half ounces of menstruum, is used in England.

The medicinal properties of hemidesmus are said to be those of sarsaparilla, in the stead of which it is used in British India; in Europe or in this country it is rarely used. Its composition has not been fairly studied, but it is safe to say that nothing physiologically very peculiar or active is contained in it. An odorous principle, perhaps cumarin, has been partially examined. The syrup in which it is prepared, like that of sarsaparilla, is scarcely more than a flavoring vehicle. *Henry H. Rusby.*

HEMIPLEGIA (*ἥμισυς*, "the half," and *πλήσσω*, "I strike"). Paralysis of one-half of the body.

Causes.—Hemiplegia, as ordinarily seen, is usually the final result of an apoplectic stroke, from cerebral hemorrhage, embolism, or thrombosis. The stroke is often attended by loss of consciousness and profound paralysis, but if the patient live the paralysis gradually lessens and leaves the final hemiplegic state. In some instances the paralysis is not ushered in in such stormy manner, but increases gradually for a day or two, either with or without loss of consciousness. The early symptoms are the expression of shock to a larger or smaller part of the brain, of pressure, and, sometimes, of inflammation of the tissues adjacent to the lesion, as well as of destruction of brain substance. The final symptoms are the expression of destruction and degeneration of brain tissue.

Hemiplegia may also come on slowly, caused by a brain tumor, brain abscess, chronic softening, meningitis, etc. In these instances the clinical picture may be complicated by a sudden paralysis from hemorrhage or thrombosis in the diseased area, or the like.

What has already been spoken of is organic hemiplegia, due to destruction or injury of the motor centres, or the cortico-muscular tract, that is, the tract of fibres carrying impulses from the motor centres to the muscles. But hemiplegia also occurs without palpable lesion. Notably this is true of hysterical hemiplegia.

Manifestations.—The paralytic manifestations are variable. Shortly after an apoplectic attack, if it be severe, most of the muscles on one side of the body are paralyzed. The arm and leg are entirely powerless. The muscles supplied by the lower branches of the seventh nerve, those of the cheek and mouth, are completely paralyzed. That side of the face is expressionless, and the mouth may be drawn toward the other side. But the muscles supplied by the upper branches of the seventh nerve—the orbicularis palpebrarum, occipito-frontalis, and corrugator supercilii—are as a rule but little affected. The tongue may remain motionless in the floor of the mouth. When protruded it deflects to the paralzyed side. The muscles of the chest are usually somewhat affected, and the breathing is less deep on the paralyzed side. The writer has found the latter symptom an aid to diagnosis of both the presence and the side of hemiplegia in cases in which the coma was so profound that it was impossible to elicit any sign of power on either side. On the other hand, some muscles almost invariably escape injury. These are the muscles supplied by the third, fourth, fifth, and sixth nerves—those of the eyeballs and of mastication—and the muscles concerned in swallowing and vocalization. The articulation is usually somewhat indistinct for a short period, or there is a loss of speech—aphasia. Aphasia occurs mostly with right hemiplegia (in right-handed individuals). But even indistinctness of speech, when there is no aphasia, is often more marked in right than in left hemiplegia.

The high degree of paralysis just described, though in rare instances it remains permanently, is usually of short duration. The paralysis of the muscles of the trunk and of the tongue, and the indistinctness of articulation usually disappear at an early period. The facial paralysis also diminishes, sometimes disappears altogether. The paralysis of the arm is usually most profound, and slowest to improve.

The hemiplegia of a later period is, as a rule, to be found only in the face and extremities, though sometimes the tongue continues, when protruded, to deflect toward the paralyzed side. If the facial paralysis be slight, it will be observed that the nasolabial fold is less marked than on the sound side, that the upper lip is less arched, and the angle of the mouth droops somewhat on the affected side. A slight paralysis becomes more marked when the muscles are actively exercised, as in smiling, exposing the teeth, etc. Not rarely the effort to expose the teeth will reveal a decided facial paralysis, while laughing will show none whatsoever—probably a psychic reflex act on the part of the thalamus. The opposite, the appearance of a more decided paralysis with laughter than with voluntary movements of the face, is observed in rare instances, probably indicating lesion of the thalamus. In the extremities usually certain groups of muscles are most likely to be paralyzed, or most deeply affected, *e.g.*, extensors of the fingers, supinators, trapezius muscles, anterior tibial, and peroneal group of muscles, and flexors of the knees. As a rule the hands and feet are more affected than the higher parts of the extremities. The skilled movements of the fingers are most affected. In walking a dragging of the toes on the paralyzed side is often observed.

In cases of permanent hemiplegia, especially if the paralysis be considerable, after a few weeks contracture of the paralyzed muscles usually occurs, a condition termed late rigidity. In a well-marked case we shall find the arm drawn toward the chest, the forearm flexed on the arm and pronated, and the fingers flexed; in the inferior extremity all the joints extended, and the foot in the position of talipes equino-varus. The rigidity is usually greater in the upper than in the lower extremity. In rare instances we find extension of the joints of the arm instead of flexion, or flexion in the lower extremity instead of extension. Sometimes the muscles of the face are also affected; then the naso-labial fold becomes deeper, and the angle of the mouth elevated on the affected side. In extreme cases the rigidity is more or less constant; but usually it is much less than in the instance above described, and it is then increased by voluntary efforts to move the parts, or by emotional excitement, while it is diminished or absent during sleep. In some cases the rigidity improves very much with time, so that it is only observable during acts requiring special skill.

Hemiplegics often succeed in walking with the aid of a cane, even though the leg be completely paralyzed, especially if the limb be at the same time rigidly extended. In this case the pelvis and hip of the paralyzed side are elevated by the contraction of the abductor muscles of the thigh on the sound side, and the foot is then propelled forward by the action of the inward rotators of the healthy limb, the toes usually scraping the floor during the forward movement. The body now rests partly upon the foot of the paralyzed limb, partly on the cane, held in the hand of the sound side, the centre of gravity being between them while the healthy limb is being brought forward.

In permanent hemiplegia the deep reflexes are usually very much increased. The knee jerk, elbow jerk, wrist jerk, etc., are exaggerated and the ankle clonus can be elicited, which is almost never found in healthy individuals. The deep reflexes may even be exaggerated, though to a less degree, on the non-paralyzed side. But it is also true that the latter side may be weaker than before the paralysis set in. There is often some alteration in the condition of the superficial reflexes. Only one of the latter has much diagnostic import, the toe phenomenon, recently described by Babinsky. The usual plantar reflex is flexion of the toes. Babinsky observed that when there is disease of the pyramidal tracts stroking the sole of the foot produces extension of the big toe. Care is usually necessary to get the proper response. The patient's mind should be distracted if possible, and then a stroke slowly made from the heel toward the toes. A not pointed pencil answers very well for making the stroke. This sign has not the full significance of the ankle clonus, because not so commonly found, yet it may have a greater diagnostic value, because it may be found very soon after the paralysis sets in, while one or several weeks elapse before the ankle clonus can be elicited. In several instances the writer has found the toe phenomenon within one, or at least a few, hours after the onset of an apoplectic stroke.

Other motor phenomena are observed more or less frequently, the probable results of irritation of, or lessened inhibition in, the motor areas. Often there is a movement of the paralyzed arm—hand lifted to the head or the like—in yawning, etc. A slighter movement in the paralyzed extremity is frequently observed at the same time with corresponding movements of the sound limb. The opposite is also observed, viz., contractions of corresponding muscles on the sound side with attempted movements of the paralyzed side. The kind of motor phenomena just described are usually spoken of as accessory movements. More rarely tremor, or choreic movements, or athetoid movements (slow continuous movements of fingers and toes) are found in the paralyzed extremities. The choreic and athetoid movements have been supposed to occur especially with lesion of the thalamus. If that be true, it is probable that it is rather because the posterior part of the internal capsule is affected than because of injury to the thalamus itself.

SEAT OF LESION.—Hemiplegia is most frequently caused by a lesion of the corpus striatum, or in its neighborhood, the paralysis being on the opposite side of the body. If the paralysis be permanent, it is because the internal capsule has been damaged, while the late rigidity is attendant on degeneration of the pyramidal tracts.

Hemiplegia, produced by lesions in other parts of the motor tracts, has in some instances special manifestations.

Cortex.—Lesions in the motor area of the cortex, the anterior and posterior central convolutions, more frequently produce monoplegia—paralysis of one limb, or of the face—than hemiplegia, but the latter may occur if the lesion be sufficiently extensive. Such lesions are often attended by convulsive movements, especially in case of a neoplasm. In such instances there occur usually periodic attacks of clonic spasms in one extremity or one side of the face; in the hand if the lesion chiefly affect its centre, etc. These spasms are likely to be at first quite limited and not accompanied by loss of consciousness. But in succeeding attacks the convulsions may extend to other parts of the body. They first travel over one side of the body. If the convulsion also seizes the other side, loss of consciousness is likely to supervene. There is often some blunting of the sensibility corresponding to the amount of paralysis, indicating that the cortical centres for motion have also direct relationship with the sensory functions. But such cases do not always give a like clinical picture. In a case of the writer's, in which there was a large tumor on the convexity, implicating chiefly the leg centre, there was paresis of the opposite arm and leg, but no appreciable impairment of sensation, and there had never been any convulsive movement.

Crus Cerebri.—Hemiplegia from lesion of the crus cerebri is often attended by paralysis of the third nerve on the side of the lesion. There is paralysis of the face and extremities on one side, and of the muscles of the eye on the other side.

Pons Varolii.—Lesions of the pons Varolii cause what has been termed alternate hemiplegia, that is, paralysis of the arm and leg on one side, and of the face on the other, the extremities being affected on the side opposite to, the face on the same side as, the lesion. The reason for this is the following: The central prolongation of the seventh nerve, like that of all other motor nerves, passes from one side of the brain to the other, the site of crossing being, in case of the seventh, in the pons. Lesions, then, in the latter locality may affect only the peripheral parts of the nerve—the nerve trunk itself, or its nucleus—and the facial paralysis be on the side of the lesion. The facial paralysis in such cases differs from that with ordinary hemiplegia, in that it has the stamp of peripheral paralysis. The paralysis is likely to be complete, all parts supplied by the nerve being equally affected, the eyelids and forehead as much as the lips and cheek. There will also be found changes in the electrical reactions, the so-called reaction of degeneration. The electrical reactions of the nerve and faradic contractility of the muscles are lost, while the galvanic contractility of the muscles may be heightened, but with a change in the normal formula of the reactions. Such changes in the electrical reaction are never found in central paralysis, only in paralysis of a peripheral type. If the degree of paralysis be great, some atrophy of the facial muscles may also take place.

Medulla Oblongata.—Hemiplegia from lesions of the medulla is likely to be attended by paralysis of other cranial nerves, while the seventh nerve escapes. There are likely to be a considerable paralysis of the tongue, indistinctness of articulation, and paralysis of the vocal cords from the involvement of the hypoglossal and pneumogastric nerves. The writer had under his observation a case of unusual interest, in which there was probably a lesion of the medulla and pons of traumatic origin. The injury was caused by an iron rod penetrating the right submaxillary space, and passing upward four inches in the direction of the foramen magnum. Immediately after the injury there was complete paralysis of the right arm and leg, of the cheeks, lips, tongue, and vocal cords. The patient was unable to swallow or to make any vocal sound. The upper part of the face was unaffected. He could move the eyes freely, open and close the lids, and was entirely conscious. There was also loss of sensation on the left side of the face. The condition of the patient rapidly improved, but there remained permanently a right-sided paralysis, considerable difficulty in articulation, and anæsthesia of the left side of the face.

Spinal Cord.—Hemiplegia from unilateral lesion of the cord is not attended by paralysis of any cranial nerve, but the arm and leg of the same side are paralyzed if the lesion be in the cervical region, and the leg only, if the lesion be at a lower level. Such a unilateral lesion produces a peculiar array of symptoms, spoken of as Brown-Séquard paralysis, because produced experimentally and first described by that distinguished physician. The symptoms are motor paralysis and loss of muscular sense, on the side of the lesion, in every part below it, and impaired or lost tactile, pain, and temperature sense on the opposite side. There is likely to be a narrow area, encircling the body, at the level of the lesion, in which there is hyperæsthesia. The explanation of the symptoms appears to be that the tracts for the motor fibres and muscular sense run up in the cord on the same side as are the corresponding nerve roots, and only cross to the other side in the medulla, while the tracts for tactile, pain, and temperature sense cross to the other side of the cord immediately after leaving the nerve roots.

Infantile Paralysis.—Some cases of hemiplegia of infancy, which are either congenital or acquired early in life, deserve special mention. The lesion is a varied one, from hemorrhage, inflammation, arrested development, etc., and is often of traumatic origin. The hemiplegia is usually attended by contractures of the paralyzed muscles, and by a considerable arrest of development. The leg and arm are smaller in circumference and shorter than those on the sound side, and the face is also frequently smaller than on the paralyzed side. The choreic, athetotic, and accessory movements already spoken of occur very frequently in these cases. Great impairment of intellect, even complete idiocy, is frequently found, and epileptic convulsions become established in many cases.

Hysterical Hemiplegia.—In hysterical hemiplegia the paralysis is mostly confined to the extremities, the face escaping. When there is an appearance of facial paralysis it is usually found that there is really spasm, not paralysis of the facial muscles. It is not so commonly true of hysterical as of organic paralysis that the arm is more profoundly paralyzed than the leg. Mostly the paralysis is not complete. There is paresis, rather than paralysis. In that case one frequently observes that the resistance of the patient to the efforts of the examiner to move the limb is done in a jerky manner. There is resistance for a moment, then none whatever, as though there were no effort on the part of the patient. More power may be manifested in emotional conditions, in gesticulation, etc. A degree of power may be revealed in an apparently paralyzed limb, by a sense of resistance on passively moving the limb, or by the limb remaining momentarily in the position in which it has been placed, a position requiring some muscular effort. The gait is ordinarily different from that of organic hemiplegia, the paralyzed foot rather dragging behind, than swinging forward in a circle.

The reflexes are commonly not affected, neither the superficial nor deep being altered in the way already described as occurring in organic hemiplegia. Not rarely contractures occur in the paralyzed limbs. As a rule they make the prognosis less favorable, at least in so far as the duration of the symptoms is likely to be much greater. Anæsthesia is commonly found with hysterical hemiplegia. The sensory symptoms are usually more extensive than is the paralysis, the face being affected as well as the extremities. There may be both superficial and deep anæsthesia and also of the special senses on the affected side. Not rarely there is partial anæsthesia, loss only of tactile, or only of pain sensation, or impairment of one more than of the other. The patient may be altogether unaware of the impaired sensation.

Hysterical hemiplegia affects mostly the left side. It has been said to occur three times as often on the left as on the right side. It may come on abruptly or gradually. Not rarely it follows a convulsive seizure. It may be caused by an injury, or any physical or mental shock. Very likely an emotional condition, or, at least, some mental impression underlies the hemiplegia in most instances, though it need not immediately follow upon the exciting cause.

The patient usually recovers from the paralysis, but it may take days or years. During this time the paralysis may remain unchanged, or it may vary greatly in its intensity. The disappearance of the paralysis, just as its inception, may be due to mental causes, shock, suggestion, or the like.

The characteristics of the paralysis just given may suggest or establish the diagnosis of hysteria. But it is well to remember the ofttime difficulties of diagnosis, not the less so that not rarely there is association of hysteria and organic disease. Where the question of hysteria has arisen mistakes have been made not infrequently even by the best men. Not only the peculiarities of the supposed hysterical symptoms should be considered, but also the personality of the patient, the apparent cause of the manifestations, as well as the history and the whole clinical picture. *Philip Zenner.*

HEMORRHAGE.—From αἷμα, blood, and ῥήγνυμι, to break through. The blood may escape from the arteries, veins, or capillaries, and from its origin the hemorrhage is designated arterial, venous, or capillary.

In arterial hemorrhage the blood escapes from the arteries in jets synchronously with the contraction of the left ventricle, and flows continuously during diastole. The blood is then of a bright or pale red according to the quality.

In venous hemorrhage the blood escapes from the veins in a continuous stream, and is dark in color. Blood has been seen to escape from a hemorrhoidal vein in jets, but synchronously with the contraction of the abdominal muscles. In capillary hemorrhage the blood oozes from the capillaries over a smaller or larger surface, and is reddish in color.

Secondary hemorrhage is bleeding that arises from failure in repair of an injured or ligated vessel or from ulceration into a vessel (Gould). The cause may be in the altered composition of the blood itself or in a rupture of the vessels, or both conditions may obtain at one and the same time. Sometimes abnormal pressure may cause the rupture of thin-walled veins, as happens, for example, in rupture of the thin-walled veins of the lower end of the œsophagus in hepatic cirrhosis.

Just what are the alterations in the blood which favor hemorrhage are not definitely determined, but the white corpuscles are greatly increased in numbers and the time required for coagulation is increased. The coagulation time may be determined by the coagulometer; normal blood clots in the tubes in from three to five minutes. In some forms of purpura the coagulation time is retarded to ten or fifteen minutes, and in hæmophilia it has been delayed for as long a time as fifty minutes (Osler).

These changes in the constitution of the blood, which lessen its coagulability and thus favor hemorrhages, obtain particularly in leukæmia, purpura, and prolonged icterus, especially if associated with malignant disease.

Of recent years there has been an increasing tendency to regard the spontaneous hemorrhages occurring in newborn children as a manifestation of micro-organismal disease; and, although this view can scarcely as yet be said to be thoroughly established, there are a great many facts in favor of it (Thompson in "Allbutt's System").

Consequences.—Repeated small hemorrhages may gradually bring about a profound degree of anæmia. Large hemorrhages result in anæmia, but they are also followed by a condition of shock. It has been shown conclusively that death from hemorrhage takes place in consequence of a lowering of intracardiac and intravascular pressure, incompatible with the continuance of the function of the circulatory organs.

Hemorrhage may result disastrously, not only from the loss to the individual of a large quantity of blood, but also from the pressure of the escaped blood on adjacent structures. This is notably the case in intracranial and pericardial hemorrhages.

Symptoms.—The symptoms vary with the rate and quantity of blood lost. In repeated small hemorrhages anæmia is the obvious result. The objective signs are pallor of the skin and mucous membranes, coldness of the surface, the degree of anæmia present being most accurately determined by a blood count. It is of course evident that a much greater quantity of blood may be lost in small quantities and at intervals without a fatal result than in one or two large hemorrhages. In the former instance repair is constantly going on and the system acquires toleration.

The shock resulting from the rapid loss of a large quantity of blood is most alarming to all concerned. The patient becomes rapidly pale, cold, and restless. The dilated pupils, blurred vision, weak voice, small or imperceptible pulse, yawning, and the appeal for more air are evidences of the resulting acute anæmia. The patient may complain of roaring noises in the ears, a cold, clammy perspiration may cover the body, and the thermometer may not register at all in the axilla, and give a very low temperature per rectum.

At other times the evidences of hemorrhage are to be sought for in focal lesions of the brain or in the presence of physical signs of fluid in the pericardium, in the pleura, or in the abdomen.

It is not always easy to differentiate the symptoms of acute anæmia the result of a large concealed hemorrhage, from shock due to other causes. Reliance must be placed upon the history of the onset, and the exclusion of other causes of shock, such as fright, local injuries to important organs, extensive superficial burns, severe pain, and the presence of the physical signs of fluid in the great cavities of the body.

Treatment may be prophylactic, constitutional, and local.

Prophylaxis.—The researches of Dr. A. E. Wright have shown that the coagulability of the blood may be increased by the administration of salts of lime. Mayo Robson has made practical application of this discovery, and has found that the administration of thirty-grain doses of calcium chloride every four hours for a few days before operation has rendered the blood more plastic and has lessened the tendency to bleeding, both at the time of operation and subsequently. After the operation the drug may be continued by the mouth or by nutrient enema.

Before beginning an operation usually attended by considerable hemorrhage, some surgeons have made it a practice to introduce into the circulation through a vein or subcutaneously a litre of normal saline solution.

In operations upon an extremity much blood can be saved by previously placing around the limb an Esmarch elastic band. The constricting band should be two inches or more in width and so placed that important nerves shall not be unduly pressed upon. Negligence of this precaution has occasionally resulted in a more or less persistent paralysis of the parts below the elastic ligature. There is no object in applying this bandage too tightly. Sufficient pressure to arrest the circulation in the arteries is better than more. Before applying the Esmarch band the limb may be elevated for a few minutes. Force of gravity will materially lessen the quantity of blood in the vessels. It is not usually wise to bandage the limb before applying the constrictor; by so doing septic matter might be forced along the vessels into the circulation. Troublesome oozing is apt to follow the prolonged application of Esmarch's elastic band. It is due to a degree of vaso-motor paralysis.

Temporary ligation of vessels may be practised with safety. Senn states that a temporary ligature may be left on a vessel for twenty-four hours without permanent injury, provided the ligature is not drawn tight enough to injure the intima. He has frequently placed temporary ligatures on the carotid at the level of the lower border of the thyroid cartilage, before operating on the parts above. He refers especially to operations performed on the pharynx, parotid, and submaxillary regions. He places a double ligature, which if need be can be made permanent. Temporary may well replace preliminary ligature of large arteries in suitable cases.

Compression of the abdominal aorta as practised by Macewen is a valuable prophylactic measure when indicated.

Constitutional Measures.—Many drugs are held in high repute as hæmostatics. Mention may be made of aromatic sulphuric, tannic, and gallic acids, spirits of turpentine, ergot, acetate of lead, and opium. Some act by producing clotting, some by stimulating the vessels to contract, and opium by equalizing the circulation and thus lessening intravascular pressure at the bleeding point. Turpentine has many advocates. It may be given three or four times daily in doses of ten to fifteen minims. In hemorrhage from the intestinal mucous membrane opium has been found very useful.

Stypticin, hydrochloride of cotamin, is the base of the opium alkaloid narcotine. It is a yellow, inodorous, bitter powder. It is usually given in doses of three-fourths of a grain from five to eight times daily. In some cases three grains or even more may be safely given. A ten-per-cent. solution may be introduced in the form of deep intermuscular injections. It is said to have yielded good results (Senn).

Suprarenal capsule is now being used largely as a styptic. Its active principle is called adrenalin. Powdered suprarenal capsule may be used locally or may be given internally in doses of two or five grains. Adrenalin is very readily oxidized, and is on the market in solution. That prepared by Parke, Davis & Co., is adrenalin chloride 1 to 1,000 of normal saline solution. Its permanence is maintained by the addition of 0.5 per cent. of chloretone. It may be used locally or internally in doses of from five to thirty minims. Locally it acts in very weak solution. A solution made by adding one part of the 1 to

1,000 solution to one thousand parts of sterilized normal salt solution is an effective local astringent. Powdered suprarenal body and its active principle adrenalin act by causing the contraction of the walls of the vessel. Evidence of its effectiveness is accumulating daily. The writer has found it most satisfactory in arresting hemorrhage in epistaxis and in bleeding piles. As it acts by stimulating the contraction and closure of the gaping vessel, it might be expected to fail when applied to vessels whose surroundings prevented contraction, as, for instance, in the indurated base of a gastric ulcer or perhaps in hemorrhage from bone.

Local Treatment.—Arterial hemorrhage may be arrested spontaneously by the contraction of the vessel wall and the clotting of the blood. "If a small artery is completely divided the circular fibres of the muscular coat contract and narrow the orifice; at the same time the internal and middle coats curl up in the interior of the vessel, and the longitudinal fibres contract and shorten it, so that it retracts within its sheath. As a result, there is clotting of blood; as soon as the blood comes in contact with the tissues which are injured, or which are not similar to the lining membrane of the vessels, it undergoes coagulation. Consequently, as soon as the blood escapes from the vessel, clotting tends to take place, unless the escape of blood be so free that the clot is swept away by it. The clotting within the vessel extends up to the nearest collateral branch." Later on, the clot becomes organized into fibrous tissue. If the vessel is only partially divided it cannot contract within its sheath and the hemorrhage is more apt to continue. The spontaneous arrest of hemorrhage from veins and capillaries is due chiefly to clotting and sealing by lymph (Cheyne and Burghard).

Of all the artificial methods of arresting hemorrhage that by *ligature* is far and away the most important. The aseptic ligature is one of the great results of Lister's work. Of the absorbable ligatures catgut is the chief, and silk is the ideal non-absorbable ligature. Catgut may now be prepared in a manner that renders it aseptic and not too readily absorbed. It is certainly the best ligature to use in a field that is, or is likely to become, infected. Silk has the great advantage of being easily prepared and may be used in aseptic tissues. It is better to use the smallest sizes of both catgut and silk that can be used with safety. It is no longer thought necessary to tie a ligature tightly enough to rupture the intima. If the walls of the vessel are brought firmly in contact adhesions between them will take place and the vessel be quite safely occluded.

Suture of wounds in large arteries and veins may be successfully accomplished. Although Lambert, of Newcastle, successfully sutured a wound of the carotid artery in 1762, but little attention has been given to this method of closing wounds of blood-vessels until recent years. This method of closure should be adopted in wounds of important vessels, such as the aorta, carotid, axillary, or femoral arteries, when not more than half the circumference of the vessel is divided and when the wound is aseptic. Experiments seem to show that if end-to-end anastomosis is performed, after complete division of the artery, complete occlusion will occur in a few weeks, but not until sufficient time has elapsed for the collateral circulation to become established. The endothelial and connective-tissue proliferation which closes the wound in a part of the vessel wall goes on to complete occlusion when the whole circumference has been divided and afterward stimulated by many needle punctures and by the presence of the suture material. Closure of wounds of veins by means of sutures has also been practised successfully. In the suturing only the outer coats should be included, the intima being avoided. The sheath of the artery should also be sutured.

Pressure is a valuable means of controlling hemorrhage from small wounds and from veins. The hemorrhage from a ruptured varicose vein is thus readily stopped. Even bleeding from the sinuses of the brain may often be effectually arrested by pressure. In applying pressure it is important to get the pad directly on to the bleeding vessel. If this is at the bottom of a deep wound and it is not desirable to enlarge it, a graduated compress may be applied. Place first simply a small pad deep down on the bleeding point, then another against the first, and so on until sufficient pressure is obtained. In emergency cases, when bleeding is taking place from an extremity, a bandage or handkerchief or a pair of suspenders may be placed around the limb above the bleeding point. This may be tightened by twisting as in the Spanish windlass.

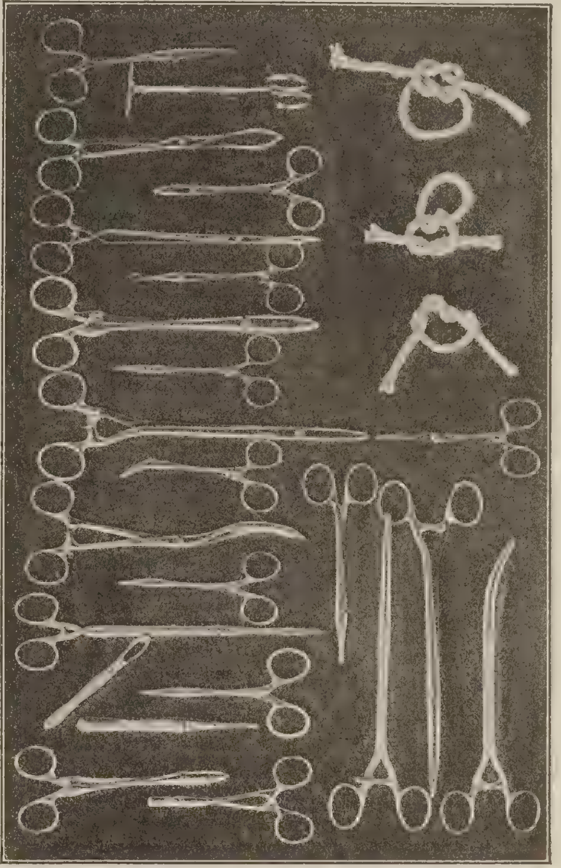

FIG. 2600.—Various Contrivances in Common Use for Arresting Hemorrhage. The three knots shown in the right-hand upper corner of the picture represent respectively (from above downward) the *surgeon's knot*, the *granny knot*, and the *reefer's knot*. Immediately below the last knot, placed transversely, is *Pean's artery forceps*; and below this are four different types of forceps known respectively (from left to right) as *Armstrong's forceps*, *Doyen's clamp forceps* (straight), *Terrier's clamp forceps* (curved), and *Richelot's clamp forceps* (lateral-curved). The left half of the picture is occupied by a series of eighteen different patterns of forceps known respectively (from above downward) as (1) *Kocher's forceps*, (2) *Pozzi's T-forceps*, (3) *Bottini's forceps*, (4) *Tait's forceps*, (5) *Pean's long light bleeding-point forceps*, (6) unnamed pattern of forceps, (7) *Greig Smith's heavy forceps*, (8) *Halsted's mosquito-point forceps*, (9) *Segond's bleeding-point forceps* (heavy), (10) *Horsley's lateral angular forceps*, (11) *angioclast*, (12) *Horsley's artery forceps* (curved on the flat), (13) *Pean's long bleeding-point forceps*, (14) *Hamilton's artery forceps*, (15) *Horsley's artery forceps*, (16) *Esmarch's torsion forceps*, (17) *Greig Smith's small forceps*, (18) *Ferguson's artery forceps*.

Elevation of the limb is of material assistance. The pressure of the hæmostatic forceps permanently stops the bleeding in many small cutaneous vessels. Doyen extended the application of this principle in his angiotribe.

Torsion has not been very extensively used. By torsion the intima and media are ruptured. They curl up, plug the lumen of the vessel, and are held by the twisted adventitia. If applied to large arteries the vessel should be caught, freed from its sheath and surrounding tissues, and held by one pair of forceps at a point above where it is desired to rupture the inner coats. The cut end of the vessel is then caught by another forceps and twisted until the rupture is felt to occur. It can scarcely be called a safe method and should be confined to small and cutaneous vessels. In such cases it is unnecessary to apply more than the one forceps and that to the cut end.

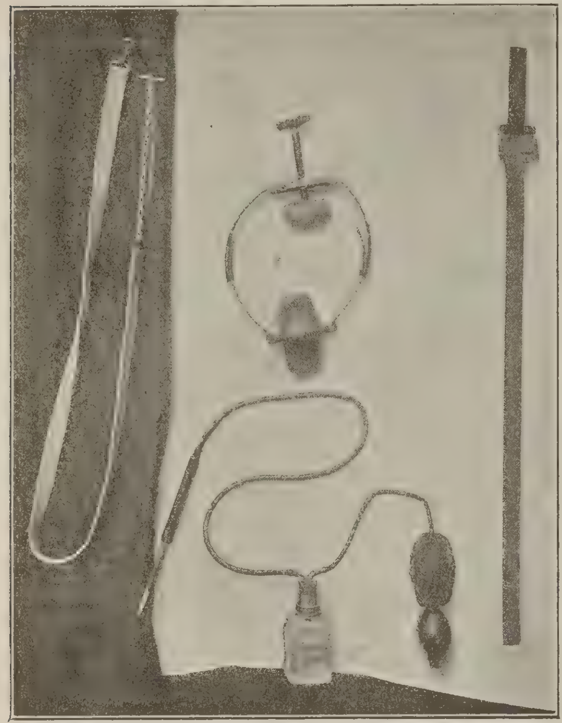

Fig. 2601.—Other Apparatus used in Arresting Hemorrhage. On the left-hand side, Esmarch's flat tourniquet; on the right, emergency tourniquet; in the centre, above, Skey's arterial compressor; in the centre, below, thermo-cautery apparatus.

The *cautery* is still sometimes found useful as a hæmostatic, particularly to arrest oozing from surfaces that are deep and inaccessible or where, because of the thinness of the tissue or its extreme friability, a ligature is contraindicated. The Paquelin thermocautery is now generally used, and for hæmostatic purposes the point should be only of a dull red heat, just turning black. If too hot it does not arrest the bleeding, and if too cold it sticks to the tissue. It is said to be less effective as a hæmostatic than the old cautery irons, but is much more convenient.

Hemorrhage from bone is sometimes troublesome. The bleeding vessel may have retracted into a bony canal, as happens, for example, in the case of the middle meningeal in the Hartley-Krause operation for removal of the Gasserian ganglion. If the vessel cannot be caught the bony canal may be plugged with gauze, an ivory peg or a bit of sterilized wood. For the oozing from the edges of divided bone Victor Horsley has prepared an antiseptic wax. It is composed of beeswax 7 parts, almond oil 1 part, and salicylic acid 1 part. It is often very helpful. Suprarenal extract or adrenalin may be found the most satisfactory of all. The writer used it successfully in a case of secondary hemorrhage in acute osteomyelitis.

Cold, locally applied, in the form of Leiter's tubes, or cracked ice, may be used in robust patients, for the arrest of oozing. It acts by stimulating the muscular coats to contract and reflexly may stimulate vessels situated beneath the surface. Cold should generally be avoided in the weak and in acute anæmia.

Heat, preferably in the form of hot saline solution, has a decidedly styptic action on tissues. The temperature may be 110° to 115° F., or as hot as the hand can bear.

Hot steam has been applied to bleeding surfaces as a styptic by Snegirew, with satisfactory results. He used it at a temperature of 212° F. in the cavity of the uterus (Senn).

Treatment of the Acute Anæmia resulting from hæmorrhage is only second in importance to the arrest of the bleeding which caused it. Stimulants must be exhibited with caution until the bleeding is stopped, as their effect is often to increase intravascular pressure. They have an important place in the treatment when used with discretion and good judgment. Opium is also valuable as an equalizer of the circulation and a determinant of blood to the cerebral centres.

Transfusion.—At the head of the list, however, stands normal saline solution, six-tenths of one-per-cent. solution. It may quickly be prepared by adding a drachm of salt to the pint of boiled water, cooled to a temperature of 100° F. A pint thrown into the rectum is useful. Much better and quicker results are obtained by injecting it beneath the skin in the infraclavicular and submammary regions. A double-branched tube with a hollow needle attached to each branch affords the most expeditious means of acomplishing this. Two pints can thus be introduced in from ten to twenty minutes. While it is being injected gentle massage should be continuously practised.

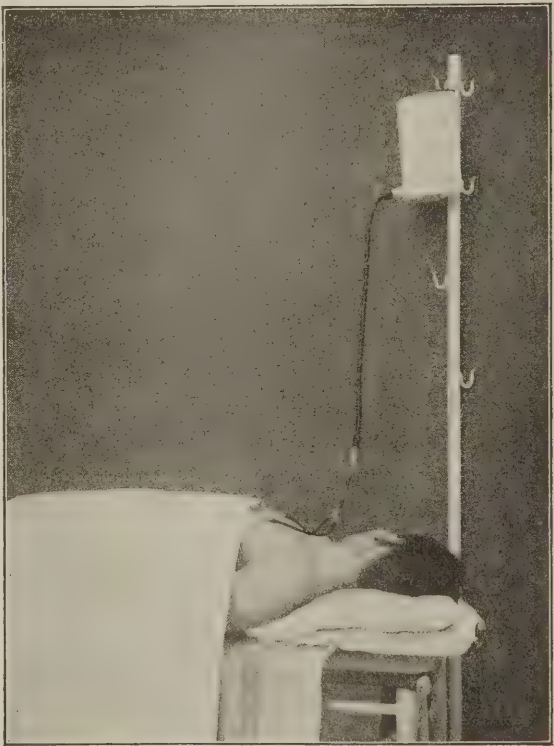

Fig. 2602.—Apparatus for Subcutaneous and Intravenous Injection of Saline Solution.

Many prefer in extreme cases to introduce the saline solution directly into the circulation through one of the superficial veins. A vein of the arm just above the elbow is usually selected. This little operation will be most readily accomplished by carefully laying bare the vein selected for a distance of an inch and then carefully passing beneath it a double ligature; tie the distal ligature; with a sharp knife make an incision in the wall of the vein just large enough to admit the end of the needle or nozzle; then tie the proximal ligature around the vein and the included needle or nozzle. As much as two or three pints of solution may be introduced. Then withdraw the nozzle and tie the proximal ligature, or pass a fresh ligature around the vein at that point. Precautions must be taken not to permit any air to enter.

In extreme cases until the bleeding is stopped elastic bands may be applied to the extremities close up to the body, thus saving the patient's blood. The foot of the bed should be raised eight or ten inches, thus sending the major part of the blood toward the great centres of the nervous and circulatory systems. This is a most effective method of auto-transfusion.

HENBANE.—Hyoscyamus. "The dried leaves and flowering tops of *Hyoscyamus niger* L. (fam. *Solanaceæ*) collected from biennial plants" (U. S. P.). Of the three forms in which this plant presents itself, the most efficient one is insured by the language of this definition and of the accompanying description. The plant grows both as an annual and as a biennial. The former, and the latter during the first year of its growth, are to be rejected. The last-mentioned bears no flowers and is excluded by the words "flowering tops." Flowers are supplied by the annual form, but they lack, to a great extent, the "purple veins" called for by the description. Thus the highly active second year's growth of the biennial plant is the only form which affords a drug markedly characterized by yellow flowers with purple veins.

Henbane is a native of Europe and Western Asia, where it is a very common and abundant weed. It is also cultivated for medicinal purposes. Rarely, it occurs as a weed in the United States. It looks somewhat like the stramonium, but is not so large and is even more coarse-looking and more strongly viscid-hairy. The habit of the inflorescence is shown in the accompanying cut.

The following is the description of the drug:

Coarsely, roughly, and glandularly hairy throughout, except the corollas; larger leaves shortly and broadly petioled, 15 to 25 cm. (6 to 10 in.) long, and two thirds as broad, the upper becoming smaller and sessile; blades angularly ovate, acute, coarsely and angularly toothed or lobed, grayish-green or slightly yellowish-green; flowers in pseudo-racemes, short-pedicelled the calyx cylindraceous, somewhat contracted above the ovary, unequally five-toothed, the teeth triangular, acute, the corolla campanulate, five-lobed, sulphur yellow, with deep purple veins; capsule a two-celled pyxis; odor heavy, narcotic; taste bitter, somewhat acrid. From tobacco, henbane is distinguished by its incised leaves, from stramonium by its hairiness, and from belladonna by both these characters.

A full account of the composition and properties of henbane would constitute, to a great extent, a duplication of our account of belladonna. It may therefore be most profitably considered by comparing it with that drug.

The alkaloidal percentage of henbane is very much lower than that of belladonna. Some authorities place it below one-tenth of one per cent., while others state it as high as three-tenths. The best authorities agree upon 0.2 to 0.25 per cent. as the standard. The most of this alkaloid is *hyoscyamine*, separately treated Whether any atropine is present, is disputed, but if so, the amount is unimportant. Atropine may readily form during manufacturing operations, by conversion of the hyoscyamine. The most important variation from belladonna is in the presence of a small amount of hyoscine or scopolamine, also separately considered, in its alphabetical order.

The general similarity of henbane to belladonna in properties and uses will readily be inferred from its composition; yet the slight characteristic differences stated are sufficient to establish noticeable differences in these directions. These differences may be stated generally by saying that henbane is more distinctly sedative than belladonna, and that this sedative action extends to the cerebral, motor, and sensory functions, though less so to the latter. The marked tendency to delirium resulting from the use of belladonna may be quite absent in that of henbane, or even the opposite effect can be induced.

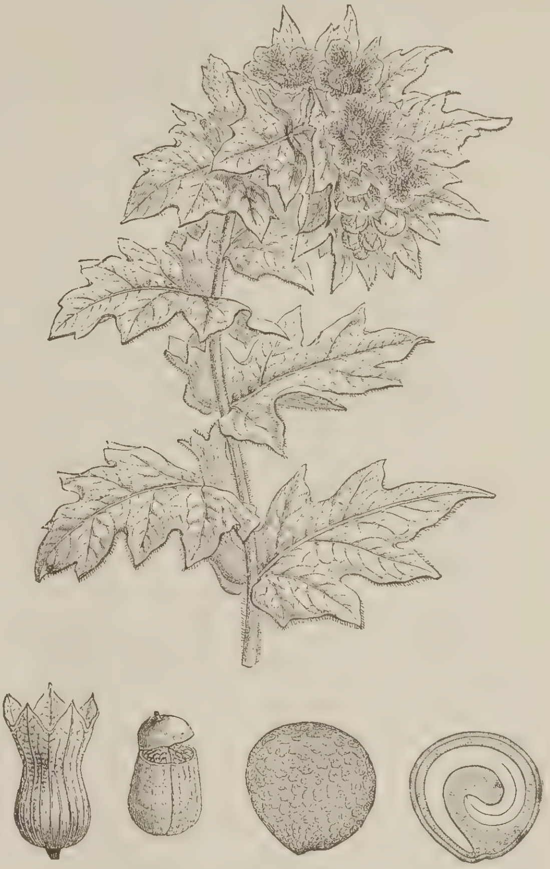

Fig. 2603.—Henbane, Plant and Fruit (about one-half natural size) — Seed Enlarged. (Baillon.)

Hence the distinct uses of henbane. It is scarcely employed in eye practice, though it produces very similar effects to those of atropine. If distinct cerebral-depressant effects are desired, it is better to give hyoscine itself, but when we wish the effects of belladonna, but desire to avoid its mental disturbances, henbane is chosen. Its commonest uses are intestinal and cystic, or renal. The former use is mostly in combination with purgatives which would otherwise be griping. At the same time that this unpleasant effect is averted, the henbane itself powerfully promotes peristalsis, and is therefore laxative, even excelling belladonna in this respect. The second-named use is as a sedative diuretic, relieving both painful and spasmodic conditions of the genito-urinary tract. Here again it is usually combined with other drugs, such local diuretics as buchu, kava, or oil of juniper. It is, however, often given alone in colic, cystitis, calculus, etc. It is commonly given in larger doses than belladonna. There are official an extract, the dose of which is 0.3 to 1 gm. (gr. ss.–iss.); a fluid extract, dose

0.3 to 1 c.c. (♏ v. to xv.); a 15-per-cent. tincture, dose 2 to 6 c.c. (fl ℥ ss.–iss. or ij.).

Henbane Seeds, though unofficial, are largely employed. They are light-brown, broadly kidney-shaped, and flattened, 1 to 1.5 mm. long and nearly as broad, and finely pitted. Thus they bear a close resemblance to stramonium seed, except in color and in their size, which is one-fourth to one-third as great. Their alkaloidal composition is about the same as of the herb, but they contain twenty-five per cent. of fixed oil, and a little resin. Since their percentage of alkaloid is a little greater, the dose of the seeds is about one-fourth or one-third smaller than that of the herb.

There are eleven species of hyoscyamus, and several of them, notably *H. album* L., have similar properties and uses to those of *H. niger*. *Henry H. Rusby.*

HENNA.—Under this name the leaves of *Lawsonia inermis* L. (fam. *Lythraceæ*) are extensively used in Eastern countries as a pigment for coloring the skin and hair and also as an astringent. Their use in jaundice is doubtless due to a superstition relating to their color. They contain a peculiar astringent resinous substance which has been called henotannic acid. *Henry H. Rusby.*

HENPUYE.—Goundou, Anakhré, Gros Nez, Dog Nose. Under the second, third, and fourth of these names the French writers, and under all of them except *gros nez* the English writers, describe a disease which up to the present has not been found outside of tropical or sub-tropical countries. The trouble in question consists of a peculiar form of exostosis or bony tumor, situated on each side of the nose. The growth is always bilateral, and usually symmetrical, but occasionally one side grows larger or more rapidly than the other. The exostosis is from the external surfaces of the nasal bone and the nasal process of the superior maxillary bone, with involvement of the body of the superior maxillary bone in severe cases. The trouble is confined to the bone; the nasal cavities, nasal cartilages, mouth, or orbits not being affected except mechanically by the presence or pressure of the tumor.

Geographical Distribution.—When first noticed goundou, or henpuye, was supposed to be limited to the Ivory Coast of West Africa and to the district watered by the river Comoë.[1] Since then it has been found in the neighboring territory of the Gold Coast;[2] and further afield at Sierra Leone (*Jour. of Trop. Med.*, ii., 145); but in every case the sufferer was a negro. But cases have since been reported of a Malay being affected in Sumatra (*Jour. of Trop. Med.*, iii., 11), a native in Southern China (*Jour. of Trop. Med.*, iii., 110), and some negroes in Jamaica, West Indies.[3] The case of goundou reported from Singapore (*Jour. of Trop. Med.*, July 1st, 1901, p. 213) was probably not one of goundou at all, as the tumor was not solid but consisted of a shell of bone covering cerebral meninges. We may safely say that the disease is confined to tropical and sub-tropical countries, with a predilection for the negro race.

General Description and Course of the Disease.—The trouble generally commences with a cold in the head followed by headaches chiefly over the frontal region; these headaches last for about a year, when a slight fulness is noticed on each side of the nose; as this swelling increases the headaches are apt to disappear. Sometimes the tumor will continue to grow for a year or two only, and sometimes it will develop slowly for many years. The overlying skin is apparently quite normal, being freely movable and quite healthy in appearance. The tumors are non-fluctuating, grow slowly and almost symmetrically with no tendency to suppurate, have an ovoid shape with the long axis outward and downward, become intensely hard, but are not as a rule painful except in wet weather. There is no tenderness on pressure. The size varies from a pea to an orange or an ostrich's egg,[1] but a pigeon's egg may be taken as an average of the dimensions attained. Of course the countenance is terribly deformed. In some cases a bloody or purulent discharge from the nose has been observed; in others there has been neither discharge nor sore. The cartilages of the nose are not involved, nor is the nasal duct; and there is no epiphora. Sometimes the tumor will press upon the anterior nares and compress the cavities, with the result that the voice obtains a nasal twang. The orbital cavities may be similarly pressed upon, but generally the growth of the tumor causes first a squint, then the patient may have to flex his head in order to see over the tops of the tumors; and later on, the tumors becoming still larger, there is a total obstruction of vision. But the eyeball is not destroyed. In Maclaud's cases[1] the patients were free from tuberculosis and syphilis. Chalmer's cases[2] had all suffered from yaws.

Etiology.—The natives of the Ivory Coast believed in a divine or diabolical origin of the disease. Maclaud[1] advanced the theory that the trouble was parasitic, being due to the larvæ of some dipterous insect; but the bilateral and symmetrical nature of the complaint remain unexplained by this hypothesis. Further, for the acceptance of this theory, it would be necessary to know the particular insect or insects with their exact habitat, and to ascertain whether this insect is found in West Africa, China, Sumatra, and the West Indies. Chalmers[2] considers the disease the result of yaws or frambœsia, which certainly seems more plausible; he asserts that goundou follows that disease, that it is caused by the absorption of the yaws poison from the mucous membrane of the nose and is carried by the lymphatics and small vessels through the foramina in the nasal process of the superior maxilla, and that in the cases which he observed there was a sore in and some discharge from the nose. But if goundou was caused by yaws there would have been hundreds of cases reported from the West Indies alone, where yaws has been carefully studied. Strachan considers it the result of atavism;[3] this theory seems the most probable of any, and, as in the somewhat similar case of the "horned men" of Africa, these bony outgrowths may be considered hereditary or at any rate characteristic of race. Of these "horned men" Macalister says "that outgrowths here may be really race characters is not to be entirely ridiculed, for the neighboring malar bone which here, according to O'Reilly's description, participates in the swelling, certainly shows certain race peculiarities, such as the bigger *Tuberositas malaris* of the Mongolians, and the *Processus marginalis*, whose race peculiarities have been pointed out by Werfer" (Bland Sutton, "Evolution and Disease," 1890, p. 197, English edition). It may be well to mention here the chief differences between goundou and the deformity of the horned men: (1) in the former the tumor is fairly parallel with the nasal bone, in the latter it is at right angles to it; (2) in goundou the exostosis is from the nasal process, in the "horned men" it is from the infraorbital ridge; (3) in goundou the malar bone is not affected, while it is apt to be involved in the latter condition.

Pathology.—The growth consists of a centre of cancellous bone, covered with a casing of hard compact bone, from which the periosteum can be very easily removed. The growth is in all probability an osteoplastic periostitis.

Treatment.—Iodide of potassium has been tried but without success. The only treatment is surgical. A longitudinal incision is made in the skin over the tumor, with perhaps a cross incision to allow more room, and the tumor can be removed with a saw, gouge, or bone forceps; the hemorrhage, which is slight, can generally be controlled by pressure; and under the ordinary aseptic precautions the parts unite by first intention.

HEREDITY.—Heredity may be defined as a correlation between the variations of characteristics in individuals related to one another by birth.

The words used as the names of phenomena are apt to influence our conceptions of their character. This is particularly true of heredity. No doubt, most persons think of heredity as similar to the inheritance of goods and chattels. To them a son has received from his father the color of his eyes very much in the same way that he may expect to receive his seal ring or his watch. Such an idea is entirely foreign to the scientific conception of heredity, and in using the term it is necessary to keep in mind always its metaphorical character in order not to confuse the metaphor with the reality that it represents. Scientifically heredity is merely a special case of the correlation of variations.

This correlation may be *direct*, as between father or mother and son or daughter, between grandfather and grandson, etc.; or it may be *collateral*, as between brothers, sisters, brothers and sisters, uncles or aunts and nephews or nieces, between cousins, etc. In man and the higher animals inheritance is always *biparental*. That is to say, every individual has two parents; but there are cases in which there is only one parent, as in certain insects and crustacea that produce young most frequently by means of parthenogenetic eggs, and among some of the lower animals and the plants, which frequently produce new individuals by means of buds, underground shoots, etc. In such cases inheritance is *uniparental*.

Of direct inheritance there are three important types: (1) *blended* inheritance, where the child is intermediate in character between the two parents, as in stature; (2) *exclusive* inheritance, where the character of the child is like that of one parent but not like the other, if they differ, as in the color of the eyes; (3) *particulate* inheritance, where the characters of both parents appear in the child, but do not blend; for example, a pup may have spots, some of which are of the color of the mother, while others are like the coat of the sire, or a boy may have a nose like his father and eyes like his mother.

Variability.—Variation is deviation from the type, and for most statistical inquiries the type taken as the standard is the arithmetical mean of the population or group. Deviations are of two kinds, abnormal, such as the "sports" of the horticulturist, and normal variations, which may be observed in every family or other group of individuals. The normal variations are found to be distributed about the mean in a way that may be expressed by certain mathematical formulæ derived from the theory of probability and chance (see articles *Evolution* and *Variation*). The relations most frequently met with are represented in Fig. 2604.

The rectangles in this figure taken together form what is called a polygon of frequency, and the flowing curve is a theoretical curve of chance, or probability, that has been fitted to the polygon, which represents graphically the observed facts. Now if we plot the curves of two sets of observations, employing units of scale of the same value in both, the differences in the forms of the curves will depend upon the number of individuals in the most frequent class, or *mode*, that is the tallest rectangle, and, supposing the curve to be symmetrical, upon the amount of *deviation* on either side of the mean. The amount of deviation, that is the *variability* of the group, is measured by what is called the *standard deviation* (the "mean error" of the mathematicians). This is obtained by multiplying the square of the deviation from the mean of each class by its frequency, adding all the results together, dividing by the total number of observations, and finding the square root of the quotient $\left(\sigma = \sqrt{\frac{\Sigma\,(x^2 f)}{n}}\right)$. The Greek letter σ is used as the symbol for this quantity. Its relation to the curve of frequency is shown at σ in Fig. 2604.

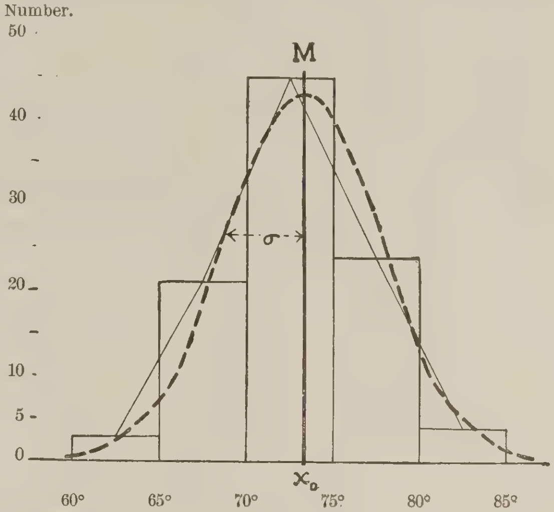

FIG. 2604.—Graphic Representation of a Series of Variations. Variation in the width of the angle at the apex of the shell in *Purpura lapillus*. Mx_0, position of the mean; σ, standard deviation.

Correlation.—"Two variable organs are said to be correlated when the variation of one is accompanied on the average by more or less variation of the other, and in the same direction" (Galton, 1888). In order to determine the degree of *correlation* between two organs accurately, it is necessary to have a large number of observations and to arrange them in a "correlation table" like the one given below, Table I.

TABLE I.—CORRELATION IN THE LENGTH OF FIRST JOINT OF INDEX FINGERS OF WOMEN, RIGHT AND LEFT HANDS. (From Whitely and Pearson.)

LEFT HAND (RELATIVE CLASSES).	RIGHT HAND (SUBJECT CLASSES).													Totals.
Length of joint in inches.	1.95 to 2.00.	2.00 to 2.05.	2.05 to 2.10.	2.10 to 2.15.	2.15 to 2.20.	2.20 to 2.25.	2.25 to 2.30.	2.30 to 2.35.	2.35 to 2.40.	2.40 to 2.45.	2.45 to 2.50.	2.50 to 2.55.	2.55 to 2.60.

2.30 to 2.35	....	....	....	....	....	....	7	41.25	24.5	3.25	....	....	....	76
2.35 to 2.40	....	....	....	....	....	....	1	5.5	17.75	13.5	0.25	....	....	38
2.40 to 2.45	....	....	....	....	....	....	....	....	3.5	12	6.5	0.5	....	22.5
2.45 to 2.50	....	....	....	....	....	....	....	....	1	2.75	1.75	0.5	....	6
2.50 to 2.55	....	....	....	....	....	....	....	....	....	....	1	....	0.5	1.5
2.55 to 2.60	....	....	....	....	...	....	....	....	....	....	....	....	0.5	0.5
Totals	5	13	29.5	48	82.5	98	100.5	82	49.5	31.5	9.5	1	1	551

The construction of this table may be understood from a consideration of the first column of entries. Five fingers of the right hand were found in which the length of the first joint was between 1.95 and 2.00 inches. These form a "*class.*" Of the corresponding fingers on the left hand only one was of the same length. One was shorter, 1.90 to 1.95 inches; and three were longer, one of these being exactly 2.05 inches long, was placed half in the relative class above and half below that mark. Thus the totals at the base of the columns show the number of fingers in each class of the right hand, while the figures in the columns show the number of associated fingers in each class of the left hand. The right hand is said to be the *subject* and the left hand the *relative* and each column is called an *array*. Conversely, we may, without altering the table, regard the left hand as subject, and the right hand as relative, and the arrays would then be the rows of figures, which are added up in the last column.

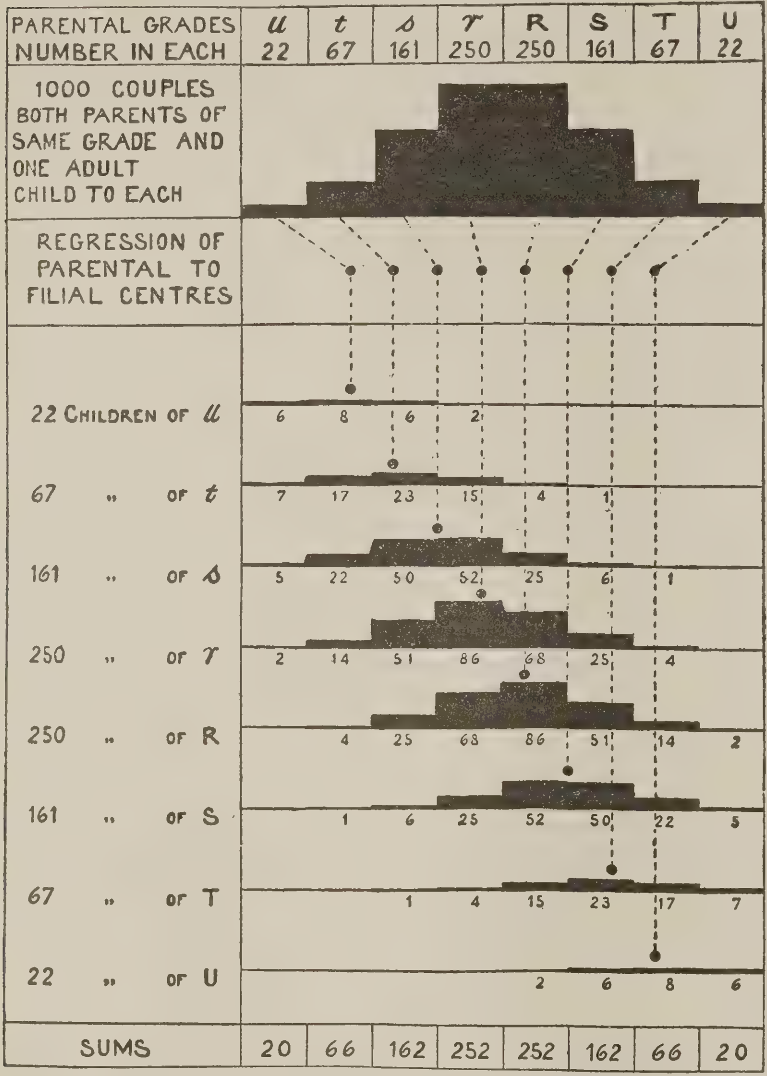

FIG. 2605.—Galton's Standard Scheme of Descent. (From Galton.)

Now by this means we may study the correlation of any pair of organs in respect to any characteristic that permits of being expressed in quantitative terms. We may compare not only different organs or parts of the same individual, but also any suitable characteristics of distinct individuals, provided they are related in some constant way, as for example husbands and wives, fathers and sons, brothers and sisters, etc. But fathers and sons, and brothers and sisters are related by birth, and when we study the correlation between them we are studying what is called natural inheritance.

The Phenomena of Heredity.—Some of the most important results of a long series of studies of inheritance are represented graphically in Galton's "Standard Scheme of Descent," which is reproduced in Fig. 2505. This scheme represents a supposed case in which there are a thousand couples of parents and in which each parent is mated to another of the opposite sex having relatively the same deviation from the mean in the character measured, and each couple is supposed to have one adult child. The parents are divided into eight classes having the relative frequency and deviation from the mean represented by the polygon of frequency at the top of the figure. The classes *R*, *S*, *T*, *U*, present positive deviations from the mean, and *r*, *s*, *t*, *u*, have corresponding negative deviations. The distributions of the variations in the children of each parental class are represented by the polygons below—drawn to the same scale. An attentive study of this diagram reveals many interesting things. In the first place the filial polygons are similar in form to the parental one. A dot above each filial polygon indicates the position of its mean; and the second point of interest is that the mean of any group of children does not correspond with the mean of its parents, nor with the mean of parents in general, but lies between the two. Still the mean of the children of *u* is much nearer the mean of *u* than the children of *U*. There is evidently a correlation between the parents and their offspring. But this is not perfect, for, while parents with negative deviations from the mean have children whose deviations on the average are negative and those with positive deviations have children who deviate on the average in the positive direction, still in each case the mean of the children deviates from that of their parents and toward the mean of parents in general, which is probably the same as the mean of the population of which they form a sample. This tendency for the mean of the children to deviate from the type of their parents toward the type of the population in general is called *regression*. The results that follow from the laws of variability and regression in children are of considerable interest and importance. If we suppose parents of grade *U* to be especially gifted in some way, we see that when both parents are of this grade they may hope to have children equally gifted in the proportion of 6 to 22 or, say, two children equally gifted with themselves in a family of seven. On the other hand, if we take twenty children in grade *U*, only six will have parents as gifted as themselves, and two of them will be derived from very mediocre parents of grade *R*. Nevertheless, the chances that the exceptional parents will produce equally exceptional children as against mediocre children are 6 to 2, while the chances of mediocre parents of grade *R* are 2 to 154. The reason that there are so many gifted children of relatively mediocre parents is that there are so many mediocre parents. When we add up all the children in each grade, as is done at the bottom of the scheme, we find that the mean and variability of children in general is nearly the same as of parents in general. They would have been more nearly the same if we had taken larger numbers. So, if no selection is being made, the population as a whole in one generation will be the same in character as the previous one.

For the exact study of inheritance use is made of correlation, or regression, tables similar to Table I. We have converted Galton's scheme of descent into such a table (Fig. 2606) represented graphically by placing each filial polygon as an array beneath the centre of the corresponding parental grade, or class; and adding up the filial grades at the right. In this diagram the parental deviations are measured on the horizontal scale, and the filial deviations on the vertical scale. The heights of the shaded areas represent the frequency of each parental class, and widths represent frequency in the filial classes.

The line *YY* occupies the position of the parental mean and the line *XX* the position of the filial mean. The two lines cross at right angles in the middle of the diagram. The line *AB* is a straight line drawn through the position of the mean (represented by a round dot) in each array and through the point of intersection of the lines *XX* and *YY*. It is called the *regression line*. In an actual regression table it would not pass through every dot, but would be placed so that the deviations of the means above and below it would balance one another as nearly as possible. Now the slope of this line may be measured by taking the ratio between the distance of any point on the line *AB* from the line *XX* and the distance from the same point to the line *YY*. A point three spaces to the left or right of the line *YY* will be two spaces below or above *XX*. So the slope of *AB* may be said to be 2 in 3, or $\frac{2}{3}$. This quantity (in this case, $= \frac{2}{3}$) is called the *coefficient of regression*. It is the quantity which multiplied by the deviation of a parental class from the mean of parents will give the average deviation of its array of children from the mean of children. For example, parents of grade *S* deviate on the average one and one-half spaces of our scale from the mean of parents. $1\frac{1}{2} \times \frac{2}{3} = 1$, which is the deviation of the mean of the children of *S* from the mean of children in general. The slope of the regression line will differ in different cases. If there were no regression, the deviations of the parental class and of the array of offspring would be the same, and the regression line would occupy the position *CD*. On the other hand, if there should be complete regression, the mean of the filial array would be the same as the mean of children in general, no matter how great the deviation of their parents, and then the regression line would coincide with *XX*. The regression line, then, may lie anywhere between the position *CD* where the coefficient is 1 and *XX* where it is 0. So the less the regression the greater the coefficient, and *vice versa*. But it is evident that the slope of the line may depend on several factors. If we should plot the parental deviations on a scale having units twice as long as in the scale of filial deviations, the slope of the line would be reduced one-half. But having equal units of scales, we should find the same result if the variability of parents were twice that of children. Now differences of variability are found in the practical study of correlations and must be taken into account. This is done if we regard the slope of the regression line as the resultant of two factors: the ratio of the two variabilities, and an unknown factor that is called the *coefficient of correlation*.

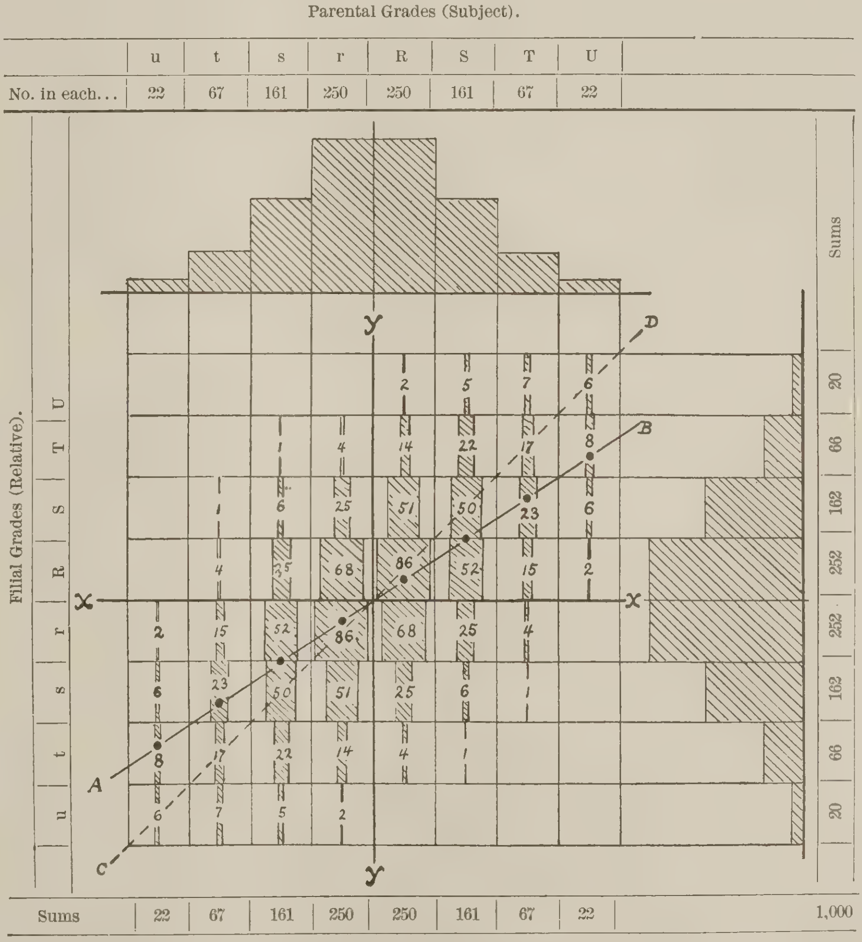

FIG. 2606.—Regression Table, Children on Parents. One thousand parents with mates of same grade and one adult child to each. (Data from Galton.)

Putting this into symbols, in this case $\frac{2}{3} = \rho\frac{\sigma_2}{\sigma_1}$, where σ_1 = standard deviation of parents, σ_2 = standard deviation of children, and ρ = coefficient of correlation. From these considerations Pearson has derived a general formula* for calculating the value of ρ as follows:

$$\rho = \frac{\Sigma\,(x\;y\;f\,)}{n\;\sigma_1\;\sigma_2}$$

When there is perfect correlation $\rho = 1$; when there is no correlation $\rho = 0$. In the theoretical example that we have been studying parents and children are supposed to have the same variability,—that is, $\sigma_1 = \sigma_2$. In such a case, of course, $\rho = \rho\,\frac{\sigma_2}{\sigma_1}$, and the slope of the line *AB* represents the coefficient of correlation as well as that of regression.

In practice the coefficients of regression and correlation are found to be essentially the same in collateral inheritance; and also in direct inheritance, if we take into account only one parent of each couple and suppose the other to be chosen at random. The value of ρ calculated from observations in a number of such cases is given in Table II. (see below).

The Mid-Parent.—But in man and the higher animals inheritance is always biparental, and in order to study the true relations between parents and offspring it is necessary to take both parents into account. This involves the correlation of three variable quantities. In order to avoid this difficulty the two parents are combined into a single artificial individual called the *mid-parent.* For example, Galton found that the mean stature of women in England is 1.08 less than that of men. So in order to study the inheritance of stature, he converted the stature of each mother and daughter into its "male equivalent" by multiplying it by 1.08; and he obtained the mid-parent by taking the mean of the father's stature plus the mother's male equivalent. Thus if the father had a stature of 70 inches and the mother of 66 inches, the stature of the mid-parent would be

$$\frac{70 + 1.08 \times 66}{2} = 70.64$$

In the study of heredity, however, deviations from the mean are used more frequently than the absolute dimensions of organs. Therefore Pearson has generalized and simplified Galton's formula for the mid-parent by putting it in this form:

$$\tfrac{1}{2}\left(h_1 + \frac{\sigma_1}{\sigma_2}h_2\right) = \mathrm{H}$$

where h_1 = the deviation in the particular father from fathers in general; h_2 = deviation of mother mated to this father from the type of mothers, σ_1 = standard deviation of fathers in general; σ_2 = standard deviation of mothers; and H = deviation of the mid-parent from the type of mid-parents. This formula will apply to measurements of any organs, and it enables one to calculate easily either the deviation or the absolute value of the organ in the mid-parent. Having calculated the mid-parents, one may study the correlation between children and mid-parents, just as if the latter were single individuals.

The Law of Ancestral Heredity.—Now we are prepared to consider the influence of each ancestor upon the characteristics of the child. Returning to Fig. 2606, if there were no inheritance, the means of all the arrays would lie along the line *XX;* and we may think of heredity as a force† tending to pull each array away from *XX* in the direction of its parental grade, that is, toward the line *CD.* Now the question is, How much of this pull is exerted by each parent, grandparent, great-grandparent, etc.?

From the study of a variety of data, Galton came to the conclusion that, of the total heritage, the mid-parent contributes one-half, the mid-grandparent one-quarter, the mid-great-grandparent one-eighth, and so on. Or, if h be the mean deviation of a given group of offspring from offspring in general and H_1, H_2, H_3, etc., be the deviations from their mid-parental means of the mid-parent, mid-grandparent, etc., of these offspring, then

$$h = \tfrac{1}{2}\,\mathrm{H}_1 + \tfrac{1}{4}\,\mathrm{H}_2 + \tfrac{1}{8}\,\mathrm{H}_3 \;.\;.\;.\; \text{etc.}$$

If the mid-parent contributes one-half, each parent will contribute one-quarter. So we may state Galton's law in the words of Pearson as follows:

"Each parent contributes on an average one-quarter, or $(0.5)^2$, each grandparent one-sixteenth, or $(0.5)^4$, and so on, and that generally the occupier of each ancestral place in the *n*th degree, whatever be the value of n, contributes $(0.5)^{2n}$ of the heritage."

Galton's series, $\frac{1}{2} + \frac{1}{4} + \frac{1}{8} + \frac{1}{16}$, . . . etc. = 1, is a geometrical series having a total of one. But the values $\frac{1}{2}$, $\frac{1}{4}$, etc., may not be true for all species, and Pearson, therefore, proposes to substitute the symbols γa, γa^2, γa^3, etc., in which there are two factors, one constant in each generation (γ), and one which varies in a geometrical series (a, a^2, a^3, . . . etc.). Galton's law would now take the form

$$h = \gamma\,(a\,\mathrm{H}_1 + a^2\,\mathrm{H}_2 + a^3\,\mathrm{H}_3 \;.\;.\;.\; \text{etc.}).$$

TABLE II. (From Pearson.)

Relationship.		Material.	Organs.		Coefficient of correlation ρ.
Subject.	Relative.		Subject.	Relative.

---

* In this formula x and y are the deviations from their means of the two organs of an associated pair, as father and son, f is their frequency, n is the total number of pairs, and Σ is the symbol for addition.

When there is no correlation $\Sigma\,(x.\,y.\,f\,) = 0 \;\therefore\; \rho = 0$.

When correlation is perfect $y = x$ and $\sigma_2 = \sigma_1$.

Then $\frac{\Sigma\,(x.\,y.\,f\,)}{n} = \frac{\Sigma\,(x^2.\,f\,)}{n} = \sigma^2$ and $\frac{1}{\sigma_1\;\sigma_2} = \frac{1}{\sigma^2}$

$\therefore\; \frac{\Sigma\,(x.\,y.\,f)}{n\;\sigma_1\;\sigma_2} = \frac{\sigma^2}{\sigma^2} = 1 = \rho.$

† Note that this is a purely metaphorical expression.

Now when $\gamma(a + a^2 + a^3 \ . \ . \ . \ \text{etc.}). = 1$,

$$\frac{\gamma a}{1-a} = 1 \therefore \gamma = \frac{1-a}{a} = \frac{1}{a} - 1 \therefore a = \frac{1}{1+\gamma}$$

So we may eliminate the quantity a from the formula by substituting this value and our formula becomes:

$$h = \gamma\left(\frac{1}{1+\gamma}\,H_1 + \frac{1}{(1+\gamma)^2}\,H_2 + \frac{1}{(1+\gamma)^3}\,H_3 \ . \ . \ . \ \text{etc.}\right)$$

But if we wish to be very exact, we must take into account the fact that the variability of all the offspring, σ, may differ from the variability of the successive generations of mid-parents, σ_1, σ_2, σ_3, etc., so the ratios of these standard deviations must be included in our formula, which then becomes:

$$h = \gamma\left(\frac{1}{1+\gamma} \cdot \frac{\sigma}{\sigma_1} \cdot H_1 + \frac{1}{(1+\gamma)^2} \cdot \frac{\sigma}{\sigma_2} \cdot H_2 + \frac{1}{(1+\gamma)^3} \cdot \frac{\sigma}{\sigma_3} \cdot H_3 \ . \ . \ . \ \text{etc.}\right).$$

This is the *law of ancestral heredity* as given by Pearson in its complete form. It is undoubtedly a generalization of great importance, and for a number of years to come the chief aim of a large number of scientific investigators will be to test and criticise this law. According to this theory the degree of correlation between parents and offspring will depend upon the hereditary influence represented by the symbol γ. In Galton's original formula $\gamma = 1$, very nearly. The effects of different values of γ are shown in the following table:

TABLE III.—HEREDITY—DIRECT LINE. (From Pearson.)

Offspring and—	COEFFICIENT OF CORRELATION, ρ.		
	When $\gamma = 1$.	When $\gamma = 0.9$.	When $\gamma = 2.35$.
Parent	.3000	.2851	.4000
Grandparent	.1500	.1425	.2000
Great-grandparent	.0750	.0713	.1000
Great-great-grandparent	.0375	.0356	.0500
*n*th order grandparent	$6. \times (\frac{1}{2})\ n.$	$.5702 \times (\frac{1}{2})\ n.$	$.8 \times (\frac{1}{2})\ n.$

These theoretical values of the coefficient of correlation should be compared with the values obtained from observation in Table II. From the study of "a really considerable amount of quantitative measurements of heredity" Pearson concludes that the values of the coefficient of heredity given in the first column of Table III. (when $\gamma = 1$) "seem to fit the observed facts fairly well in the case of *blended* inheritance." The coat color of horses and dogs appears to belong to one of the other types of heritage, either exclusive or particulate; and it seems to be doubtful if these types come under Pearson's law of ancestral heredity.

Table II. gives cases also of collateral inheritance, and the theoretical values, when $\gamma = 1$, are given below:

TABLE IV.—COLLATERAL HEREDITY. (From Pearson.)

Relatives.	Correlation when $\gamma = 1$.
Brothers	.4000
Uncle and nephew	.1500
Great-uncle and nephew	.0625
First cousins	.0750
First cousins, once removed	.0344
Second cousins	.0172
Second cousins, once removed	.0082
Third cousins	.0041

We see that brothers are more closely related than parent and offspring, and the correlation between first cousins is the same as that between offspring and great-grandparent.

Uniparental Inheritance.—The coefficient of correlation, or heredity, between brothers is of special interest because of its similarity to certain other correlations.

In Galton's standard scheme of descent it is supposed that both parents are of the same grade and the coefficients of regression and correlation were found to be equal and have the value $= \frac{3}{5}$. When $\gamma = 1$ this value would be 0.6. But this is a condition that would not be met with ordinarily in nature. More often there is little or no correlation between husband and wife in the characters measured, that is, mating is at random so far as the character in question is concerned, and under these conditions the mid-parents will be less variable than the offspring; and therefore the coefficients of regression and correlation will differ. Pearson has shown that, when $\gamma = 1$, if there be no sexual selection, the coefficient of regression of offspring on mid-parents remains 0.6, but the coefficient of correlation is reduced to 0.4242. With random mating, then, the offspring will resemble their mid-parents more nearly than they will either single parent, the correlation between single parents and offspring under these conditions being = 0.3.

Dr. E. Warren has made an interesting comparison between these results and observations that he has made upon heredity in parthenogenesis. Daphnia is a small fresh-water crustacean that reproduces rapidly under favorable conditions by means of parthenogenetic eggs, thus presenting good material for the study of uniparental inheritance. From 23 individuals Warren obtained 96 young in broods of three to six, and these were allowed to grow up. He measured the length of the first joint of the second antenna of the right side in each individual and recorded the results in thousandths of the body length. Constructing a correlation table he found a coefficient of regression of offspring on mothers of 0.619 ± 0.0809, and a coefficient of correlation of 0.466 ± 0.0539, the offspring being more variable than the mothers. While these results are somewhat uncertain, owing to the small number of individuals measured, the resemblance between these results and those obtained with mid-parents is striking and somewhat surprising.

Very recently (1901) Pearson has published the results of twenty-two series of correlations of serially homologous organs (homotypes) in plants, as, for example, the correlation between the number of prickles on the leaves of a holly tree, of the sori on the fronds of a fern plant, etc. The result was an average coefficient of correlation of 0.4570.

In nineteen cases of fraternal correlation in the animal kingdom he obtained a mean coefficient of correlation = 0.4479. These results from various sources are compared in the following table:

TABLE V.—CORRELATIONS.

Relationship.	Coefficients.
Offspring and mid-parents (theoretical)	0.4242
Offspring and mothers, Daphnia (observed)	0.466
Homologous organs on same individual (observed)	0.4570
Brothers (observed	0.4479

The similarity of these coefficients may be the accidental result of dissimilar causes. But Pearson has suggested that they may have a profound significance. The ova and spermatozoa that are produced so abundantly by a single individual are homologous organs, and may be expected to exhibit the same degree of correlation that other homologous organs do. As we shall see later, the characters of brothers depend to a great extent upon the characters of the germ cells from which they are derived. So there may be some one fundamental law of growth that determines the variability and heredity alike of individuals and of organs.

Exclusive Inheritance.—So far we have dealt chiefly with heritages that are blended in the offspring. But there are some characteristics that appear in the individual child as if derived from one parent only. Galton found such to be the case in regard to the color of the eyes. If one parent have dark eyes and the other light eyes, the eyes of each child will be either light or dark, seldom intermediate in color. The laws governing this form of inheritance are so uncertain at the present time that they need not be considered in this article.

Particulate Inheritance.—Every one will recall instances of particulate inheritance. It is especially well shown when individuals of two races are crossed. The writer has in mind a family in which the father was a European and the mother a mulatto. Some of the children had pronounced negro features with fair complexions, others had dark skins and regular features; the characteristics of the two parental races were not evenly blended in any one of the children. Particulate inheritance is so similar to exclusive inheritance that it is sometimes difficult to determine to which type a given case belongs, as is true for example in regard to the color of the hair of horses and dogs.

Prepotency.—Sometimes the offspring on the average will resemble one parent more than the other, and then the parent with which the correlation is the greater will be said to be prepotent. Breeders find as a rule that pure-bred animals are prepotent over mongrels. The prepotency may affect all offspring alike or it may affect only one sex. Abnormal variations are said to be highly prepotent, and Darwin gives a number of cases of the inheritance of such variations by one sex only.

Inheritance at Corresponding Periods of Life.—Correlations may be observed not only between adult parents and adult offspring, but also between the immature stages of parent and offsprings, and, of course, these correlations come at corresponding periods of life, or there would be no regularity in the course of development. But it has been observed that abnormalities in parent and offspring tend to appear likewise at corresponding periods of life. Of this Darwin gives a number of examples.

Characters that may be Inherited.—In general all congenital characters exhibit the phenomena of heredity, either of one type or another. This includes not only normal variations but also various abnormalities and those constitutional weaknesses that predispose the subject to disease. Pearson has shown that fertility may be inherited and every horticulturalist knows that variability is an inheritable characteristic. As to the inheritance of modifications acquired as the result of external influences upon the cells of the body, we have but few observations of value. The results from Fay's observations on the inheritance of deafness are given in the following table:

TABLE VI.—INHERITANCE OF DEAFNESS.

Condition of parents.	Number of children.	Per cent. deaf.
Both deaf, acquired	1,720	2.3
Hearing and deaf, acquired	713	2.2
Deaf, congenital and acquired	1,820	6.3
Hearing and deaf, congenital	528	11.9
Both deaf, congenital	779	25.9

The difference of the results between the cases in which congenital deafness appears in the parentage and cases in which it apparently does not is very striking. It is possible that it might be still more so if it were not for the difficulty of distinguishing in every case between congenital and acquired deafness, a difficulty which may perhaps account for the appearance of even the small percentage of deaf children credited to parents that appear to have acquired deafness. (See *Evolution.*)

Reversion.—The discussion of reversion and atavism is reserved for another place. (See article *Reversion.*)

Telegony.—Many breeders of domestic animals are firmly convinced that a previous sire may influence the progeny of a subsequent one. This supposed influence is called telegony and is regarded as a phenomenon of heredity. The subject has been investigated experimentally by Ewart, using horses and zebras, and he found no evidence of such an influence. Pearson has attacked the problem from the statistical point of view and likewise reached negative results.

In plants there is a phenomenon called *xenia.* In Indian corn when two varieties are crossed the maternal part of the fruit takes on the characteristics of the male parent, which one would not expect to appear until the formation of the fruit of the next generation. De Vries and Webber have explained this as due to a process of double fertilization first observed by Nawaschin and Guignard (see *Impregnation*).

In concluding our review of the phenomena of heredity it should be noted that little is to be learned by the study of isolated cases. We can acquire ideas of value in regard to heredity only by dealing with large numbers of observations by approved statistical methods. And it has been with the hope of giving some notion of the first principles of that new and important branch of biological science that we have devoted so much space to the subject. We now turn to the theories of heredity.

THEORIES OF HEREDITY.

Importance of the Subject.—We are all interested in the question as to how we have come to be what we are, and we have seen that what we call the principle of heredity has been an important factor in determining the present condition, not only of every human being, but also of every living thing whether animal or plant. We now turn naturally to the study of the mechanism of heredity. But this is a thing which is not open to direct observation, and the best that we can do is to construct a theory of heredity from such facts as we can observe. Such an inquiry is not only of importance to the students of pure science desirous of fully comprehending the origin of organic individuals, but is equally important to the practical breeder of domestic animals and plants wishing to maintain his stock at the highest value and to the practical philanthropist anxious for the perfection of the human species. The medical practitioner is also constantly face to face with questions of heredity, and the value of his advice in such cases will depend on whether or not they are founded upon a sound theory.

We often hear it stated that theory is one thing and practical experience is another. But all experience goes for nothing, if it does not lead to the formation of correct theories. It is the comprehension of theories that makes the difference between the skilled engineer who plans great bridges or powerful machines and the day laborer who mixes the mortar or hammers the iron; and when we realize the immeasurably greater complexity of the simplest organism over the most intricate mechanism of human construction, we can see how much more important a correct theory is in the effort to improve the races of higher animals and plants.

Requirements of a Theory of Heredity.—A theory of heredity is not required to explain the multiplication of organisms, but it must explain the relations of form between parent and offspring. These relations are expressed by the terms heredity and variation. We have seen how intimately connected variation and heredity are with one another, that they are in fact but the opposite phases of the same phenomena. A theory of heredity, therefore, must be also a theory of variation. But heredity and variation are both the result of the process of development and to explain them one must first explain development. The embryologist has explained the development of any structure sufficiently for his purpose when he has shown how this structure is the necessary result of a certain observed order of cell division, growth, and differentiation. For him the cell is the fundamental structure, and unequal growth, fusion, and fission of tissues are fundamental processes. For the student of heredity, however, it is necessary to go deeper and to try to discover the fundamental structure of the cell itself and to investigate the minute processes of cell division to determine, if possible, the causes that result in unequal growth and differentiation and thus control the development of the organism as a whole. A theory of heredity and variation, therefore, must be also a theory of development in the deepest sense. It follows from this that our theory, to be valid, must be capable of explaining all of the phases of development, including direct development, both sexual and asexual, metamorphosis, sexual dimorphism, other forms of polymorphism, regeneration of lost parts, and the alternation of generations. It will readily be seen, moreover, that such a theory necessarily involves some conception as to the essential structure of living matter.

The Fundamental Conceptions in Theories of Heredity.—Theories of heredity are nearly as numerous as the thinkers upon this subject. It would be very interesting to take up the views of each author in their historical order and to study the effects of previous observations and deductions upon them and their influence in turn upon the opinions that have been expressed later. If we should do this, we should find, however, that in spite of multiplicity of distinct theories, there is a comparatively small number of fundamental conceptions, one or more of which form the basis of each of the theories. We should find, also, that as the knowledge of anatomy, physiology, and embryology has advanced with the invention of more precise methods of research, the theories of heredity have come to depend more and more upon observed facts and less upon *a priori* principles. The result, however, has not been, as one might suppose, to simplify the theories, but rather to make them more complex. In fact, the more we know about heredity the more wonderful the phenomena appear and the more difficult becomes their explanation. To discuss all of these theories in their historical relations would unduly extend this article, and we shall have to content ourselves with an examination of the fundamental conceptions underlying them. These conceptions may be enumerated as follows: (1) animism, (2) physiological units, (3) heredity as a form of motion or as memory, (4) pangenesis, (5) idioplasm as distinguished from trophoplasm, (6) germ plasm as distinguished from somatic idioplasm, (7) continuity of germ plasm, (8) evolution, and (9) epigenesis. We shall take these up one by one, judge them in the light of the facts and from such as seem valid try to build up for ourselves a theory of heredity and development.

Animism.—The earliest views as to the causes of the phenomena of heredity may generally be classed under the head of animism. Most of them agree that the character of the material body is controlled by a spiritual body, the soul, or *animus,* which enters the material body at its conception.

Van Helmont and other writers of the middle ages have supposed that there is an actual transfer of spiritual substance not only through the sexual products but also through the milk of the mother or nurse. Indeed, it is said that such is the belief of many persons at the present time.

Others believe that the thoughts of the mother may affect the mental and physical character of the developing child. Birth marks, supposed cases of telegony, and the like, have been explained in this way. When Jacob set up the rods before the cattle he was acting upon this theory.

The animistic theories have the great advantage of simplicity, but they are utterly without scientific basis and, therefore, must be rejected.

Physiological Units.—In direct contrast with the animistic theories of heredity are the materialistic theories, —those that postulate a *physical basis* for heredity. One of the earliest attempts to ascribe a physical basis to heredity is that of Buffon. According to his conception, organic matter is essentially different from inorganic matter and the two are equally indestructible. *Organic molecules* are to be found everywhere and are capable of uniting to form an organism wherever they come together under certain conditions, hence his theory of spontaneous generation.

When Herbert Spencer wrote his "Principles of Biology," it was known that there is no chemical element found in living bodies that is not found also in inorganic substances and that Buffon's idea of organic molecules was without foundation. Spencer, however, made a very decided step forward when he revived the idea in another form.

If living material be separated into its constituent chemical molecules it ceases to be alive. Life is not a property of any ordinary chemical substance. Still you can divide living material, and even particles of a cell will retain for a time at least their vital properties. Therefore living matter must be made up of units, much smaller than a cell, and much larger and more complex than a chemical molecule. Spencer calls these ultimate particles of living matter *physiological units.* He regards them as possessing the physical basis of life and as being the bearers of the hereditary qualities.

Haeckel accepts Spencer's theory but refuses to believe that the physiological unit, which he calls a *plastidule,* is anything more than a very complex chemical molecule.

Weismann agrees with Spencer in regarding protoplasm as made up of units which are of a higher order than a molecule. He calls them *biophors* (the life bearers) and attributes to them somewhat different properties from those that Spencer supposes his physiological units to possess. The biophors carry with them only the elementary qualities of the organism. The true bearers of heredity are higher units, the *determinants,* which are themselves composed of biophors having certain properties and arranged in a definite order.

Nägeli takes a somewhat similar position. According to him, when proteids are formed in a watery solution they are precipitated in minute crystal-like masses that he calls *micellæ,* but they do not form part of the living material until they are united into larger masses which are drawn out into threads. These threads of micellæ are the ultimate particle of living matter and the bearers of the hereditary qualities.

Darwin, who was one of the first to give to the world a definite theory of heredity, made no attempt to discover the ultimate structure of living matter. He believed, however, in a physical basis of heredity, which he thought could be found in minute bud-like bodies, *gemmules,* given off from the various cells of the body. He was followed by Brooks and to a certain extent by Galton, and de Vries attempted to improve his theory by supposing the gemmules, which he named *pangenes,* not to be produced by the cell, but by the nucleus.

In all of these theories the bodies that are supposed to carry the hereditary characteristics are too minute for observation, and therefore it is equally impossible to prove or disprove their existence. In fact, these theories are not intended to be anything more than working hypotheses. The main question with us is, not whether one or the other of these hypotheses is correct, but whether the general principle that underlies them all should be accepted or rejected. It seems to the writer that no one who has carefully studied the phenomena of fertilization and development, and has considered the results of heredity, can fail to believe that it has a physical basis and that this must consist of units that are much less than the cell and much more complex than the molecule.

Heredity as a Form of Motion.—The earliest theory of heredity that is sufficiently well founded to deserve serious consideration is that of Herbert Spencer. But even this theory is conceived to a great extent independently of any facts, and is therefore largely metaphysical and to be understood only in connection with Spencer's philosophical system of cosmic evolution.

He compares the organism to a crystal. The molecules which go to make up a crystal are originally all exactly alike, but in the crystal they do not all have the same relative position nor the same morphological value. One will form part of an angle, another part of a face, etc. In a similar way the organism is made up of physiological units that are all alike but differ in position. The molecules of the crystal on the one hand, and the physiological units of the organism on the other, have a certain *polarity* that causes them to unite whenever possible into aggregates having a certain definite form. If a crystal be mutilated and then placed in a saturated solution of the same salt, deposition of new material will take place in such a way as to restore the crystal to its original shape. Spencer regards the regeneration of lost parts in organisms as an exactly analogous process.

The form alike of the crystal and of the organism is due to interaction of internal and external forces. But the organism differs from the crystal in being much more sensitive to external conditions; it is due to them that variations occur. When a permanent variation is produced the polarity of the physiological units has been changed. But any force affecting a part affects the whole and, therefore, the polarity of all the physiological units in the body will be altered, including those of the germ cells. Consequently when the physiological units of the germ grow and multiply to form a new organism, they will tend to arrange themselves, not in the form that the parent had originally, but in the form that it acquired as the results of the action of external conditions. In this way all characteristics, whether congenital or acquired, tend to be inherited. According to this view heredity may be regarded as a form of motion or energy that is propagated from all parts of the body to the germ cells.

The famous botanist, Nägeli, spent the latter years of his life in working out a very complete theory of heredity that in many of its essential features closely resembles Spencer's. The threads of micellæ that, according to Nägeli, constitute the active living material are arranged in bundles which are continuous throughout the body and into the germ cells. Each thread is the seat of one of the fundamental characters of the organism, and all of the different kinds of threads necessary to make a complete organism are present in each bundle. From time to time new threads may arise, causing congenital variations in a certain definite direction. External conditions affect the micellar threads, and their reactions lead to adaptive modifications. These morphogenic stimuli set up by external conditions may be transmitted along the threads to the germ cells with the result that the adaptive modifications of the parent may be inherited by the offspring.

If a stone be dropped into the edge of a pond, the surface of the pond at that point is momentarily altered. This disturbance sets up a wave motion in adjacent particles and these set other particles in motion and so on until the wave finally reaches the farthest shore. Spencer and Nägeli think that in the same way anything that affects the physiological units or micellæ in one part of the organism sets up a sort of wave motion that extends throughout the body and into the germ cells affecting their physiological units so that they may give rise to similar modifications in the offspring. Nägeli makes an improvement on Spencer's theory in furnishing a path for heredity along the micellar threads.

Several other authors have attempted to construct similar theories, but none of them presents any advantage over the ones that have been outlined.

Haeckel's theory is intimately connected with the monistic system of philosophy and is almost entirely metaphysical. The cycle of life from egg to egg is, according to Haeckel, a great wave motion. As each individual gives rise to numerous offspring, this wave motion becomes branched with the act of generation. This branched wave motion is called *perigenesis*—and the *plastidules* of which the living material is composed have a similar wave motion, or perigenesis. Heredity is due to the propagation of this wave motion. Haeckel sums up his theory by saying that heredity is the memory of the plastidules; variability, their power of perception.

Orr has made rather an elaborate attempt to show that heredity is a phenomenon akin to habit. The protoplasm of the parent acquires the habit of growing in a certain way, and when a small piece of this protoplasm is separated to form a child it retains its previously acquired habits, with the result that the child grows in the same way that its parent did. Cope also favored a theory following somewhat these same lines.

The only evidence of importance in favor of these theories is the fact that in certain tissues of animals and plants the cells are found to be connected by minute protoplasmic threads. This line of evidence has been gathered together recently (1898) by O. Hertwig, who calls attention also to the interesting experiments of Pfeffer, which show that in one case at least these protoplasmic filaments may transmit a formative impulse. A vegetable cell deprived of both its nucleus and cellulose wall will not regenerate either, but if the nucleus be present a new cell wall may be formed. Pfeffer prepared cells of the protonema of a moss in such a way that an isolated mass of protoplasm without a nucleus remained connected to its neighboring nucleated cell by the fine protoplasmic filaments traversing the cell wall. In such a case a new cell wall was formed around the protoplasm. But if both cells were deprived of nuclei the cell wall was not regenerated.

On the other hand, there are certainly in the bodies of both animals and plants cells that have no such connections, and a general continuity of protoplasm has not been demonstrated in any organism except in certain algæ and in the earliest stages of cleavage in the eggs of some animals. We cannot tell, of course, what future experiments may bring forth, but there is no evidence at present that any formative impulse may pass from one cell through a series of cells to a distant one, as would be required by the dynamic theories of heredity.

The objection to these theories that occurs to one at once is their fanciful character and lack of any really substantial basis of fact. Their real motive is to account for the supposed inheritance of acquired characters. If any one of these theories is true, then the inheritance of acquired characters should be a matter of every-day occurrence. It is impossible to prove that acquired characters are never inherited and it is therefore impossible to disprove any such theory. But the ablest advocates of the doctrine of the inheritance of acquired characters are admitting now that such inheritance is not common, and, therefore, such a theory cannot be a complete explanation of heredity, but must represent at most only a small factor.

We may conclude, then, that the idea that heredity is a form of motion or something akin to memory cannot be accepted until more evidence in its favor is presented, and such evidence does not seem to be forthcoming.

Pangenesis.—Four years after Spencer published his "Principles of Biology," Darwin gave to the world his provisional hypothesis of "Pangenesis," as the concluding chapters in his book on the "Descent of Man."

The fundamental conception in this hypothesis had been expressed about four hundred years before Christ by the Greek philosopher Democritus when he said that the seed of animals is elaborated by contributions from all parts of the body; and Buffon likewise had supposed that the different parts of the offspring are made up of organic molecules derived from corresponding parts of the parents. But the influence that this conception has had on scientific thought is due to the brilliant manner of its presentation by Darwin.

Darwin supposed that the contributions from the various parts of the body are in the form of *gemmules*, little buds given off from each cell in the body. The gemmules circulate in the blood and are finally collected in the sexual products. When the egg develops each gemmule may give rise to cells like the one from which it was derived. Thus by a simple and perfectly intelligible process Darwin explains the inheritance by the child of the various characteristics of the parent, both congenital and acquired. All of the gemmules in the egg are not supposed to develop, but some may be passed on to subsequent generations. This is always the case with the gemmules representing the sexual characters. Individuals of one sex always contain the gemmules of the other in a latent condition. All cases of reversion are supposed to be due to the development of such latent gemmules. Other forms of variation are explained as due to the rearrangement of the gemmules in the egg, or else as due to the direct action of the environment, or the effects of use and disuse upon the cells of the parent which are transmitted by the gemmules given off from them.

The central fact upon which Darwin's theory is based is the supposed inheritance of acquired characters, but it explains equally well the inheritance of congenital variations, reversion, particulate inheritance, alternation of generation, etc. It is therefore a very complete theory of heredity.

As early as 1872, however, Galton was led to doubt Darwin's theory. He urged his objections in the first place on *a priori* grounds. He did not believe that acquired characters are generally inherited. The gemmules, he said, are purely imaginary, and therefore their existence is an unwarranted assumption. But, waiving this last objection, another and more serious one arises. If we suppose that every cell is continually giving off gemmules, the number present in the organism must be enormous; and, if every cell of the offspring is represented by a gemmule in the germ, we see that if a spermatozoon is to contain not only these gemmules, but also a large number of latent ones, in order that so many may lodge in so small a space, they must be excessively minute.

In the second place, Galton tested the question experimentally. He took silver-gray rabbits, which generally breed true, and into eighteen of these he transfused blood from rabbits of other breeds. He reasoned that, if gemmules be given off, as Darwin supposed, the blood must contain a large number, and, if blood of one breed is transfused into the body of another, the offspring of the latter should show some traces of characters of the former. Eighty-six young were reared from the individuals experimented upon, and none of them showed any trace of foreign blood.

He concluded, therefore, that pangenesis pure and simple is an incorrect hypothesis. He was willing to admit, however, that acquired characters might rarely be inherited and that this might be explained by the occasional giving off of germs by cells.

In 1876 Brooks outlined a theory of heredity which was very fully developed in his book on "Heredity," in 1883. This theory is a modification of Darwin's theory of pangenesis changed to meet the objections of Galton and others. According to Brooks, the phenomena of heredity in the strict sense are due to the *continuity of the germ cells,* a principle that will be discussed later, while variability is explained by pangenesis. Brooks supposes the germ cells to contain gemmules representing all parts of the body. Most of these gemmules are derived from more or less remote ancestors, having been passed on in a latent condition from generation to generation. New gemmules are not being given off all the time by cells of the body, but are produced only by cells which for the time being are subjected to unfavorable conditions. The new gemmules may circulate throughout the body, but in the male the sperm cells constitute a special apparatus for the collection and storing of new gemmules. When fecundation takes place the new gemmules unite with the corresponding ones in the egg and hybrid gemmules are produced which *like any other hybrids* are variable. This causes variability in parts of the offspring which correspond to those subjected to unfavorable conditions in the parent, especially in the father. According to this view, the mother is the conservative element, the father the progressive, or variable element in heredity. External conditions affecting the parent cause variability in the offspring, but not in any particular direction. Acquired characters are not inherited. Brooks brings a strong array of facts and much skill in argument to the support of his theory, but, nevertheless, it is far from convincing. The gemmules of Brooks are just as much products of the imagination as Darwin's, and none of the investigations of cell structure or of cell function has revealed any process analogous to the formation of gemmules.

To sum up, the theory of pangenesis presented in various forms by Darwin and Brooks supposes the germ to be made up of material particles derived from all parts of the parents or more remote ancestors and able by developing to form corresponding parts of the offspring. This theory agrees with the dynamic or memory theories in supposing that the characters of the offspring depend on the character of certain physical substances in the germ, and that the germinal characters in turn are influenced directly by the corresponding parts of the parents. The theories differ in the method by which this influence is supposed to be exerted. According to the dynamic theories homologous parts of the parent and offspring are alike because the germinal rudiments of the parts of the offspring have been subjected to the influence of some sort of formative energy radiating from homologous parts of the parent. According to the theory of pangenesis, homologous parts of the parent and offspring are alike because they are of the same substance (II., Fig. 2607). But these theories are found to be equally unsatisfactory when tested by the light of recent knowledge of the history of the germ cells.

Idioplasm.—The theory of epigenesis is intermediate between the idea of heredity as a form of energy and a third fundamental conception,—*continuity* of the physical basis of heredity. The doctrine of continuity depends upon observations of the structure and history of the germ cells, and involves two other fundamental conceptions in regard to the relations of the parts of the cell. These are the doctrines of *idioplasm* and of *germ plasm.* We owe the first of these ideas to Nägeli. He regards protoplasm as composed of two substances. Both of these consist of proteids in the form of minute rounded micellæ and of water. In one of these substances, the "Nahrplasma" or trophoplasm, the micellæ are scattered through the water without any special arrangement. In the other substance, to which he gave the name *idioplasm,* the micellæ, on the contrary, have a very definite arrangement into threads which in turn are united into bundles.

The idioplasm is the true living substance and all of the characters of the organism are due to its activities. The trophoplasm, on the other hand, is not really alive, but is the nutritive material upon which the idioplasm draws in order to grow and to make good its waste. The threads of micellæ have been mentioned before as being, according to Nägeli, the bearers and conductors of hereditary qualities. These threads constitute the idioplasm.

Weismann adopts Nägeli's conception of the idioplasm with some important modifications. He agrees with De Vries in holding that Nägeli's view that the idioplasm forms a connected network throughout the organism is untenable. According to Weismann, the idioplasm is to be looked for only in the nuclei of the cells. It is in the nucleus that new living material is constructed, and it is from the nucleus that it migrates into the cytoplasm where it is used up in the course of its functional activities,—such as secretion, contraction, and the like. The formation of new material takes place in the nucleus, the functional activities of the cell take place in the cytoplasm; or, in other words, the nucleus is the seat of the anabolic processes, while the cytoplasm is the seat of the katabolic processes. According to this view, then, the cytoplasm is actively alive and not merely a mass of nutritive material, but its character is due to the stamp impressed upon it by the idioplasm within the nucleus. There is considerable evidence in favor of the view that such a division of labor between nucleus and cytoplasm really exists, as will be seen later.

Germ Plasm as Distinguished from Somatic Idioplasm.—Weismann goes a step further and divides idioplasm into two kinds,—somatic idioplasm and germinal idioplasm, or *germ plasm.* It follows as a matter of course that the idioplasm of the germ cells must be capable of bearing the heredity qualities of the organism. It is idioplasm of this kind that Weismann calls germ plasm. He thinks that the somatic cells do not contain germ plasm as a rule, but each cell contains only a certain kind of idioplasm which constituted only a small part of the original germ plasm. Thus muscle cells contain only muscle idioplasm, liver cells only liver idioplasm, ganglion cells only nerve idioplasm, etc. It is differentiated idioplasm of this sort that he calls *somatic* idioplasm.

Many critics of Weismann refuse to accept these distinctions. They say that there is no evidence that there is any real difference between germ plasm and somatic idioplasm. We shall be better able to judge of the merits of this controversy later on. In the mean time we may employ germ plasm as a convenient term to designate the idioplasm of germ cells without implying anything in regard to the somatic idioplasm. Minot goes still further and declares that the whole idea of idioplasm is wrong. That we have no right to say that any part of the cell is more essential to its life than another, that we must regard the life of the cell as the total effect of everything that it contains, whether streaming protoplasm, food particles, products of excretion, or what not, and that the form and functions of the cell depend upon all of these. Minot calls this the theory of panplasm.

In view of these opinions and others that are to follow, it will be interesting at this point to glance at the evidence in favor of the theory that the nucleus is the centre of control for the activities of the cell, and especially of the germ cell.

The Location of the Idioplasm in the Nucleus.—The theory that a part of the protoplasm is differentiated as an idioplasm controlling the destinies of the cell, and that this idioplasm is situated in the nucleus—more especially in the chromatin of the nucleus—rests upon three principal arguments.

In the first place a study of the phenomena of heredity shows that the correlation between parent and offspring is practically equal for both parents (see Table II.). Therefore, if the physical bases of heredity be an idioplasm, it must be contributed to the fertilized ovum in equal proportion by the two parents. Now observations show that the chromatin of the fertilized egg is derived in exactly equal proportions from the two parents, and, moreover, the chromatin is the *only* part that is equally of male and female origin. It was supposed at one time that the centrosomes of the first cleavage spindle (see *Segmentation of the Ovum*) are derived from the centrosomes of both the male and female germ cells. But it has been pretty thoroughly demonstrated in a large number of cases that the centrosome of the ovum disappears at the time of the formation of the female pronucleus (see *Ovum*) and that the centrosomes of the first cleavage spindle are either derived from the spermatozoa only or else arise *de novo*, in the cytoplasm. The centrosome, therefore, cannot be the bearer of the hereditary characteristics. Therefore, if present, the idioplasm must be looked for in the chromatinic element of the nucleus. The evidence upon which this argument is based has been discussed in the article *Chromosome.* (See also *Reduction-division*, *Ovum*, *Spermatozoa*, and *Impregnation.*)

Secondly, it is known that the correlation between homologous parts of parent and offspring is approximately equal for all parts of the body in which the heritage is blended. From this it is evident that physical basis of the hereditary characteristics must be distributed equally from both parents to all parts of the body of the offspring. Now we know that all cells of the body are derived by fission from one single cell, the fertilized ovum. Further, during the first division of the ovum the chromosomes are divided in such a way that the two daughter cells receive chromatin of both male and female origin in exactly the same proportion as found in the fertilized egg; and in each subsequent cell division the chromatin is distributed equally between the daughter cells. Therefore we may infer that under ordinary circumstances the chromatin of every cell in the body is equally of maternal and paternal origin,—provided that it can be shown that the chromosomes maintain their individuality during the so-called resting stage between two cell divisions. It is well known that there is no appearance of such individuality in most resting nuclei. Neverthelesss, as the reader may see by reference to the article *Chromosome,* there is a considerable body of evidence to show that this is only an apparent loss of individuality, and that the chromosomes formed preparatory to division are essentially the same as those present at the end of the previous fission, only grown larger.

Historically, then, the chromatin fulfils all the requirements of the supposed idioplasm. It remains now only to examine the third argument, that the chromatin and the nucleus, which contains it, have a controlling effect more than other parts upon the activities of the cell, especially upon the formation of structures.

As early as 1877 Brandt showed that fragments of a protozoan, if lacking a nucleus, would die quickly, while portions containing nuclear material would heal their wounds and live. These observations have been confirmed and extended by Nussbaum, Gruber, Verworn, Lillie, and others. They find that enucleated fragments of various protozoa may live under favorable conditions for a number of days, or even weeks, and "will perform perfectly normal movements, show the same susceptibility to stimulus, and have the same power of engulfing food as nucleated fragments." "They lack, however, the power of digestion, secretion, and regeneration." In like manner, if a nerve fibre be cut in two the portion connected with the cell containing a nucleus lives and grows, while the distal portion dies and disintegrates. Verworn has found, however, that an isolated nucleus is equally incapable of regeneration, and Lillie has shown that in Stentor a fragment containing a nucleus cannot regenerate its lost parts if the cytoplasm is reduced beyond a certain amount—one-twenty-seventh of the original volume in this case. From this it is evident that the life of the cell depends upon the combined activities of the nucleus and the cytoplasm. Perhaps regeneration is impossible because the means of engulfing food has been destroyed. It does not disprove the theory that the nucleus is the nutritive and dynamic centre of the normal cell, a theory that is supported by several other lines of evidence.

The *position* of the nucleus indicates that it plays an especially important part in the economy of the cell. For example, Haberlandt (1877) showed that in plants the nucleus lies nearest that part of the cell which is undergoing most rapid growth, as in the formation of root hairs, thickening of cell walls, etc.; and Korscheldt (1889) has called attention to the fact that in animal cells the nucleus lies on the side nearest the source of food supply. Changes in the *form* of the nucleus indicate the same thing. In both animals and plants it has been seen that in cells actively forming new material the nucleus becomes enlarged, and sometimes branching. Moreover, an actual *transfer of material* from the nucleus to the cytoplasm has been observed. Hodge found that the nuclei of ganglion cells shrink during functional activity. In cell division all parts of the nucleus except the chromosomes and sometimes parts of the chromatin disappear in the cytoplasm. They may be lost as products of metabolism, but it is probable that part of them remain as permanent structures in the cytoplasm. Upon the formation of a new nucleus after division the nuclear membrane, linin network, and nucleoli are regenerated from the chromatin.

Finally, we have the interesting experiments of Boveri, which, while unfortunately not perfectly conclusive, tend to show the great importance of the nucleus in heredity. He mixed fragments of eggs of one species of sea urchin with spermatozoa of another and obtained dwarf larvæ, presumably by the union of spermatozoa with enucleated egg fragments, and these larvæ possessed purely paternal characteristics.

In the cells of higher plants, there are small protoplasmic bodies called *plastids,* and some of these are the chorophyll bodies and give the color to the plant. Plastids multiply by fission. They are present in the egg cell and are passed on to the daughter cells in cell division. But there are no plastids in the pollen tube so that these structures if they are, as they appear to be, permanent cell organs, are of purely maternal origin. Nevertheless, hybrid plants may exhibit more or less of the color of the male parent, showing that the male component of the nucleus influences the character of these apparently independent plastids.

It is well known that the character of the grain of Indian corn is modified by the kind of pollen that falls upon the stigma. The part affected seems to be of purely maternal origin and this phenomenon, known as xenia, was for a long time an unsolved puzzle. Webber has recently suggested that its explanation is to be found in the discoveries of Guignard and Nawaschin, that in the lily and Fritillaria there is a double fertilization. While one nucleus from the pollen tube unites with the nucleus of the egg cell, a second one from the same source unites with the nucleus of a cell that by its division is to give rise to the main part of the seed. If the same process can be shown to occur in maize, then xenia is explained and the important formative influence of the nucleus is demonstrated, for there is no evidence that any other structure passes from the male plant into the embryo sac.

Continuity.—We are now prepared to consider one of the most important of the fundamental conceptions found in the more recent theories of heredity. The idea is important because it is founded upon the facts of observation which have been outlined in the preceding sections of this article. This is the theory of continuity. Like the theory of pangenesis, it attempts to discover a physical basis for heredity in the germ cells. But it differs from that theory in the view taken as to the history of the bearers of the hereditary qualities, and in regard to the relation of the germ cells to the somatic cells of the parent.

According to the theory of pangenesis, the germ gives rise to an individual like the parent, because the germ is composed of material particles, called gemmules, derived from every part of the parent and capable of reproducing the parts from which they arose (II., Fig. 2607).

In strong contrast with pangenesis is the theory of continuity. According to this theory, the germ gives rise to an individual like the parent, not because any part of the germ is derived from the parent, but because this germ which produces the offspring is a part of the *same* germ that gave rise to the parent (III., Fig. 2607). An egg or a spermatozoon is a cell, and like every other cell is derived from a pre-existing cell by division. If we trace the history of the germ cells in any individual, we find that they have arisen by a succession of cell divisions from the same fertilized eggs that produced the whole body (see *I.*, Fig. 2607). They are the lineal descendants of that egg, and having undergone little or no differentiation they share its qualities. The two germ cells that united to form that egg have had a similar history, and so on back for all generations, and in every case this history is shared by the nucleus and more especially by the chromatin. If we regard the chromatin as the seat of germ plasm, then we have good reason to believe that the germ plasm in every germ cell to-day has been derived by growth and an unbroken series of divisions from germ plasm that existed when germ plasm was first differentiated in organisms living so long ago that even the rocks can tell nothing of their history. According to this view, the successive generations in a family may be compared to a string of pearls in which the cord that holds them can grow at one end and by an annular enlargement and division produce a new pearl one after another. Each pearl would represent the somatic cells (body cells) of an individual and the cord would represent the germ plasm.

Lloyd Morgan has expressed the difference between pangenesis and the continuity of the germ plasm very graphically by saying that by pangenesis the hen produces the egg which in turn gives rise to a new hen, while by continuity of the germ plasm the hen does not produce the egg but the egg produces the hen.

The first to recognize that the germ cells differ from the body cells and are continuous in descent from generation to generation, and that this may serve to explain heredity was Sir Richard Owen, who published this opinion in 1849. Afterward, however, he denied that such an explanation is possible.

The next one to express a similar opinion was Francis Galton, writing in 1872 and 1876. He gave the name "stirp" to the sum total of all hereditary principles, or germs, in the germ cells and, according to his theory, heredity is explained by the multiplication and transmission of this stirp.

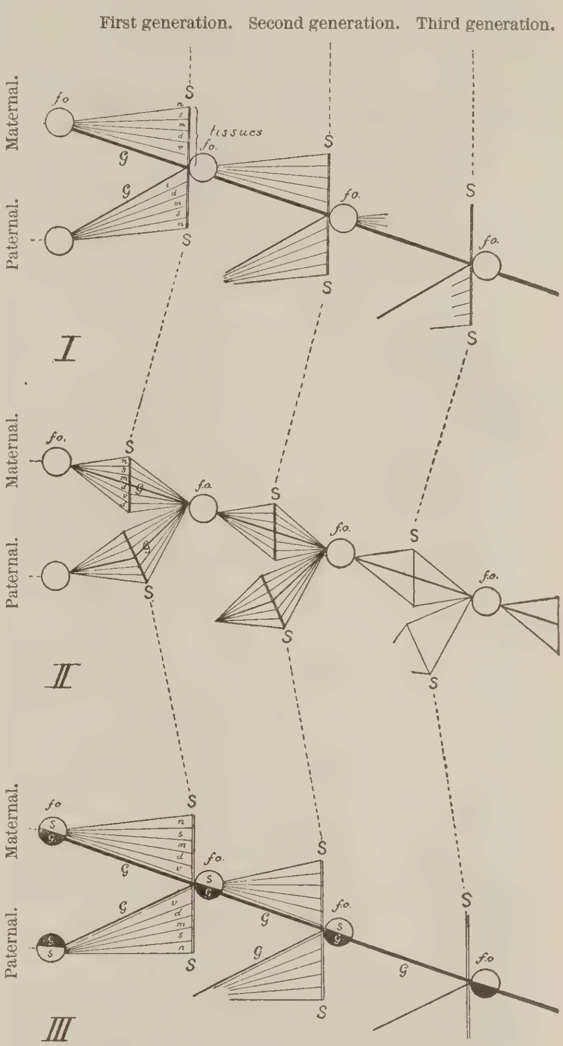

FIG. 2607.—Diagram Illustrating, I. Normal Histogenesis; II. Theory of Pangenesis; III. Theory of Continuity of the Germ Plasm. The fertilized ovum (*f.o.*) by the process of cell division gives rise to the adult body, or soma (*S*), composed of *somatic cells* (*n*, *s*, *m*, *d*, *v*) constituting the nervous, secretory, muscular, digestive, and other tissues, besides the *germ cells* (*G*) of the reproductive organs. I. Histogenesis, showing the successive rise, *G*, and union (*f.o.*) of the maternal and paternal germ cells by direct histogenesis. II. Pangenesis, showing the tissues of the body, *S*, contributory to the germ cells, *G*, so that each *f. o.* is composed of elements, gemmules, from both the somatic and germ cells. III. Continuity of the germ-plasm, showing the division of the idioplasm, *f.o.*, of the egg into somatoplasm, *S*, from which the body cells arise, and germ plasm, *G*, which passes directly to the germ cells establishing a direct continuity.

Brooks outlined his theory of heredity in 1876 and published it in full in 1883. He says: "The ovum is a cell which has gradually acquired a complicated organization and which contains material particles of some kind to correspond to each of the hereditary characteristics of the species. The ovum, like other cells, is able to reproduce its like, and it not only gives rise during its development to the divergent cells of the organism, but also to cells like itself. The ovarian ova of the offspring are these latter cells or their direct unmodified descendants." The child will therefore be like the mother except in so far as it is affected by new gemmules introduced chiefly in the process of fertilization. Here we have the theory of the continuity of the germ cells stated very clearly, but pangenesis is added to it to explain the origin of congenital variations.

The continuity of germ cells had been recognized by Jäger and Nussbaum in 1879 and 1880, but this did not lead in either case to any important generalizations.

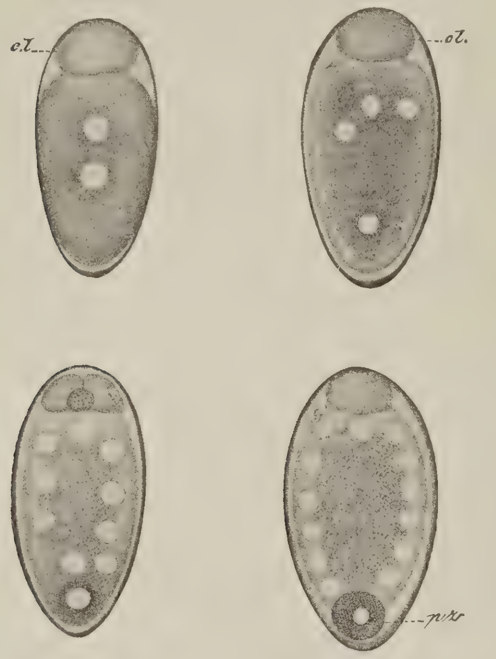

FIG. 2608.—Early Stages in the Development of the Parthenogenetic Egg of the Gall-fly, Cecidomyia. *p.z*, Primary germ cell. (After Meschnikoff.)

From studies on the origin of the germ cells in insects and in hydromedusæ, Weismann arrived at a similar view at about the same time and quite independently, and it is due to his series of brilliant essays, beginning in 1883, that the theory of continuity has taken so important a place in recent discussions.

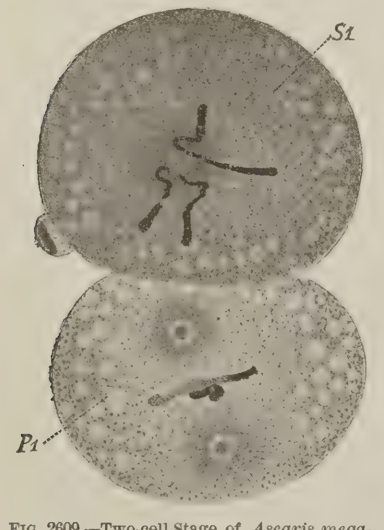

FIG. 2609.—Two-cell Stage of *Ascaris megalocephala* var. *univalens*. *S1*, First somatic cell; *P1*, first cell of the germ tract. Highly magnified. (After Boveri.)

Weismann draws a distinction between continuity of germ cells and continuity of germ plasm. In a few organisms, the germ cells are really continuous. In the Diptera (flies) for example the first cleavage of the egg (Fig. 2608) results in the formation of two nuclei, one of which gives rise to the nuclei of all the germ cells of the embryo and to them only, while the other gives rise to the nuclei of all the somatic cells. A remarkable case of continuity of germ cells has been discovered by Boveri in Ascaris. Figs. 2609 to 2615 represent some of the principal stages illustrated in his beautiful memoir. Fig. 2609 shows the egg in the two-cell stage and both cells, *S1* and *P1*, which are apparently alike, are preparing to divide. In Fig. 2610 the division is farther advanced, and a striking difference is noticeable in the mitotic figures. The chromosomes of the cells *A* and *B*, daughter cells of *S1*, are numerous and very small, and in the plane of division there are some dark bodies composed of chromatin, the rejected ends of the chromosomes of *S1*. These will take no further part in the formation of the nucleus and will finally disappear. On the other hand in *P1*, which we may call the first cell of the *germ tract*, using Weismann's terminology, there are only two large chromosomes moving toward each pole to form the daughter nuclei. *A* and *B* are purely somatic cells. Of the daughter cells of *P1*, one is likewise a purely somatic cell, and when it divides the chromosomes undergo the same transformation that has been observed in *S1*. The other daughter cell is *P2*, the second cell of the germ tract. This is seen preparing for division in the dorsal view of the six-cell stage, Fig. 2611. The two large chromosomes have been reformed. This cell behaves exactly as *P1* did, giving rise to a somatic cell and to the

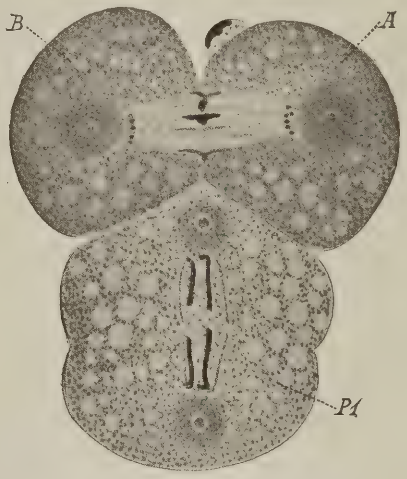

FIG. 2610.—Same. Second Cleavage. *S1* is dividing into *A* and *B*; *P1*, is also in process of division. Note difference in size and number of chromosomes.

third cell of the germ tract, *P3*, Fig. 2612. This cell divides again in the same manner, producing *D* and *P4*, Fig. 2613, and one of the daughter cells of *P4* is *P5*, Fig. 2614, which in turn produces the two priordial germ cells *UGI* and *UGII*, Fig. 2615. Thus the remarkable difference between the nuclei of the germ cells and the somatic cells in this form has enabled Boveri to trace every stage in the genealogy of the germ cells and their nuclei back to the fertilized egg.

In most animals, however, the cells which arise by the cleavage of the ovum appear to be somatic cells, some of which after a greater or less number of divisions give rise to germ cells. In the plants and plant-like animals, such as the Hydroids, we have extreme cases in which there is no trace of recognizable germ cells until we reach the end of a series of several generations of asexually produced individuals. Such being the fact, how are we to explain heredity? There are two possible explanations, according to Weismann. Either the somatic idioplasm in certain cells is reconverted into germ plasm, or else cells in a certain series contain two kinds of idioplasm: their own peculiar somatic idioplasm that controls their activities, and also germ plasm in a latent condition, which is a part of the original germ plasm of the egg. Weissman holds to the latter view. He believes that at the time of the first cleavage of the egg its germ plasm divides into two similar parts. One of these becomes converted into active somatic idioplasm to form the embryo, the other remains latent and is passed on in this condition to certain cells which become the germ cells for the production of the next generation, as represented schematically at *III.*, in Fig. 2607. In some cases, as in the Hydroids, these germ cells are differentiated, according to Weismann, from ordinary somatic cells. Nevertheless, these cells, like all other cells of the body, have arisen by an unbroken series of cell divisions from the cleavage of the original egg. Therefore, while it is shown that in most cases the germ cells are not really continuous as such, we can suppose that there is perfect continuity of germ plasm. Weismann has invented the name "*germ tract*" to designate the series of cells which forms the line of descent from the egg to the germ cells of the embryo and which may be supposed to contain the germ plasm, for example, *P1* to *P5*, Figs. 2609 to 2615. In the Diptera, Fig. 2608, the germ tract is very short. There is practically none at all, for the primary germ cell is formed at the first cleavage. In Ascaris, as we have seen, it runs through five generations of cells. In the Daphnidæ the germ cells are separated off, likewise, during the early stages of cleavage. In Sagitta this takes place in the gastrula stage. In the Annelids and Molluscs, the germ tract is longer, but may be traced through a relatively small number of very definite cell divisions.

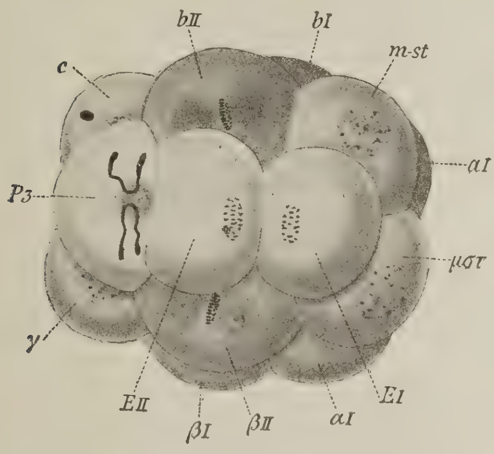

FIG. 2612.—Same. Fifteen-cell Stage. *P3*, Third cell of germ tract.

In the vertebrates there is a large number of cell divisions between the cleavage of the egg and the appearance of germ cells in the embryo. Still they appear early, within the first half of embryonic life at most. Finally we come to the plants and the Hydroids where the germ tract is very long, extending through several generations of asexual individuals. Thus if we studied a sufficient number of species we should probably find all grades from the condition of the Diptera to that of the Hydroids.

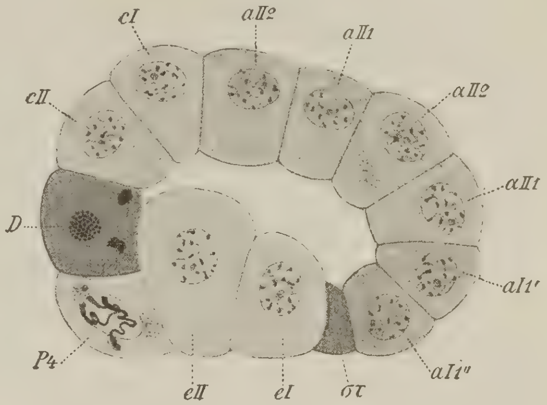

FIG. 2613.—Same. Optical Longitudinal Section of a Blastula. *P4*, Fourth cell of germ tract.

The distinction between somatic idioplasm and germ plasm is upheld by the fact that, except perhaps in rare cases, cells outside of the germ tracts are incapable of becoming differentiated into germ cells. If the gonads (ovary or testis) of any of the higher animals be removed, germ cells never reappear. In this connection there is an interesting experiment published by F. Braem in 1893. The subject was a large female polychæte of the genus Ophryotrocha with ripe eggs and having thirty-five segments bearing parapodia. The animal was cut in two. At the end of three weeks the anterior part had regenerated seven segments bearing parapodia. It was then killed and cut into serial sections and no trace of germ cells could be found in the regenerated part. Evidently here is a difference between somatic cells and germ cells in the powers of regeneration. Of course germ cells might have appeared later, but in the annelids the germ cells are restricted to certain areas of the peritoneum, and it is probable that in this case the wound did not pass

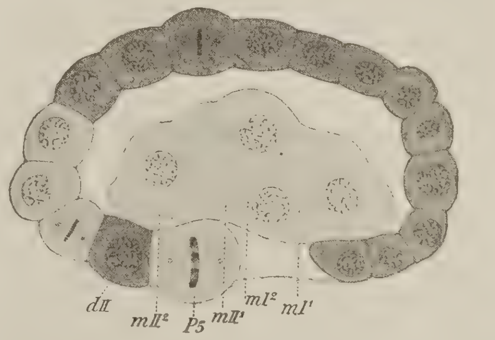

FIG. 2614.—Similar Section of Embryo in the Gastrula Stage. *P5*, Fifth cell of germ tract undergoing division to form the primordial germ cells *UGI* and *UGII*, Fig. 2615. The cell to the left of *dII* is a somatic cell in the same stage of division.

through one of these areas. So it is probable that the germ cells did not receive the same stimulus to growth that affected the other tissues and that therefore no part of the germ tract was included in the regenerated part.

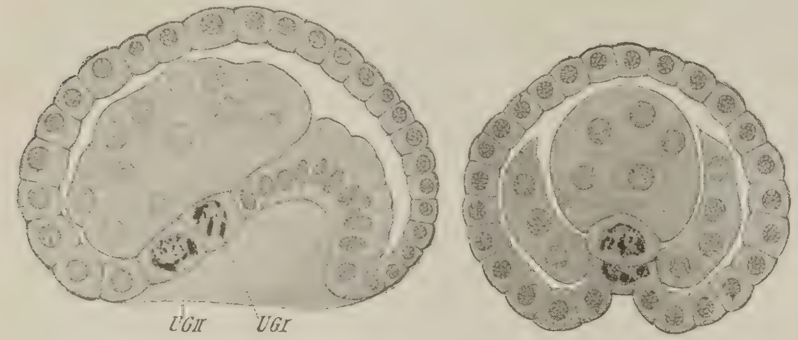

FIG. 2615.—Longitudinal and Transverse Sections of an Older Embryo. *UGI, UGII,* Primordial germ cells beginning to retreat into the interior of the body. (Figs. 2609 to 2615 after Boveri.)

According to Weismann, the best evidence in favor of the existence of distinct germ tracts is afforded by the history of the germ cells of the Hydromedusæ. It is needless to repeat his rather complex argument here, for much better evidence has been furnished recently by Boveri in the history of the germ cells of Ascaris, of which an outline has just been given. The fact of especial importance from Weismann's point of view is the difference between the nuclei of somatic and germ cells; compare, for example, the nuclei of the primordial germ cells, *UGI* and *UGII,* with the nuclei of the somatic cells in Fig. 2615. The origin of this difference may be seen in the two- and four-cell stages, Figs. 2609 and 2610. In the first somatic cell, *S1,* the ends of the large chromosomes are thrown off into the cytoplasm and finally disappear, while the middle part of each chromosome divides transversely into small segments, which behave like ordinary chromosomes in cell division, give rise to small round nuclei, and reappear in subsequent generations of the somatic cells. On the other hand, the large chromosomes of the cells of the germ tract, *P1* to *P5,* behave exactly like the chromosomes of the fertilized egg and give rise to large-lobed nuclei rich in chromatin. "Through this remarkable process," as Wilson remarks, "it comes to pass that in this animal only the germ cells receive the *sum total of the egg chromatin handed down from the parent.* All the *somatic cells contain only a portion of the original germ substance.* The original nuclear constitution of the fertilized egg is transmitted, as if by a law of primogeniture, only to one daughter cell, and by this again to one, and so on; while in the other daughter cells the chromatin in part degenerates, in part is transformed, so that all of the descendants of these side branches receive small reduced nuclei." Wilson adds that it would be difficult to overestimate the importance of this discovery.

All of the evidence goes to show that there is some kind of continuity between the germ cells of one generation and those of the next. The earlier investigators said, "This is a continuity of germ cells." Then came Weismann, who said, "Hold on, you are trying to prove too much. Continuity of germ cells is very rare. Ordinarily the egg gives rise entirely to somatic cells, and then some of these somatic cells give rise to germ cells. But the germ plasm is continuous for it is passed along by the somatic cells of the germ tract until it is finally separated out in the new germ cells. This is proven by the fact that germ cells cannot be produced except by cells of the germ tract." Now come various critics of Weismann and say: "This idea that the cells of the germ tract contain two kinds of idioplasm is a pure assumption that is not warranted by the facts"; and they present a good deal of evidence to show that there is no real difference between somatoplasm and germ plasm. They might add that in the case of the germ tract this distinction is unnecessary, because in every group, not excepting the Hydroids, these cells remain in a more or less undifferentiated embryonic condition. Even if they do form part of the lining of the body cavity or some other organ, the cells which give rise to germ cells have never been highly differentiated as somatic cells. If a muscle cell could by division produce a germ cell, we might be forced to assume that it originally contained two kinds of idioplasm. But there is no reason why the cells which usually produce germ cells should contain anything but germ plasm, for they are not as a rule differentiated in any other direction.

It would seem then that Weismann has been trying to draw too fine distinctions and we must fall back upon the observed facts. These are that the germ cells produced by any individual are derived by growth and fission from the fertilized egg that produced that individual. There is strong evidence to show that the chromatin is the seat of the controlling power in the cell and that the individuality of the chromosomes is maintained during successive mitoses. If this be true, then it is an important fact that the chromosomes in each germ cell are derived by growth and precisely equal fission from the chromosomes of the fertilized egg that produced the individual containing them. I believe that these observations must stand as facts and that they form the only safe foundation for a theory of heredity.

Preformation and Evolution.—The theory of continuity postulates that the child and its parent are alike because both of them have been produced by the same germinal substance. This is a satisfactory explanation of heredity so far as it goes, but it leaves unanswered two large questions, How is variability introduced? and How is differentiation brought about? An attempt to answer these questions involves us at once in the old controversy of Evolution *vs.* Epigenesis (see *Evolution*).

The observations of Wolff, von Baer, and their successors settled this controversy forever so far as the visible phenomena of development are concerned, but the question acquired a new meaning with the advent of scientific speculation on heredity.

Darwin's theory of heredity was the first one in which the theory of preformation was clearly stated. He regarded the egg as made up of gemmules, each one of which is capable of growing and producing one or more cells of a certain definite part of the body. Differentiation is merely the development of the different kinds of gemmules. Congenital variations are due to the transmission from the parent of gemmules having new qualities. Every part of the embryo is represented in the egg by one or more gemmules. The embryo is, therefore, just as much preformed in the egg as it was according to the views of Bonnet a century earlier.

Brooks differs from Darwin in his theory of the origin of the gemmules and of the kind of variability that they produce, but he fully agrees with him as to their function in development. He regards a theory of preformation as the only kind of theory of development that can be defended.

Before Brooks published his theory Wilhelm His, in 1875, presented a theory which has had considerable influence upon subsequent thought. He did not attempt a complete theory of heredity, but aimed to explain only development and differentiation. He rejected the hypothesis of gemmules and relied upon two principles: (1) the principle of differentiation of areas (Princip der organbildenden Keimbezirke), and (2) the principle of unequal growth. He had in mind an egg like that of any of the higher vertebrates, in which the embryo is formed in what is practically a flat blastoderm (see *Area embryonalis*). According to his views the embryo is mapped out at first upon the surface of the egg, each organ and part of organ being represented by a certain area (differentiation of areas). These different areas of the egg differ from one another in density, viscosity, chemical composition, etc., and therefore, when growth begins, it occurs at different times and to different degrees in the different parts. This unequal growth results in the well-known processes of folding, invagination, and the like.

The principle of unequal growth is now universally accepted as one of the fundamental principles of modern embryology. So far as it goes it is undoubtedly a correct theory of development, but we still want to know what causes this inequality. It is due, according to His, to the differentiation of areas; but he does not explain how they arise, and their existence in the unsegmented egg is, to say the least, not self-evident.

Development, according to His, is clearly a process of evolution. In 1888 Roux published the results of some experiments on frogs' eggs that would seem to demonstrate the truth of the principle of differentiation of areas, or germinal localization, as Wilson calls it. By puncturing one blastomere in the two-cell stage he could kill the blastomere operated upon without affecting the other. The result of the operation was that, while the injured blastomere remained inactive, the uninjured one developed into a complete half embryo. Apparently the right and left halves are predetermined in the egg before it divides.

But in the mean time Nägeli had published his idioplasm theory, and various observations upon the functions of the nucleus in fertilization and development had made it seem probable that the idioplasm should be looked for in the chromatin of the nucleus. Roux, therefore, did not look for the predetermination of the two halves of the embryo in the cytoplasm of the egg, as His would have done, but sought for it in the nucleus. In fact, he had five years before these experiments presented the important idea that the chromatin may divide in two ways. It may undergo a *quantitative* division which results in *growth*, by division of the cell into two similar cells, or it may suffer a *qualitative* division, which results in differentiation by the division of the cell into two dissimilar cells. The first cleavage of a frog's egg would be, accordingly, a qualitative division separating the idioplasm of the right side from that of the left.

De Vries in 1889 seemed to help the theory of preformation by supplying a reasonable hypothesis to account for the control of the cell by the nucleus. Although he calls his theory "intracellular pangenesis," it has very little resemblance to Darwin's theory. According to de Vries, the idioplasm has the same composition in all the cells of the body. It is composed of minute particles called *pangenes*, each one of which, like a micellar thread of Nägeli, represents one of the elementary qualities of the organism. The pangenes in the nucleus are in an inactive, or latent, condition and only a few pangenes of each of the many kinds are to be found there. The cytoplasm is made up likewise of pangenes surrounded by a nutritive fluid. But, unlike the nucleus, the cytoplasm contains a great number of pangenes of only a few kinds, and they are all in an active condition. From time to time a pangene in the nucleus will divide. One half remains in the nucleus, the other half migrates into the cytoplasm, where it may undergo repeated divisions. In this way the nucleus controls the cell, while at the same time its idioplasm remains unchanged. Differentiation is brought about by different kinds of pangenes becoming active in different cells.

De Vries argues that various hereditary qualities must be represented by separate material factors, because these qualities may vary independently of one another. It may be supposed that the nucleus controls the cell by liberating some form of energy which acts as a stimulus. But this implies something in the cytoplasm having definite vital properties to receive the stimulus. Or it may be thought that the nucleus secretes a ferment, but this again implies something in the cytoplasm for the ferment to act upon. This something in the cytoplasm requires to be explained, and de Vries concludes that the only tenable hypothesis is that the control of the cell by the nucleus is exercised, not through any power of stimulation nor by means of a ferment, but through the migration of particles of the nucleus into the cytoplasm, of which they then form a part.

We come now to a theory of heredity where the theory of evolution, or preformation, is carried to its ultimate conclusion. This is the theory of Weismann, which has for its basis the hypothesis of the continuity of the germ plasm with the total denial of any inheritance of acquired characters. Superimposed upon this is the idioplasm theory of Nägeli, the theory of qualitative cell-divisions of Roux, and the theory of intracellular migration of pangenes of de Vries.

As has been stated before, heredity pure and simple is explained by Weismann as due solely to the continuity of the germ plasm, some of which is held in reserve in each individual and is passed on to the next generation without receiving any formed material from the somatic idioplasm. We use the term *formed* material, for, of course, the germ plasm receives nutriment just as do all other living parts of the body, and it utilizes this in growth. Weismann rejects entirely both the dynamical and the pangenesis theories of heredity.

According to this view strictly new congenital characters can arise only by the modifying influence of external conditions acting directly upon the germ plasm. External conditions which may affect the germ plasm in this way are food, temperature, and perhaps chemical composition of the surrounding medium. Any change in these factors of the environment may affect the germ plasm within an individual and result in the appearance of a new character in its offspring. The appearance of really new characters, however, is rare. Most variation is brought about by new combinations of old characters, just as any number of new words may be constructed from the twenty-six letters of the alphabet, and innumerable combinations of this kind are produced according to Weismann by sexual reproduction.

The process of fertilization results in the bringing together of two masses of germ plasm having slightly different histories, and, therefore, slightly different qualities. This mingling of two germ plasms is called by Weismann the process of *amphimixis*. In this process the two germ plasms do not fuse, for if they did the child would always have the average character of its parents. As a matter of fact this is a rare occurrence; the individual child is more apt to resemble one parent or a grandparent. We must suppose, therefore, that the germ plasms derived from each parent remain as distinct units in the child, and Weismann calls each one of these units an *id*. If there existed an animal in which sexual reproduction had never taken place its germ plasm would consist of a single *id*. That such units do exist in all organisms now living is shown, according to Weismann, by the presence of a special device for preventing the doubling of the ids that would otherwise occur with each sexual act. This is the reducing division that always precedes fertilization (see *Reduction-division*).

Weismann does not think that the chromosomes are the ids, which of course lie within the nucleus, but he thinks that the small granules of which they are sometimes seen to be composed may be the ids, and therefore he would substitute the word *idant* for chromosome. Each idant of the germ cell he regards as composed of a large number of ancestral germ plasms, or ids, any one of which is capable of directing the entire development of the organism.

Now each id cannot be a homogeneous unit, for we find that a child may resemble one parent in some particular, the other parent in another particular, and perhaps a grandparent in a third, and connected with this there is frequently a lack of correlation so that not only different parts of the adult but different stages in its ontogeny may be independently variable. As Galton puts it, inheritance is particulate. Each id must therefore contain at least as many smaller units as there are independently variable parts in the organism. Weismann calls these units *determinants.* The id, then, has a certain structure. It is composed of determinants that are arranged in such a definite way in relation to one another that they give rise to an organism of their species. Each determinant may control a single cell or a large number of cells if they all vary together.

But a cell may vary in part and not as a whole. Moreover, the determinant must be supposed to reside in the nucleus and its control over the cell must be accounted for. The determinant must, therefore, be composed of still smaller units which are able to pass out from the nucleus and become a part of the cytoplasm, like the pangenes of de Vries. Weismann points out that we must not regard protoplasm as a chemical substance composed simply of atoms and molecules, for no chemical molecule has the power of assimilation and growth. We have to suppose the living material to be a structural combination of dissimilar molecules. These molecules must be arranged in groups, thus forming units of protoplasm which have the power of assimilation, growth, and multiplication by division, but which if further divided would be separated into their constituent molecules and would then cease to be living matter. These units Weismann calls *biophors.* He insists that their existence is not a mere assumption, but that they must exist. All living material is composed of them, and he asserts that the nucleus exerts its control over the cell body by means of the biophors, which pass through the nuclear membrane and become a part of the cytoplasm, like the pangenes of de Vries. Each determinant, therefore, must be composed of a large number of biophors, and when the part that it controls, its *determinate,* presents a differentiation of parts, it must contain a different kind of biophor for each part.

This, then, is Weismann's conception of the structure of the germ plasm. We can understand now from his point of view how ontogeny would take place. Suppose a species where reproduction had always taken place by means of an unfertilized egg, the simplest possible case, then the germ plasm would consist of a single id containing one determinant for each independently variable quality of the species, and each determinant would contain at least as many biophors as there are distinct parts in its determinate. Now before cleavage begins each determinant divides into two, and one set of determinants forms an id of reserve germ plasm, which is to be handed on to the future offspring; while the other forms the idioplasm for the developing organism. The first stage in development is the rapid growth of one determinant of the active id. This is followed by its division into its constituent biophors, which migrate out of the nucleus into the cytoplasm of the egg and cause it to divide into the first two blastomeres. With the division of the cell, the id and its determinants likewise divide, so that each cell contains an id, but this is no longer an id of germ plasm but an id of somatic idioplasm, for it has been changed by the loss of the determinant that was used up to cause the first division. At least one cell, however, (corresponding to the cell *P1* in Ascaris, Fig. 2609) will contain, besides its own particular id of active idioplasm, also an id of inactive reserve germ plasm. Ontogeny thus proceeds by the orderly division of the determinants and the separation of their biophors. In the course of ontogeny two kinds of cell division will occur. In one the daughter cells will have the same hereditary qualities; in the other they will be unlike. In the first, the division of the id is preceded by the division of each determinant into two; in the second, there is no division of the determinants, but they become separated into two sets, one of which goes to form each new id. Thus at the first cleavage one nucleus may contain all the determinants for the ectoderm and the other all of those for the endoderm, or one may contain all determinants for the right side of the body and the other for the left. When ontogeny is completed the idioplasm of each cell contains but a single determinant, which continues to control the cell by sending fresh biophors into the cytoplasm to replace those that are used up in performing their functions. In addition to this, each cell in the germ tract contains a complete id of reserve germ plasm, which remains inactive or simply grows without influencing the cell which contains it.

Now probably in the history of all living organisms sexual reproduction has occurred during innumerable generations. The germ plasm would therefore consist not of a single id, but of a great many. Each one of these would behave in ontogeny, however, just as we have supposed the single one to act.

Now we can see how sexual reproduction aids variation. When there was but a single id of germ plasm, congenital variations could arise only by the slowly modifying influence of external conditions upon its biophors and determinants; but with sexual reproduction we have brought together a number of ids differing slightly in hereditary qualities and each trying to control the development, the result will bring about variation.

The determinants in the various ids will be related in two ways. Those determinants are homologous that control homologous parts of the body, and homologous determinants may again be either homodynamous or heterodynamous to one another, according as they have the property of impressing the same or a different quality upon the part that they control.

When the homologous determinants of the two parents are homodynamous, the offspring will possess the quality that they control in a greater degree than either parent. When they are heterodynamous there will be a struggle between the determinants and the quality in the offspring will be dependent upon the relative strength or numbers of the two sets. All of the determinants from one parent are not likely to have the same relative strength, and hence it is that the child generally resembles one parent in some peculiarities and the other one in others.

If we accept this theory of the structure of the germ plasm, it is easy to explain all of the phenomena of heredity and development.

Variation in the protozoa is due to the direct effect of the environment and to amphimixis. The metazoa and higher plants inherit their fundamental characters from their protozoan ancestors. New characters have been added to these by direct action of environment upon the germ plasm; but the most usual cause of variation is the formation of new combinations of old characters as a result of amphimixis.

Reversion in hybrids is due to the extrusion of ids of one line of descent in the reducing divisions during the formation of ripe germ cells. In pure races it is due to ids acquiring new strength and thus becoming the more powerful after a latent period.

Sexual dimorphism is due to the doubling of the determinants for the sexual character in each id.

Regeneration of lost parts is produced by special determinants in the germ plasm, and reproduction by fission is due to a higher specialization of the same process.

Budding is explained as the result of a doubling of the ids of germ plasm and the distribution of parts of the reserve germ plasm to the somatic cells from which the buds arise.

Alternation of generations is accounted for by supposing each reproductive cell to contain two kinds of germ plasm, one of which becomes active in each alternate generation.

According to this theory every peculiarity of the organism in every stage of its development is represented by a distinct and definitely located structural element in the germ plasm. Development is an evolution, a becoming visible of pre-existing potentialities.

On its face it is a very satisfactory theory, but we shall find that when tested by experiment it fails in many parts.

Epigenesis.—As was noted at the beginning of the preceding section, if we start with the idea of continuity of idioplasm as the basis for a theory of heredity, we soon find ourselves involved in the question as to whether development and differentiation are due to preformation and a process of evolution or are due to a process of epigenesis. Just as we may take Weismann as the champion of the preformation theory, so may we take Oscar Hertwig as the champion of the more extreme side of the theory of epigenesis. His position is supported to a greater or less degree by de Vries, Driesch, and E. B. Wilson.

Hertwig agrees with Weismann in regarding heredity as being due to a continuity of germinal idioplasm which resides in the nucleus and controls the activities of the cell by migrating out of the nucleus into the cell body and there becoming part of the active cytoplasm. Like Weismann he supposes the idioplasm to be made up of minute structural elements which have the power of assimilation, growth, and reproduction by fission; but he differs from Weismann in regard to their other qualities. He calls these bodies *idioblasts* and they correspond in general to Weismann's biophors, to de Vries's pangenes, and to Nägeli's micellar threads.

According to Weismann, the germ plasm is made up of determinants that represent every part of the body that may vary independently, whether this be made up of one cell or of a group of cells. According to Hertwig, on the other hand, the germ plasm is made up of idioblasts that represent only cell characters. All of the different cellular structures that may occur anywhere in the organism may be represented by separate idioblasts in the germ plasm, but characteristics that depend upon combinations of cells cannot be represented there. The egg and the spermatozoon are cells formed by fission from pre-existing cells, and the fertilized egg is likewise a cell capable by division of giving rise to a colony of cells. An egg may contain elements representing nerve fibre, muscle fibrillæ, and the like, because these structures may occur within a cell; but it cannot contain elements representing a hair or a biceps muscle; for hair and muscle are formed only by the union of many cells, and it is impossible to suppose that characters which can be formed only by the union of many cells may be represented in the structure of a single cell. Nevertheless, Hertwig agrees that the characteristics of the adult depend fundamentally upon the structure of the idioplasm in the fertilized egg from which it springs. He compares the organism to a *state*. If we suppose a community or a state to be composed of the offspring of a single pair, the schools, the markets, the courts of justice, and all departments of the government will be the result of the character of that first man and woman, and yet it would be absurd to suppose that these institutions were present in them in a latent condition. Just as all the characteristics of such a state will be the necessary result of the human nature of the man and woman from which it has descended, so all characteristics of the organism are ultimately due to the cell nature of the fertilized egg from which it has developed. We find Hertwig, therefore, opposing two of Weismann's fundamental conceptions, viz., *preformation* and the *qualitative* division of the idioplasm, and it would be well to make a digression here to test these ideas by the results of experiment.

Let us take up first the facts of normal development. According to Roux's theory of qualitative divisions, which is one of the fundamental conceptions of Weismann's theory, the egg is at first *isotropic*, that is, there is no predelineation of the embryo or of its planes of symmetry in the cytoplasm. But when cleavage begins, the qualitative divisions of the idioplasm have the result that the embryo becomes a mosaic made up of cells having different qualities and capable of giving rise only to certain definite parts of the definitive organism. This is called the mosaic theory of development.

As already pointed out, Roux found evidence for his theory in his experiments on frogs' eggs. Since then other evidence has been produced. Crompton experimenting on the eggs of a marine gasteropod (Ilyanassa) found that isolated blastomeres from embryos in the two-cell or four-cell stage (Fig. 2616), "exhibit a typical partial development; that is, each one develops as if the missing portions of the embryo were present. No regeneration of the missing parts takes place." This bears out what we are led to expect from a study of the normal cleavage of the gasteropods and annelids, two large groups in which the method of cleavage is almost identical. The division of the egg in these groups follows a complex but very definite plan. Wilson found that in Nereis every cell division follows a prescribed order up to the fifty-eight-cell stage. At that stage the chief organs of the body are represented by separate cells. Similar results have been obtained by later investigators working upon the development of other annelids and on molluscs. Conklin has traced the cell lineage in Crepidula to the one hundred and nine-cell stage (Fig. 2617). The cells appear in such definite and similar succession in the various species that each cell has been given a distinctive designation, and the history of each cell division has been traced to the time when the principal organs are outlined. In such a form the embryo is really "a visible mosaic work, not one ideally conceived by a mental projection of the adult characteristics back upon the cleavage stages." There can be no doubt about the truth of these observations, and if they constituted all of the evidence, Roux's theory of qualitative divisions and of the mosaic character of the embryo would be fully verified.

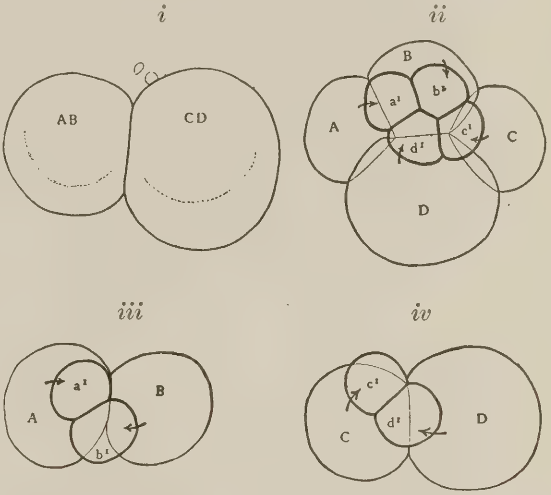

FIG. 2616.—Early Stages in the Development of the Marine Gasteropod, Ilyanassa. *i*, Normal two-cell stage; *ii.*, normal eight-cell stage; *iii.*, half eight-cell stage developed from the smaller isolated blastomere, *AB*; *iv.*, half eight-cell stage developed from the larger isolated blastomere, *C D*. × 112. (After Crampton.)

Unfortunately for the theory, however, there is a great mass of evidence to show that these observations must be interpreted differently.

Beginning with the phenomena of normal development, observations of Miss Clapp on toad fish, and of Morgan on other Teleosts and on frogs show that there is no constant relation between the first cleavage plane and any plane of the adult body. Observations of H. V. Wilson on the sea bass, of Jordan on Amphibia, and of E. B. Wilson on Amphioxus show that there may be considerable variation in the process of cleavage and yet normal embryos will result. E. B. Wilson found three types of cleavage in Amphioxus, a radial form, a spiral form, and a bilateral form, with all grades between, and all of these are equally capable of producing normal larvæ.

These cases are enough to prove that the mosaic theory is not universally applicable, and there is experimental evidence that is still more convincing.

Driesch was the first to experiment with segmenting eggs under *pressure.* Ordinarily in the sixteen-cell stage of an echinoderm egg the cells are separated by alternate vertical and horizontal planes. Driesch found that if the fertilized egg were compressed between glass plates cleavage would take place, but all the planes would be vertical, so that at the end of the sixteen-cell stage the embryo would consist of a one-layered plate of cells. Relations of the nuclei in such an embryo would be very different from the normal, yet if the pressure were now released the embryo would develop into a perfect larva.

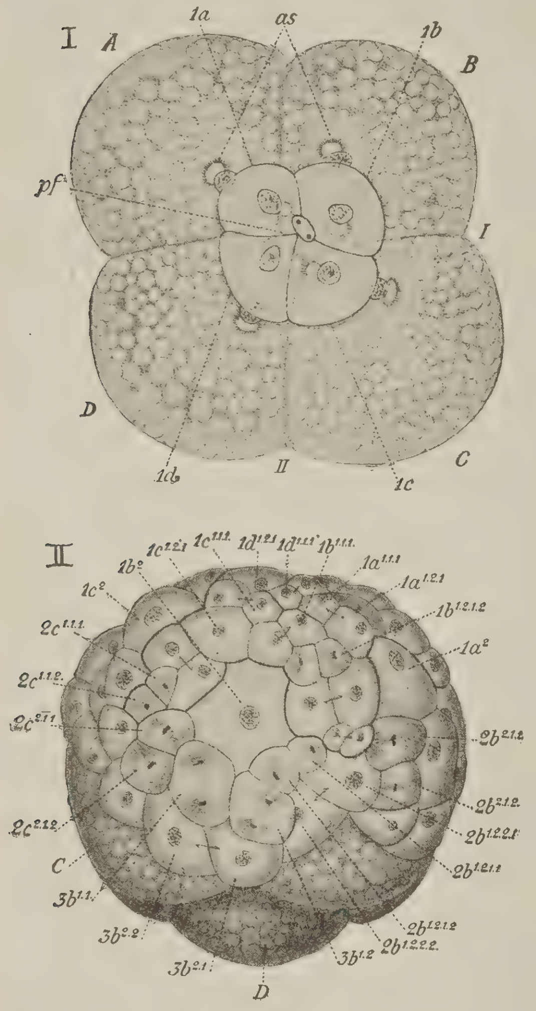

FIG. 2617.—Two Stages Illustrating the Mosaic-like Cleavage of a Mollusc, Crepidula. *I.*, Eight-cell stage; *II.*, stage with one hundred and nine cells. Highly magnified. (After Conklin.)

Hertwig obtained the same results from experiments on frogs' eggs. These are of more interest because of the early differentiation of the egg into micromeres and macromeres. Hertwig obtained a different mode of cleavage, according as he compressed the eggs between horizontal or vertical plates, and both of these forms were found to differ very greatly from the normal, cells becoming macromeres which should normally be micromeres and *vice versa.* Yet upon pressure being removed, all developed into normal embryos.

The most interesting experiments in this line are a few performed by E. B. Wilson on fertilized eggs of Nereis (Fig. 2618). They are especially interesting because of the great definiteness of the cleavage in Nereis and because of the results that Crampton obtained from the isolation of the blastomeres of Ilyanassa. Under pressure beneath a cover-glass, the eggs would divide, each forming a flat plate consisting of a single layer of eight cells. "If they are now released from the pressure, each of the cells divides in a plane approximately horizontal, a smaller granular micromere being formed above, leaving below a larger clear macromere in which the oil drops remain. The sixteen-cell stage, therefore, consists of eight deutoplasm-laden macromeres and eight protoplasmic micromeres (instead of four macromeres and twelve micromeres, as in the usual development). These embryos developed into free-swimming trochophores containing eight instead of four macromeres, which have the typical clear protoplasm containing oil drops. In this case there can be no doubt whatever that four of the entroblastic nuclei were normally destined for the first quartet of micromeres (ectoblast) from which arise the apical ganglia and prototroch. Under the conditions of the experiment, however, they have given rise to the nuclei of cells which differ in no wise from the other endoderm cells. The immediate cause of differentiation must therefore be sought not in the distribution of the nuclei or their mode of division, but in the conditions existing in the cytoplasm."

This conclusion is borne out by the converse experiments performed by Morgan upon the egg of Fundulus. In this minnow, as in other fishes, the blastoderm in the eight-cell stage consists of a single layer of cells lying on one side of the yolk. Morgan discovered that by pricking a fertilized egg so that part of the yolk escaped, he could apparently reduce the pressure on the germinal disc, which would become rounded and would divide so

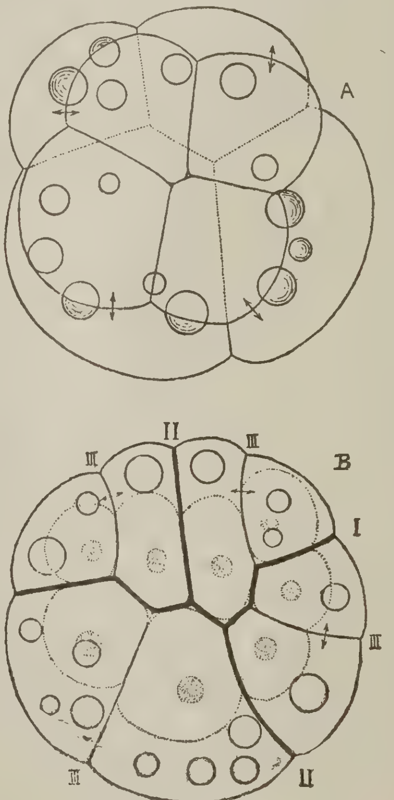

FIG. 2618.—Eight-cell Stage of Nereis. *A*, Normal; *B*, under pressure. Dotted lines show the outlines of the micromeres formed after release from pressure. (After Wilson.)

that the eight-cell stage consisted of a clump of cells separated by two vertical and one horizontal planes. But in spite of this abnormal cleavage a normal embryo was produced.

The results of the *isolation* of blastomeres are complicated. On the one hand we have experiments like Crampton's, where an isolated blastomere of the two-cell stage continues to develop into a half embryo, as if the other half were present; while, on the other hand, we have the experiments of Zoja, who found that isolated blastomeres of the medusæ, Clytia and Laodice, in the sixteen-cell stage would develop into free swimming larvæ which could not be distinguished, except for their small size, from larvæ developed from whole eggs. (Apparently, however, a one-fourth egg of Clytia was the smallest that would develop into a complete medusa.) Between these two extremes there are species presenting intermediate grades in their capacity to develop from isolated blastomeres. So far as we know now, the form that comes nearest to the medusæ described by Zoja in power to develop from isolated blastomeres is Amphioxus. Wilson discovered that blastomeres of the two-cell stage isolated by shaking would develop precisely like whole eggs, giving rise to perfect blastulas, perfect gastrulas, and nearly perfect larvæ one-half the normal size. The same result was obtained from groups of two blastomeres of the four-cell stage. Single blastomeres of this stage, however, might give rise to perfect blastulas and gastrulas, but the larvæ were less perfect. While from the eight-cell stage single blastomeres would produce only imperfect blastulas, most of them developing as if still part of a whole embryo. Morgan found that if one blastomere of the two-cell stage of Fundulus were killed, the other would develop into a perfect embryo two-thirds of the normal size.

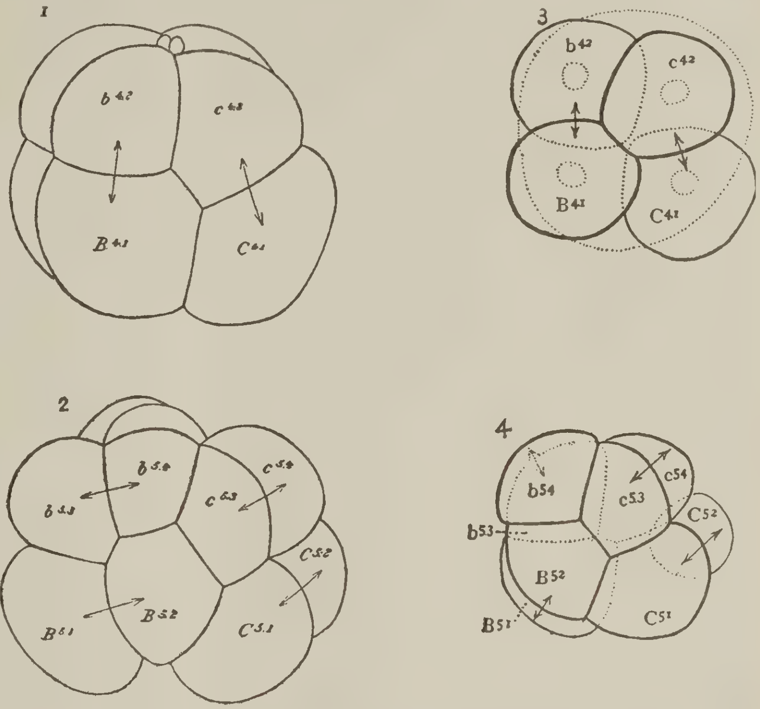

FIG. 2619.—Early Stages in the Development of an Ascidian. 1, Normal eight-cell stage, viewed from the left side; 2, same, sixteen-cell stage; 3, half eight-cell stage developed from an isolated left blastomere of the two-cell stage; 4, same in the half sixteen-cell stage. Note the relative positions of corresponding cells, $B^{4\cdot1}$, $B^{5\cdot2}$, etc., in normal and half embryos. × 250 to 280. (In part after Castle, from Crampton.)

An isolated blastomere of the sea-urchin, Echinus, according to Driesch, develops at first as if it were a half of a whole embryo producing a half blastula. Then the opening closes forming a complete blastula which develops into a gastrula and pluteus. Crampton obtained similar results with eggs of an Ascidian (Fig. 2619).

In the ctenophore, Beroe, we have, as Driesch and Morgan have shown, a condition similar to that found in the gasteropod. Isolated blastomeres of the two- or of the four-cell stage segment as if forming a half or a quarter of a whole embryo, and they give rise finally to imperfect larvæ. Driesch and Morgan made also the interesting discovery that if a fertilized ctenophore egg have part of the cytoplasm removed, it also gives rise to an imperfect larva "showing certain defects which represent the parts removed." This last observation shows that the cytoplasm may be of importance in directing development. For here a defect in the cytoplasm gives rise to a definite deformity in the larva.

All of these results, taken together, make a very strong case against the theory of qualitative divisions. The isolation experiments show that in many cases a nucleus which normally should give rise to nuclei of only one-sixteenth, one-eighth, one-fourth, or one-half the embryo may when isolated produce all of the nuclei of a normal larva. The pressure experiments show, moreover, that even in cases in which isolated blastomeres will not produce whole larvæ, these same blastomeres, if all together, may be shuffled like a pocket full of marbles and yet produce perfect larvæ. Evidently we must seek some cause other than qualitative divisions to explain differentiation.

According to Weismann's theory of determinants, we must not only have qualitative divisions, but the cells of the body must become diverse by a process of self-differentiation. That is to say, the cause of differentiation lies within the cell itself and not only within the cell but in the idioplasm residing in the nucleus. There is no room left in this process for the effects of external conditions. Hertwig, on the other hand, maintains that external conditions form a very important factor in differentiation. That this must be true is demonstrated by the numerous modifications of form that occur as reactions to external stimuli. (See article *Differentiation.*)

It should be borne in mind in this connection that if the idioplasm resides in the nucleus, as we have reason to believe that it does, then the yolk and other constituents of the cytoplasm in the same cell form part of the external conditions relative to the idioplasm. Since the days of Balfour morphologists have universally accepted the belief that the presence of yolk has a profoundly modifying effect upon the course of cleavage.

Morgan and Driesch have presented experimental evidence that not only is this true, but that later stages may be affected by the presence or absence of portions of the yolk in the egg.

Weismann's theory of determinants breaks down, then, when examined critically in the light of the most recent observations. Let us see now what Hertwig would give us in place of it.

According to Hertwig, the fertilized egg is after all merely a cell, and can have no characteristics other than those that properly belong to cells. The impulse for the first division comes either from the nucleus or the centrosome, but the plane of the division is determined by the shape of the egg, the distribution of the deutoplasm, its relative amount, the plane of union of the pronuclei, and so forth. For example, if the egg is oblong, the plane of cleavage will be at right angles to the long axis. If there is more deutoplasm, yolk granules, in one side of the egg than in the other, the egg will divide unequally, the larger segment including that part of the egg which is richer in deutoplasm. In the next stage internal structure of the blastomeres again may have a controlling effect. Blastomeres may again divide unequally for the same reason as before, and those which are the less cumbered with deutoplasm will divide the more rapidly. Now another factor comes in, for as soon as the organism consists of more than one cell, the interaction of one cell upon another affects the mode of cleavage and the differentiation of the cell. At the same time the cells are being affected by stimuli from without the organism, such as light, heat, gravity, and chemical composition of surrounding media. Although the cytoplasm may divide into parts differing in composition and specific gravity, the division of the idioplasm in the nucleus is always *quantitative* only. The two daughter nuclei are exactly alike. Nevertheless, the nucleus controls the differentiation of the cell, and this is affected by the different idioblasts which become active in different nuclei. Which idioblasts shall become active in any cell is determined by the different positions of the nuclei relative to the whole mass and the consequent difference in the stimuli that they receive. Hertwig quotes with approval the remark made by Driesch that "the differentiation of the cell is a function of its position."

There is no preformation of the embryo in the egg. The mosaic theory of the cleavage is a myth, and it is still more mythical to carry this mosaic idea back to the idioplasm of the egg. Preformation exists only in so far that the structure of the egg as a whole determines the character of the first cleavage. The structure of the whole embryo in the two-cell stage determines what the next step in development shall be. *The new characters that appear in ontogeny are really new formations* and not merely the becoming visible of pre-existing latent possibilities. The form of the embryo is the resultant of two factors, viz., the character of the idioplasm, and the nature of the stimuli to which it is subjected. Of these stimuli, those which arise within the organism are the most important in ontogeny, for they are the ones that are constantly changing as development proceeds. The character of the idioplasm determines primarily what the reaction shall be to any given stimulus, and this reaction in turn determines what the stimulus shall be in the next stage. Development is purely a process of epigenesis, and each stage determines only what the next stage shall be.

Wilson takes a position that is somewhat less advanced than that held by Hertwig. He points out that while it is generally true that the relative position of a blastomere determines what shall develop from it, this relation cannot be a purely geometrical or mechanical one, for in different species of eggs blastomeres may exactly correspond in origin and relative position, yet have entirely different morphological value. This is strikingly shown by a comparison of the polyclade egg with that of the annelid or gasteropod. Cells with exactly similar geometrical relations give rise to entirely different organs in the two groups.

Wilson agrees with Hertwig that the differentiation of the cytoplasm in one stage has a determining influence upon the next stage, and he explains the difference between eggs of the gasteropod and the medusa in the ability of single blastomeres to produce a whole embryo by supposing this differentiation to have begun in the former early in the history of the ovarian egg. He does not agree with Hertwig in supposing the somatic nuclei to retain their embryonic character. He points out that the facts of regeneration indicate that the nucleus has undergone a change, and he suggests that the change may be due to a process like that observed in the somatic cells of the segmenting egg of Ascaris. That is, the somatic nuclei do really differ from germ nuclei, but this is because they have given up part of their substance to the cytoplasm, and not, as Weismann would suppose, because they have undergone qualitative division.

Conclusions.—We have now completed a review of the principal fundamental conceptions to be found in theories of heredity. We have seen that the animistic theories belong to the age of mysticism, and receive no confirmation from scientific investigations. We have seen that there is reason to believe that heredity has its foundation in a physical basis, which is the protoplasm of the cell; and this may perhaps be differentiated into physiological units of some kind. Further there is much evidence from observation and experiment to show that the physical basis for heredity forms an idioplasm residing in the nucleus of the cell and more especially in those parts of the nucleus which are composed of chromatin. Whether the idioplasm of the germ cell is essentially different from that of somatic cells is doubtful. The view that such a differentiation does exist is strongly supported on morphological evidence in the single case of Ascaris. The physiological evidence is clearly against a qualitative division of the idioplasm. On the other hand, it indicates some sort of progressive differentiation in the idioplasm of somatic cells during development, a differentiation which begins earlier or later in different species. The causes of this differentiation appear to lie partly within the idioplasm itself and partly in the conditions surrounding it. Both experiment and common sense favor the view that the cell can contain no elements presenting other than purely cellular characteristics. Development is essentially a process of epigenesis. There are as many species of germ cells as there are species of organisms, and the germ cells of any single individual have probably the same degree of variability that other serially homologous organs of that individual have. The normal offspring is similar to its normal parent, because the germinal idioplasm of the two are of common origin, and both have developed under normal conditions. There is no evidence that the germ cells in an adult organism may be affected in any direct way by any changes that may take place in the cells of the body. Therefore the inheritance of acquired modifications of somatic cells is theoretically improbable. *Robert Payne Bigelow.*

HEREDITY IN RELATION TO THE DEVELOPMENT OF MORBID STATES.—It is almost of the nature of a truism to state that morbid conditions are and can only be either inherited or acquired; yet we are apt to confuse these two modes of production; hence in dealing with heredity as a factor in the development of states of disease it is essential at the outset to lay down clearly what is and what is not inherited. A little consideration shows us that only that is inherited which is the property of the individual at the beginning of the existence of that individual, for once existence has begun any disturbances set up by influences from without—by injury, infection, or intoxication—are obviously acquired. Now individual existence certainly does not begin at the moment of birth; it begins at the moment that the nuclear material of the spermatozoon fuses with the nuclear material of the ovum to form the fertilized cell. Hence that only is inherited which has been conveyed to the individual by the spermatozoon or the ovum, or which directly results from the fusion and interaction of the substances of these two parental cells.

It follows, therefore, that conditions acquired by the individual during intra-uterine existence must be carefully separated from inherited states.* Thus we have to divide morbid conditions into:

A. *Inherited.*
  (1) From the father.
  (2) From the mother.
  (3) Resulting from the interaction of the paternal and maternal germ plasms.
B. *Acquired.*
  (1) Of antenatal acquirement.
  (2) Acquired during parturition.
  (3) Of postnatal acquirement.

In our determination of what is truly inherited we have to recognize that infection as such cannot be inherited; syphilis and tuberculosis, for example, cannot be spoken of as inherited conditions. Not that these infections of the parent may not tell upon one or other of the conjugating germ cells and so lead to disturbed states of ovum or spermatozoon which may materially influence the resulting individual; such indirect influences may, as I shall point out later, lead to the manifestation of *parasyphilitic* and *paratuberculous* lesions; but the actual infection cannot be inherited. There is no such thing as inherited syphilis in the proper sense.

For such infection presupposes the passage of microbes from one or other parent to the offspring through the instrumentality of the germ cells. Apart from the fact that such microbes cannot strictly be regarded as properties of the parental organism, and apart from the fact that the spermatozoon, the germ cell through which this transmission is supposed often to occur, is so small and of such a structure that it cannot be conceived as a carrier of microbes save by adhesion to its exterior, were a microbe or microbes to gain entrance by any means into the ovum, that would be at the most a fortuitous inclusion, and we are not justified in imagining that it could be present without so seriously injuring the cell as to render it barren or monstrous. As a matter of fact the laborious observations of Gärtner upon the number of tubercle bacilli present in the semen of tuberculous guinea-pigs have demonstrated that the probability of a bacillus-bearing spermatozoon fertilizing an ovum is so extraordinarily minute that it may be neglected, while the statistics of Chiari upon the specific lesions of infants suffering from antenatal syphilis show that the liver is the organ most extensively involved in nearly all cases—a sure indication that the channel of infection has been from the placenta; for the blood coming from the placenta first passes through this organ, which thus bears the brunt of the infection.

The not infrequent cases in which a syphilized father begets syphilized children without the mother showing signs of general syphilis, must therefore be due to intra-uterine infection, either by passage of the specific virus from the uterine cavity through the cells of the amniotic sac (this has recently been shown possible in connection with other pathogenetic microbes), or by local infection of the fœtal placenta from the uterine cavity, or by *local* infection of the uterine mucosa and maternal placenta without extension of the disease in the mother, although with conferment of relative immunity upon the mother.

Having now cleared the ground it is possible to discuss the effects of heredity pure and simple. The inheritance of morbid conditions may be: 1. Specific or ex specie, *i.e.*, peculiar to all the members of a species. 2. Racial. 3. Familial. 4. Individual.

1. Ex Specie.—This shows itself mainly in predispositions to certain infections including the disturbances set up by the grosser parasites. The infectious diseases of cold-blooded animals, for example, are quite different from those of warm-blooded, and, while some diseases occur inc ommon, the diseases to which man is liable are, as a series, well differentiated from those affecting cattle. Certain infections like syphilis, gonorrhœa, and typhoid would appear to affect man alone under natural conditions.

An interesting line of thought has been touched upon by Bland Sutton in his "Introduction to General Pathology," where he points out that certain structural features so characteristic as to be differential in certain species and races, are essentially inherited morbid conditions or malformations. He notes that the race of tailless trout of Islay (and we may add the race of Manx cats), the albinic or non-pigmented species of snails; the Chætodon with its remarkable osteomatoid enlargements of the bones, the race of horned men of Akim in Africa with their huge symmetrical exostoses of the malar bones, are all examples of such morbid inheritance. He is inclined to believe that horn and horny outgrowths in general have originated as pathological states, and what is more he would regard the descent of the testicle into the scrotum in man, and other animals which assume the more or less erect position, as an inherited anomaly. Another good example of inherited pathological structures is the pair of "castors" situated on the inner side of either foreleg of the horse. These familiar objects are of cuticular origin, are horny and unconnected with bone; they are constant and apparently useless. The only satisfactory explanation he can suggest for the inheritance of these anomalies is that some prepotent ancestor of the horse conveyed this to its descendants along with other more valuable properties; in other words, that there is a certain correlation in the inheritance of variations.

2. Racial.—Among the members of one species those of a different race show peculiar susceptibilities. Thus among the lower animals, the "Buffel" or native cattle of Austria-Hungary have been found largely insusceptible to tuberculosis, in this differing widely from ordinary domestic cattle; the race of Algerian sheep is refractory to anthrax when ordinary domestic European breeds are peculiarly susceptible. Numerous similar examples can be cited among the races of mankind; negroes are peculiarly liable to succumb to tuberculosis, they suffer from sleeping-sickness, ainhum, etc., and on the other hand appear not to be so susceptible to malaria as are white races. Malaysians show a marked tendency to contract beri-beri, they and the Hindoos (though to a somewhat less extent) and Eastern peoples in general are more liable to contract and to die from the plague than are those of European descent, although the latter show themselves more susceptible to yellow fever. In Canada, as in France, the greater severity of scarlet fever when it attacks those of Anglo-Saxon descent as compared with those of French origin is distinctly noticeable. I have already in the previous paragraph cited some examples of the racial inheritance of anomalies.

---

* Chantemesse and Podwyssotsky suggest for the former the term "Uterine Inheritance." I strongly object to this on the ground that in discussing inheritance, we who deal with one branch of biology must conform to the usage of those working in other branches. Intra-uterine existence is characteristic of only one division of animals and that a somewhat limited one. To speak of intra-uterine acquirement as inheritance is a sure means of continuing the present confusion which exists among medical men in connection with this subject.

3. FAMILIAL.—Very numerous examples may be cited of familial inheritance. These examples range themselves in various groups:

(I.) *Inheritance of Anomalies.* Numerous well-recorded examples of cases of polydactyly, syndactyly, abnormal shortness of the phalanges, hypospadias, phimosis, are noted as occurring through several generations.

(II.) Other conditions which may be regarded as *probably anomalies of defect,* and which are markedly inherited, are hæmophilia, albinism, Daltonism, myopia, strabismus, ichthyosis.

(III.) *Diathetic.* The last example together with the tendency to the formation of cataract may possibly come under the heading of diathesis, or liabilities to abnormal functional disturbances occurring at certain periods of life. Among these also are to be included obesity, gout, chronic rheumatism, and diabetes.

(IV.) *Infectious.* It is a matter of popular knowledge that certain families are much more susceptible than is the race in general to acquired conditions like tuberculosis or one or other zymotic disease.

(V.) *Nervous.* The familial nervous conditions are especially worthy of note, because in a remarkable proportion of cases of mental and other nervous disturbances we find a history of antecedent nervous conditions, either homœomorphic, *i.e.*, of the same order, or heteromorphic, of different type. Among the former we recognize inherited paralytic and ataxic conditions, pseudo-hypertrophic and amyotrophic paralyses, Friedreich's disease, etc.; among the latter and more frequently we find mental disorders traceable to ancestral disturbance. There is one well-known county family in England in which a state of weak-headedness varying in its manifestations is traced back to the seventeenth century and is popularly attributed to the prominent part played by a celebrated ancestor in connection with the beheading of Charles I.

"The tendency of late years has been to lay increasing emphasis upon the hereditary factor in the production of insanity, but it is doubtful whether even yet the true bearing and significance of this factor has been recognized."

Carlos F. MacDonald lays down that the so-called exciting causes of insanity play a very unimportant part in the etiology of this disease, except in so far as they may operate to bring about a lowered and disturbed state of the brain and those set in motion hitherto latent inherited conditions or tendencies. In support of this he points out that substantially every individual at some time during his life is exposed, in many cases repeatedly, to many of the so-called exciting causes of insanity, both mental and physical; and yet despite this fact we find that sanity is the rule, insanity the exception.

4. INDIVIDUAL INHERITANCE.—Thus far we have had no difficulty in recognizing and to a large extent comprehending the influence of inheritance in passing down from individual to individual of one species, race, or family, certain peculiarities of constitution. We can understand, that is, that just as there are passed down those grosser properties whereby each member of a species resembles all the rest and differs from members of other species, so there are passed down these morbid constitutional states. It is when we come to study the subject of individual inheritance, the inheritance of conditions that is which have first manifested themselves in one or other parent, that from a medical as from a general biological standpoint we find ourselves in difficulties. So that in order to understand what is and what is not capable of inheritance we find it necessary to probe deeply in order to discover if possible some principle or principles which shall make it comprehensible why certain individual characteristics can thus be passed on in later generations, why others cannot. As Virchow has pointed out, every variation from the normal is strictly a pathological state, however slight it may be, and this whether it acts favorably or unfavorably upon the individual. Hence in discussing theories of inheritance which of necessity bear upon this subject of the production and descent of variations we are still strictly within pathological limits.

But in the first place, before considering these theories, it is well to analyze individual variations, for these it will be seen may be of two orders, some being due to the interaction of the conjugating germ plasms and so truly inherited, others being of the nature of acquirements. Among the latter are conditions of excessive development of one or other function or organ, brought about by continued use of the same; the muscular development of the athlete, the specialized development of the musculature of the fingers and of the nerve centres controlling the same in a pianist, and so on. Of the same order are the general results upon the organism of disease affecting the individual, as of infection due to tuberculosis and syphilis and the zymotic diseases, of injuries, *e.g.*, to the brain, and of intoxications, *e.g.*, plumbism and alcoholism.

In addition to these we have to recognize the occasional occurrence of what is known as "spontaneous variations," resulting in the production of sports. The most clearly marked examples of these are to be found among plants; in a bed of tulips, all apparently growing under the same conditions, an occasional flower may be met with possessing four, five, seven, or eight, instead of the usual six petals. Now while one or more of these variations may be ascribed to atavism—to a breaking back to an ancestral state—all cannot be; that is, the tulip must be derived in the distant past from the precursor of the Liliaceæ having either more, or less than six petals; it cannot be derived from both. And as these conditions of excess and defect are of the same order, it is probable that atavism plays little or no part in the development of sports of this nature. Discussing such cases the only conclusion we can reach is that some influence affecting the root bud at its origin, or, it may be, the abnormal interaction of the pollen and ovum, has brought about an abnormal development. Similarly in man and animals in general, the appearance of a sport in one member of a family is rarely if ever to be ascribed to atavism, but to similar influences acting either at the time of fusion of the ovum or spermatozoon, or telling upon the embryo during the very earliest stages of development.

Further than this, admittedly, we cannot advance in the explanation of so-called spontaneous variations. I refer to this matter because it is necessary to point out that both qualitative and quantitative variations like sexdigitism, Albinism, Daltonism, and hæmophilia, may and do constantly present themselves in the individual, and it is not necessary to assume that some ancestor exhibited a like condition; they may arise *de novo.* What is more, it would seem that there is a peculiar liability for these spontaneous variations to show themselves in succeeding generations, and to become familial. The strain of creamy-white horses preserved for more than a century at Hanover originated from a single sport of this order by careful in-and-in-breeding; as again did the Mauchamp strain of merino sheep with their peculiarly silky wool.

THE INHERITANCE OF CONDITIONS ACQUIRED BY THE INDIVIDUAL.

To us as medical men it is of special interest to determine how and to what extent acquired characteristics tend to be propagated; to what extent does disease in the individual tell upon the offspring; is it possible that besides resulting, it may be, in the production of offspring of lowered vitality, the different acquired infections or constitutional states are liable to influence that offspring in a specific manner in one or other direction and so afford examples of an inheritance of acquired characters?

According to Weismann in multicellular individuals characters acquired by the individual cannot be inherited, or at least it has still to be proved that they can. This I might add is a position that is generally taken by biologists of the present day (*vide* article on *Evolution*).

Weismann's Theory.—To understand Weismann's theory it is necessary in the first place to realize the importance of the nucleus in the cellular economy. This is the controlling agent in the cell: remove it and the cell is incapable of regeneration and proliferation (Nussbaum, Verworn). What is more it is the essential agent in fecundation. As is shown by Van Beneden (1875) in animal forms and by Strassburger (1884) in plants, fecundation is essentially the fusion of portions of the nuclear material (chromatin) of the male and female germ cells. At a later date Boveri showed that equal portions of the male and female chromatin unite to give origin to the new individual. Here then in this remarkable nuclear material is the physical basis of heredity. There is no substance in the fertilized cell which is similarly and equally derived from both parental germ cells.

When now the fertilized ovum proceeds to segment and to develop into the embryo and ultimate mature form, the process is seen to be primarily a division and distribution of the chromatin, so that the nucleus dividing before any signs of fission of the cell body show themselves, there are distributed to each daughter cell apparently equal quantities of the chromatin of the parent cell. Hence, as this process of division continues and the whole cell mass of the adult individual—the whole organism—is developed, each cell in that organism contains a portion or derivative of the original chromatin of the fertilized ovum. But a differentiation is to be made out. The majority of these cells form the tissues of the body and as such are found incapable of undergoing fecundation and giving rise to new individuals. These are Weismann's *somatic cells.* Only a certain number present in the reproductive glands maintain this capacity; they are the *germ cells.* And it is these germ cells which convey to the offspring the parental germ plasm; it is through them and through their nuclear chromatin, in which, as above said, the germ plasm would seem necessarily present, that descent occurs, and as in their turn they are the direct descendants of the germ cells which gave rise to the parent individuals and so contain germ plasm directly derived from ancestor after ancestor, so their essential germ plasm is potentially eternal. It has been passed on from generation to generation; the somatic cells of one generation after another have inevitably undergone death and dissolution; they have, after the simile of Lucretius, served but as the runners passing on the torch of life from one to the other.

Thus far we must follow Weismann, and further, with him we must see that the characters of the individual do not directly depend upon the characters of the body, or soma, of the parents. For these characters are transmitted by the germ plasm of the largely undifferentiated ovum or spermatozoon—by germ cells, that is, which are *not* derived from the body cells, and which never have been in other than a latent condition within the parental body. That body has grown and become differentiated and has been acted upon by its environment, but its function throughout has been to form a protecting envelope for the germ cells.

Such being the relationship, it is inconceivable that any character acquired by the parent in the nature of a gross lesion (the loss of an arm, for example), or again in the nature of a special development of one or other faculty (as, for example, the special dexterity of the finger muscle in a pianist) can be transmitted to the offspring. And as a matter of fact we know that the children of those who have lost a limb are born with a full complement of limbs; that ritual circumcision practised for long centuries by Jews and Mohammedans has not resulted in inherited phimosis, and that the docking of tails of horses has had no effect upon the length of tail of their offspring.

These considerations, while they throw light upon the exact nature of descent and while they explain largely the likeness of successive generations in one species or family, do not explain the other important condition of *variation.* For if, as Weismann repeatedly affirms, the environment of the germ cells while in the parental organism has a minimal effect upon them, we do not so far gain any comprehension of how it is that, although derived from intermingling of the same germ plasms, the various offspring of one pair of mankind, fish, or any other animal, while resembling each other in their main features, differ obviously the one from the other, so that no two animals of the same species or even of the same family are absolutely alike. Still less do these considerations explain the occurrence, in certain of the offspring of one pair, of features absent from either parent but present in one or other ancestor (atavism).

To explain this individual variation and kindred matters Weismann has developed a most elaborate theory, so elaborate, and undergoing so many modifications as new facts have presented themselves, that it is impossible to present it in its entirety in the limits of this article. Briefly, he has conceived the germ plasm or nuclear chromatin to be composed of an enormous number of individual particles or *biophores* derived from the ancestral germ plasms on either side. Prior to fertilization a remarkable process of reduction is observable in the nuclei of both the male and female germ cells whereby, according to Weismann, at the time of fertilization each conjugating cell contains only half the number of biophores originally present. By this reduction it comes to pass that through conjugation the fertilized ovum contains the normal number of biophores, half of them derived from the male and half from the female germ cell. Thus in each successive generation the germ cells will contain biophores derived from the male and female germ cells of the previous generation. And, carrying out this conception, it will be seen at the end of say, one hundred generations, the number of representative biophores derived from the whole chain of ancestors (even if as Weismann suggests these are so small as to be quite invisible) would be so enormous, but for this process of reduction with their number being halved prior to each fertilization, that they could not be conceived as capable of being crowded into one nucleus.

Now in this process of reduction Weismann lays down that there is no regular order of discharge of the biophores or ids; they are intimately commingled; representatives or determinants derived from certain near or remote ancestral germ plasms, must drop out; and so it happens that each mature germ cell contains a different series of these. Thus each individual is the outcome of the action of a different series of combinations of these biophores, and as such differs from every other individual.

This theory also demands that if these biophores are the essential and controlling constituents of the nuclear material, then, in division or segmentation of the fertilized ovum, nuclear chromatin and with it germ plasm is transmitted to each cell forming the organism. And to explain the difference in structure and characters of the cells forming the different tissues Weismann is forced to suppose that there is a *qualitative* difference in the transmission to the different cells and that so the different organs and tissues depend for their characters upon different combinations of the biophores, which in the process of successive segmentation of the blastomeres gain entrance into and determine the composition of the nuclei of the different forms of cells. The inheritance of special, racial, and familial features peculiar to and showing themselves in structural and other features of the body is thus, according to him, essentially due to these biophores, their particular distribution and their controlling action.

These, for our present purposes, are the main outlines of Weismann's celebrated theory. Others, among whom may be mentioned Darwin, Roux, de Vries, and we ought specially to mention Francis Galton, had previously enunciated theories or considerations along the lines here indicated, but to Weismann certainly must be given the incredit of elaborating a theory which attempts to cover the whole subject. As this theory has influenced the whole study of the subject of heredity, it has been necessary to explain to this extent its main tenets.

It will be seen from what I have stated that chromatin exists, and in the fertilization of the germ cells undergoes a remarkable series of changes; prior to fertilization there is a remarkable reduction in the nuclear substance. In indirect cell division a somewhat parallel series of changes are to be made out. All these are known facts which can be followed and readily observed; but biophores, ids, and idants have never been recognized; they are creatures of the imagination, and what is more, recent researches have shown that they cannot account for the facts of heredity.

From what I have stated it will be seen that this theory requires for the upbuilding of the organism that a special set of these biophores becomes distributed to each of the early blastomeres, so that eventually sundry of these find their way into the mother cells of each separate tissue. As a general rule in bilaterally symmetrical animals it has been determined that the first segmentation of the ovum leads to the formation of two blastomeres, one on either side of the median plane, which correspond and give rise to the future right and left halves of the body. Thus, according to Weismann, a set of biophores which will lead to the development of the organs of the right side passes into one blastomere, a set for the organs of the left side into the other. But now the observations of Driesch, confirmed and expanded as they have been, more especially by Morgan of Bryn Mawr, by E. B. Wilson of Columbia, by Zoja and others, show that in the two-, four-, eight-, and even sixteen-cell stage of the segmenting ovum of quite a number of animals, the blastomeres can be shaken apart and each separate cell may show itself capable of developing into a complete, if dwarfed larva. Again, as Roux, of Breslau, showed years ago, if a given blastomere of the frog's ovum be destroyed, that is to say one holding a definite position in regard to the rest, the individual is liable to develop minus one special portion of the body—one side of the head for example, one hind limb or quadrant. This, while it would seem at first to point in favor of Weismann's view, is nevertheless no proof that individual blastomeres contain special germ plasms, for as Driesch and others have shown, if the segmented ovum in the morula stage be submitted to pressure and the blastomeres be forced into abnormal relationships, upon removing the pressure the individual blastomeres do not continue to segment and produce those organs and parts which they would have done in normal conditions, but, according to their newly acquired position and relationship toward the rest so do they now proceed to develop; there is, in short, an exchange of properties. So that to a very large extent the prospective development of given cells is, as Driesch has laid down, a function of their relative position. It certainly is not determined by primary qualitative modifications of the nuclear chromatin.

Yet clearly this is not all. Mere relative position of the segmenting cells of the ovum does not determine the eventual structure of the adult. The eggs of a vast number of species are curiously alike, and what is more, under like environment, the earlier segmentations are along the same lines, and yet these eggs give rise to individuals absolutely dissimilar and belonging to wholly different species. There is, I need scarce say, a something in the nature and composition of the ovum—nay more, we can go further and say—of its nuclear constituents, which determines the eventual structure of the individual and this something is conveyed by the parental germ plasm. Thus while denying as wholly inadequate Weismann's theory of "determinants" and also being unable to explain heredity and variation by any conception of fixed morphological gemmules, pangenes, biophores, etc., we nevertheless have to attribute directive properties to the germ plasm and its contained idioplasm. Is it possible to conceive the idioplasm of the fertilized germ cell as being of such a nature that with the progressive growth and segmentation of the embryonic cells, set up by its agency, it undergoes progressive modification according to the forces acting upon it in the different cells of the embryo to which it is distributed? Let me indicate the lines along which we may develop such a theory:

THE CHEMICO-PHYSICAL THEORY OF INHERITANCE.

The primary property of living matter, whereby it is distinguished from non-living matter, is the capacity of growth—is the capacity manifested by that living matter to assimilate non-living matter of certain orders, to absorb it and, in so doing, convert it into matter like unto itself, in doing which work is performed. As I have pointed out elsewhere, looking upon living matter in this light and recognizing that its other properties are but secondary manifestations and outcomes of this capacity for growth, we see that multiplication of the cells composing the individual, and multiplication of the individual (whether by simple fission as in certain unicellular organisms or by the development and emission of germ cells as in multicellular organisms) are in essence means whereby it is insured that the living matter of the individual continues to absorb and assimilate new material, means whereby to insure its continued existence and activity. Reproduction thus, as it occurs in man, is but a form of interrupted growth and a means of carrying on and carrying downward the living human substance.

When we come to inquire what is the nature of growth we see, as above indicated, that it is essentially a process of conversion—a chemical process. Certain substances through the agency of this living matter undergo chemical change and are united with and converted into the living substance. The living cell unit is thus to be regarded as composed of at least two substances—the *idioplasm* or essential and directive living matter, and the *cytoplasm* or, better, *paraplasm* consisting of substances absorbed but not yet converted, of the remains of substances, portions of which have been assimilated, and of various formed elements developed and controlled by the idioplasm. Accepting this as the chemical basis of life and of growth, can we go further and picture to ourselves the manner in which the molecules of living matter undergo the process of accretion and multiplication? The modern working conception of the structure of complex molecules is that these are composed of a central radicle or series of radicles which are united relatively firmly in the form of a ring. This method of attachment does not necessarily result in the attachments of all the combining atoms and radicles being brought into play and "saturated" and the ring thus becoming closed. The atom of carbon, for example, is quadrivalent; capable, that is, of uniting with four atoms of hydrogen. If in such a ring it is united with an atom of hydrogen on either side, this still leaves two attachments free, and to these two surfaces there may be lateral attachments of other atoms or radicles.

Our conception, therefore, of the molecule of idioplasm is that it consists of such a central ring with attached side chains formed of various radicles and combinations of atoms. Judging from the results of analysis of cell substance, the molecules of living matter are extraordinarily complex; the figure here given is, I need scarcely say, but diagrammatic and illustrative of the structure of these molecular rings; in it the composing atoms or radi-

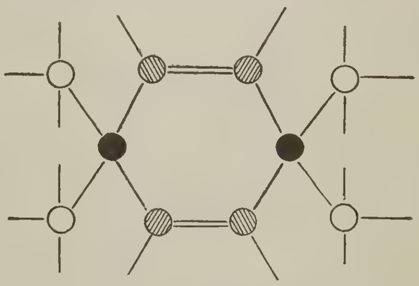

FIG. 2620.

cles are supposed each to be capable of gaining four attachments.

Assimilation then must be regarded as a process in which certain unsaturated surfaces of constituents of the side chains become saturated, and we can conceive growth, that is, multiplication of the molecules of idioplasm, as being brought about by a process of progressive building up of new rings with their attached side chains in intimate connection with pre-existing rings, the new molecule when completed breaking apart (*vide* Fig. 2621).

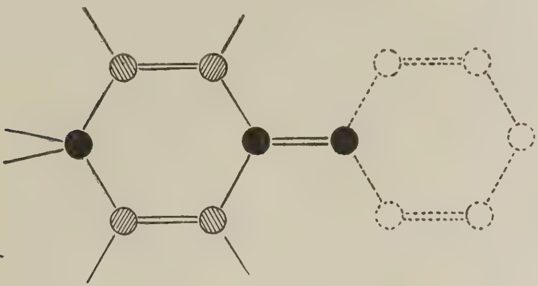

FIG. 2621.

If now we take this as our fundamental conception and postulate further that sundry side chains may be added or removed without destroying the cardinal properties of the molecule, as also that the longer a side chain remains in relation to the central ring (or it may be the more multiple the attachments it gains to that central ring), the more fixed it becomes as an integral portion of the molecular constitution,* we then gain the basis for a physico-chemical theory of inherited variation.

Let us take the simplest example that offers, that, namely, of the bacteria. We know that, preserved in the same environment, these retain the same characteristics for a long series of generations. In other words, the same food-stuff being presented for assimilation, the idioplasm enters into combination with a certain definite number of the constituents of the same; when the increase of this idioplasm has reached a certain point fission or division occurs and the substance of the individual divides into two like parts, each containing idioplasm of the same composition. Hence these two members of the second generation are identical in characters and carry on the particular and distinguishing properties of the species. We know also that, grown on different media the same strain of bacteria exhibits fine points of difference in size, rate of growth, pathogenicity, etc. In other words, a different food-stuff being presented for assimilation the idioplasm combines with somewhat different substances and so forms somewhat different side chains. If this growth on different media is not continued for too long, return to the original medium leads to complete return to the original characters.

But we know also from several examples that growth under widely different conditions for a short period, or subjection to less widely different conditions for a long period, is capable of impressing such alterations upon bacteria that these modifications persist, it may be for years after return to previous environment, *i.e.*, the change in the constitution of the idioplasm has become *relatively* fixed. Thus Roux with the action of minute quantities of carbolic acid added to the medium of growth has developed an asporogenic variety of the anthrax bacillus; by growth at higher temperatures several observers have produced more or less permanent colorless races of pigment-producing bacteria, while Vincent has succeeded in making non-virulent bacteria, like the B. Megatherium, intensely virulent for the animals of the laboratory.

Without discussing at length the modifications introduced by multicellular organization and by descent following upon conjugation of germ cells emanating from different individuals, following these lines of reasoning it will, I think, be evident that we can conceive heredity in higher animals as being brought about by the transmission from generation to generation of idioplasm of a certain chemical composition, which idioplasm, present in one form in the germ cell, becomes inevitably modified in one or other direction as the ovum segments and the cells of different areas of the embryo and developing tissues of the body become subjected to different chemical and physical activities according to their relationship one to the other and to the exterior; so that the eventual structure of the different tissues is the manifestation of the different modifications which this controlling idioplasm has undergone in the course of embryonic and fœtal life. Or, otherwise, a given idioplasm in a given normal environment must follow a particular line of growth and differentiation, so that under like conditions successive generations inevitably resemble each other (*heredity*). With conjugation, however, and the fusion of distinct idioplasms *variation* is induced. The result of the conjugation is an idioplasm having properties not absolutely identical with those of either parental idioplasm. The resulting individual, while resembling, varies from either parent.

We now are in a position to discuss how and to what extent conditions acquired by either parent are capable of being inherited, either directly—the offspring showing the same morbid state as did the parent, or indirectly—disease of the parent having an influence upon the organism of the offspring, but this of a different order from that manifested in the parental organism.

1. *Mutilation.* Gross lesions of the body tissues can at most, according to this theory, only affect the offspring indirectly. They cannot be directly reproduced in the offspring; only in certain cases, by bringing about a poorer state of nutrition of the parental organism in general, and so of the germ cells, may they lead from the offspring not attaining full development.

The only well-authenticated example frequently quoted as an instance of the inheritance of gross lesions—viz., Brown-Séquard's experiments in which by sections of nerves, etc., in guinea-pigs, he produced epilepsy which manifested itself in the offspring—is not, it may be noted, an example of the inheritance of gross lesions, but is an example of the inheritance of a constitutional state set up in the parents by such a lesion. What is more, repeated attempts to confirm these experiments have failed. We do not doubt that Brown-Séquard obtained the results recorded by him, but under the circumstances the only valid explanation is, that he experimented with animals of lowered vitality, this showing itself especially in the direction of nervous instability, and that the nutritional changes following upon his operations led to the offspring being of still poorer constitution and still more unstable. (*Vide* paragraph 3 A, following.)

2. *Acquired Overdevelopment and Relative Excessive Function in One or Other Direction.* Similar considerations show that these cannot be directly transmitted to the offspring. At most, full and harmonious exercise of sundry functions of the body by leading to increased nutrition may tend toward a healthy sound state of the system, and by insuring general good nutrition may insure good nutrition and assimilation on the part of the germ cells, and so tend toward a sound condition and good development of the offspring.

3. *Intoxications (Including Infections); Indirect Effects.* Inasmuch as we cannot regard the germ cells as lying absolutely inactive and inert within the parental reproductive organs, and must from every consideration regard them as undergoing metabolism—assimilating food-stuffs from the surrounding lymph and discharging the products of their metabolism, so does it follow that the diffusible toxic substances capable of acting upon the cells of the body generally, when circulating through the tissues, must be liable to be absorbed by the germ cells and

---

* I have discussed the grounds upon which we may make these assumptions in the article already referred to.

so *may* alter the constitution of their idioplasm.* Nor do we lack clear evidence that this actually occurs. Thus Mairet and Combemale have subjected male dogs to chronic or acute alcoholic intoxication and found that the young exhibited various arrests of development and were predisposed to epileptoid seizures. The only explanation is that the alcohol had caused deterioration of the spermatozoa so that these conjugating with a healthy ovum nevertheless gave origin to impaired individuals. Nor are clear cases wanting of similar degenerations occurring in the progeny of alcoholic fathers and healthy mothers in man. The most clear example, however, of this order was afforded years ago by Constantin Paul in connection with the effects of lead poisoning. Studying a series of cases in which the father alone in the course of his work became the subject of plumbism, he was able to obtain the history of 32 pregnancies. Of these 12 resulted in the death of the fœtus before term; 20 children were born alive, of which 8 died during the first year, 4 died during the second year, 5 died during the third year, and 1 died later. Two alone were found to be alive, one of these aged twenty.

The only conclusion from these observations is that substances which lead to intoxication in the parental system tend also to act deleteriously upon the germ cells. It will be seen that the individual offspring itself is in one respect the direct victim of the intoxication; inherited plumbism is lead poisoning acting initially upon one or both of the conjugating germ cells, but it must be clearly understood that the mental and other disturbances showing themselves after birth are not the results of the action of lead salts still circulating in the system and that thus the lesions of inherited plumbism are of a totally different order from those of acquired plumbism. These are one and all lesions of incomplete development.

3 A. *Neuropathies.* The effects of parental intoxications are peculiarly liable to show themselves in the form of conditions of imperfect organization of the nervous system. This is in accordance with the principle or law, the action of which we repeatedly see in evidence: the law, namely, that characters which are the last to be acquired by the individual, the race, or the species are those which are the first to be lost. Thus in the evolution of man, one of the last acquirements—that acquirement whereby man is distinguished from all other animals—has been that of the higher mental organization. Another has been the development of relative insusceptibility to sundry infectious diseases. Thus the individual whose full development is arrested is particularly liable to manifest a greater or less degree of mental instability, the development of the higher nervous centres being incomplete; or again to manifest a peculiar susceptibility to the infections liable to attack human beings. Thus nervous instability of various orders may be regarded as an evidence of familial degeneration and as due to a condition acquired by one or other parent or to inheritance from previous ancestors, and noticeably may be accompanied by other stigmata of incomplete development and degeneration, liability to contract infectious disease, etc.

3 B. *Increased Susceptibility toward Infectious Diseases.* What I have stated regarding neuropathies may be stated *mutatis mutandis* with regard to infections. That is, the toxins of one or other infection circulating through the system, becoming absorbed by the germ cells and acting chemically upon the idioplasm, may result in the weakening of that idioplasm. As a matter of fact Gheorghiu has pointed out the frequency with which one notes the history of parental infection in cases of various monstrous developments.

It may be and it has been urged that here we are not dealing with the inheritance of conditions acquired by the parent, that the toxic substances produced these results not by their action on the body cells, but by direct action on the germ cells, and that so the inheritance is blastogenic, not somatogenic. We are quite prepared to grant that these inheritances are of blastogenic origin, nevertheless they are of individual acquirement. The individual consists of body plasm and germ plasm, and whether the defect tell primarily or secondarily upon the germ plasm of the individual we here have examples of conditions acquired by the individual transmitted to the offspring. We have to admit, that is, that the environment of the germ cells when present in the parental organism is capable of bringing about modifications in the germinal idioplasm, and so of producing variations in succeeding generations.

4. *Intoxications, Infections, and Diatheses; Direct Inheritance.* From the above considerations it will be seen that we have reduced the possibilities of the direct inheritance of acquired conditions to a relatively narrow field. We have not, however, completely removed all of them; certain conditions remain to be discussed. Is it possible, for example, that these various parental intoxications, telling as they do in one or other direction upon the parental constitution, tell also in a differential manner upon the germ cells, so that alcoholic inheritance differs from inherited plumbism, and these again from the indirect inheritances of syphilis and tuberculosis? *A priori* if these toxic substances, circulating in the parental system and gaining entrance into the germ cells, forming different combinations with the idioplasmic molecules, combine with, that is, or alter different side chains, we must conclude that it is possible. As a matter of fact, children of syphilitic parentage not the victims of intra-uterine syphilis, tend to show parasyphilitic lesions which are of a somewhat different order from the paratuberculous lesions of the progeny of tuberculous parentage. Here, however, it has to be admitted that fuller statistics are necessary regarding the lesions of those whose fathers and mothers respectively have suffered intoxication; for in maternal intoxication of any order, placental absorption of the circulating toxic substance must tell upon the fœtal existence. Nevertheless, taking the germ cells as, from their potentialities, apparently representative of the body cells in general, the abundant studies upon immunity made during recent years give us the strongest grounds for believing that the different toxins act specifically and affect the idioplasm in one particular direction. At this point it will be seen that our theory falls into line with Ehrlich's side-chain theory of immunity.

In short, the facts gained from the study of immunity point to three possibilities:

(*a*) Where through disease or through introduction of toxins the cells of the body become inmunized to one special infection, those cells are so modified that they now produce substances antagonizing the toxins of that infection. We might therefore expect specific parental immunity to be accompanied by specific immunity of the germ cells and a condition of relative immunity of the offspring.

(*b*) When through disease immunity is not attained, but on the contrary the parental tissues—as in progressive tuberculosis—become progressively weakened and susceptible to the deleterious action of the toxin, the germinal idioplasm may also be weakened and an offspring be developed more susceptible to the particular infection.

(*c*) The idioplasm of the germ cells, being relatively undifferentiated while within the reproductive glands, might not in this state possess side chains capable of being acted upon by the circulating toxins; so that while the parental organism in general is affected thereby in one or other direction, the germ cells may be uninfluenced, and the offspring in consequence may present neither increased susceptibility nor increased powers of resistance to the specific disease.

Here it will be seen that we are in a region of hypothesis pure and simple; indeed, our researches into the inheritance of specific morbid constitutional states have not been sufficient to indicate positively which, if any, of these possibilities accords with the ascertained facts. Even granting that the first of these possibilities is correct, it has to be noted that according to the principle already mentioned—that conditions last acquired are those soonest lost,—we should expect that acquired immunity of the germ cells, if obtained, would tend to be of slight duration, not strongly impressed. Hence for the development of acquired immunity as of acquired susceptibility, not a single act of immunization of the parent but repeated immunizations through several generations might be requisite before any marked and permanent influence showed itself. As a matter of fact, the various attempts to confer immunity by immunizing the male parent have in the main given negative results. Gley and Charrin alone have detected such; Ehrlich strenuously denies that it is obtainable.

---

* I say *may* because it has to be remembered, as pointed out by Meyer, that the cellular absorption of toxic substances is of two orders: (I.), absorption into the cell without resulting chemical combination (as in the case of the alkaloids), the absorbed substance interfering with metabolic processes, and (II.) absorption with chemical combination, the toxic substance becoming fixed, *e. g.*, tetanus toxin in the cells of nerve tissue.

Nevertheless I think it is useful to call attention to these possibilities in order that more exact studies be made which shall prove or disprove them. Thus far the importance of determining the part played by acquired disease, more especially in the father, in the development of morbid constitutional states of the offspring has not been sufficiently recognized. It has not been grasped by our profession that in the study of these states we have a more subtle means of determining this question of the inheritance of acquired states than can possibly present itself to the morphologists, dependent as they are upon the more extensive gross anatomical changes before they can determine whether any alteration has been impressed upon the offspring.

We have, as I have pointed out, definite evidence that constitutional disturbance in the parent affects the germ plasm, and having this, it is for us sedulously to collect all the evidence which presents itself in order that we may determine the limitations of this affection of the germinal idioplasm within the parental organism.*

The views here enunciated are, I know, contrary to the generally expressed opinions of morphologists. It is well to point out once again that the conception of the existence of micelli, ids, gemmules, etc., can only lead to the view that acquired characters, not being able to tell on these ancestral bodies, cannot possibly be inherited. Save in the matter of spontaneous variation I do not suggest that visible anatomical changes can be expected in the course of one generation; but this physico-chemical theory, by realizing the possibility of progressive modification in the constitution of the idioplasm while within the parental organism, is fitted to explain not only what we observe in connection with the effects of disease, but also the development of familial and racial characters, and to aid materially our comprehension of the nature of evolution in general. *J. George Adami.*

HERMOPHENOL, mercury phenol-disulphonate of sodium, is a white, amorphous powder soluble in five to seven parts of water. It is said to contain forty per cent. of mercury, and to be strongly bactericidal without caustic effect on the tissues. It can stand a heat of 120° C. without decomposition. Bérard uses it as a disinfectant for the hands, and in three-per-cent. solution for ophthalmia neonatorum, and Reynes injects 4 c.c. (ʒ i.) of a half-per-cent. solution, every two or three days, for syphilis.

W. A. Bastedo.

HERNIA.—This term, derived from the Greek *ἕρνος* (a spout), is employed for denoting the protrusion of a viscus from the cavity in which it is normally contained. Although it may be used to denote the escape of organs from other cavities, yet when unqualified it signifies, as does the vulgar term "rupture," a protrusion from the abdominal cavity. As usually employed it implies a pouching of the containing wall forming a continuous sac for the displaced contents. An escape of the viscera through a wound in the wall is better termed a "protrusion." The term "internal hernia" is employed to denote either the protrusion of the abdominal contents into the thoracic cavity—*i.e.*, *diaphragmatic hernia*—or the introsusception of the intestine into one of the peritoneal fossæ. The latter condition is, however, more properly classified as one of the forms of intestinal obstruction.

A hernia may occur at one of the openings of the abdominal wall normally present in fœtal life, which has not become closed at the time of birth, and is then termed a *congenital* hernia; *i.e.*, a congenital inguinal hernia is one in which the abdominal contents push their way into the unobliterated processus vaginalis. All herniæ developed subsequently to birth are termed *acquired.* They occur at the points where the abdominal wall is relatively weak. Hence arises the anatomical classification of herniæ: inguinal, femoral, umbilical, lumbar, diaphragmatic, obturator, etc. The parts constituting a hernia are, first, the sac and, second, the contents. The sac consists of peritoneum continuous with the parietal peritoneum of the abdominal cavity. The coverings of the sac vary with the anatomical variety of the hernia, and are as a rule fascial with the exception of the skin. The shape of the sac depends upon the nature of the opening in the abdominal wall and the degree of restraint afforded by the fascial coverings. If the opening be circular with more or less sharp margins the sac as a rule is globular, as in umbilical and femoral herniæ.

In inguinal hernia the sac is elongated, owing to the fact that the fascial coverings are tubular. If the hernia is incomplete the sac is sausage-shaped. On the other hand, it is pyriform in shape when the hernia becomes scrotal. Bands of the investing fasciæ may constrict the sac in such a manner as to produce hour-glass forms; or from the same cause diverticula may result, the pressure being unequally exerted. The parts of a sac are termed the mouth, the neck, and the fundus or body. The contents of the sac usually consist of small intestine or omentum, or both; more rarely they consist of the colon, cæcum, or appendix, sigmoid flexure, bladder, or uterine adnexa. When the contents consist of intestine alone the hernia is called an enterocele; when of omentum alone an epiplocele; when of both, an entero-epiplocele. Fluid may be found in the sac either free or encysted by adhesions—*hydrocele of the hernial sac.*

ETIOLOGY.—Causes predisposing to hernia are:

1st. *Heredity.*—Weaknesses in the abdominal wall predisposing to hernia are undoubtedly inherited.

---

* More especially I would call attention to the valuable material in the possession of the great American insurance companies and the possibility of gaining information as to the effects of acquired disease of the parent upon the offspring by employing the mathematical methods elaborated by Carl Pearson (*vide* article on *Evolution*); if they can give mathematical expression to the influence of, say, acquired parental tuberculosis, upon the life period of the offspring, we shall make a most material advance.

Macready[1] estimates that twenty-five per cent. of patients with hernia give an ancestral history.

2d. *Sex.*—About six males suffer from hernia to one female. This is to be explained both by the much greater frequency of inguinal hernia in males, due to the necessary enlargement of the inguinal canal, and by the nature of their occupation.

3d. *Age.*—Except in the period of infancy, when the influence of congenital weakness upon the development of hernia is most marked, the greater number of herniæ occur in the active period of life, between fifteen and fifty.

4th. *Elongation of the Mesentery*, although generally given as an etiological factor in the production of hernia, is rather a concomitant result—with hernia—of causes such as weakness and laxity of the abdominal wall.

Exciting Causes of Hernia are: 1st. Occupations necessitating violent muscular efforts. 2d. Strains, as lifting, coughing, sneezing, and parturition. 3d. Conditions producing stretching of the abdominal wall, as pregnancy, ascites, obesity. 4th. Atrophic changes, as senility. 5th. Traumatism resulting in the replacement of normal by cicatricial tissue, or in the destruction of nerves, thus causing paralysis and atrophy of muscle.

Clinical Varieties of Hernia.

The clinical classification of herniæ is based upon the condition of the contents and the relation of the contents to the sac. Thus we have: (*a*) Reducible; (*b*) irreducible; (*c*) inflamed; (*d*) obstructed; and (*e*) strangulated herniæ.

(*a*) Reducible Hernia.—A reducible hernia is one in which the entire contents can be wholly reduced to the abdominal cavity, without recourse to a cutting operation. Reduction is often effected by posture, but may be accomplished only by taxis. It is the most common class of hernia.

Symptoms.—The earliest subjective symptom in an acquired hernia is usually pain (ninety per cent. of cases).

In a hernia caused by a strain the pain may be sharp and accompanied by a sense of something giving way. Usually it is dull and dragging and, after a varying period of time, is replaced by a sense of fulness which is marked on standing or straining and disappears in the reclining position. Large herniæ are not infrequently accompanied by gastric or intestinal symptoms, which are probably reflex in character.

The objective symptoms depend upon the size of the hernia and the nature of its contents. A small hernia exhibits a tumor as a rule only on standing or coughing, and the latter disappears when the patient lies down. A large hernia is often not spontaneously reducible; but it increases in size in the erect position or on coughing, and if inguinal it may then be seen to descend into the scrotum or labium.

In both small and large herniæ a characteristic impulse is felt on coughing. In an enterocele there may be a gurgling felt or heard either at the moment when the bowel descends into the sac or on reduction of the hernia, and at the same time the tumor is more or less tympanitic. An epiplocele is dull or flat and feels more irregular and does not give so marked an impulse.

Diagnosis.—See Anatomical Varieties.

Treatment.—For taxis, see Strangulated Hernia. For operative and mechanical measures, see under Anatomical Varieties; also under Mechanical Treatment.

(*b*) Irreducible Hernia.—This term is applied to a hernia in which the contents, although practically normal in condition, cannot be wholly returned to the abdominal cavity. The chief causes of irreducibility are, first, adhesions of omentum to the sac or between the contents, or thickening of the imprisoned omentum (according to Macready the contents consist of omentum in ninety per cent. of cases); secondly, the formation of part of the sac by the gut itself (more fully described under cæcal and sigmoid herniæ); and, thirdly, the bulk of the hernia may be so great that the contents cannot be received into the abdominal cavity.

Irreducible hernia is more frequently observed in middle life and in the umbilical variety. It is uncommon in children. It may be permanent or transitory. It is said that it seldom persists throughout life.

Symptoms.—The symptoms depend upon whether the hernia is large or small and upon the nature of the contents. Small epiploceles usually give no especial symptoms, while larger ones, from dragging upon the omentum, are liable to cause digestive disturbances and are prone to inflammation. In irreducible enterocele the condition is more serious. The imprisoned bowel is apt to become obstructed, which condition may be evanescent or may persist, and furthermore strangulation may supervene. Hence the symptoms vary from occasional attacks of colicky pain and flatulence, with more or less constipation, to those of complete obstruction and strangulation.

Treatment.—Herniæ which have only recently become irreducible are, as a rule, more or less inflamed or at least congested; so that rest in bed and the application of cold with moderate pressure are indicated. Prolonged efforts at reduction under such circumstances are more than likely to aggravate the condition, and hence considerable judgment has to be exercised in the employment of taxis. In old cases or those in which the above treatment does not suffice, operation is indicated. The contraindications to operation do not exist to the same extent as in reducible hernia, since the condition *per se* is more dangerous. In cases in which operation is distinctly contraindicated, as in the aged or diseased, or in which the hernia is so large that the return of the contents to the abdomen would not be feasible, the employment of some device for supporting the hernia and preventing its increase is indicated.

For umbilical hernia some form of abdominal support is useful. In large scrotal herniæ a stout canvas bag, supported from the shoulders, has been found advantageous.

The employment of special trusses, as the "hinged-cup truss" for inguinal hernia, can be recommended only when operation is out of the question, although Macready claims sixty-eight per cent. of reductions by its use. But even then a cure of the hernia is seldom attained.

(*c*) Inflamed Hernia.—When a local peritonitis occurs in the hernial sac the hernia is said to be inflamed. It is usually the result of trauma, either from a truss or from prolonged taxis, but it also occurs from disturbance of the contents as from obstruction or possibly enteritis. A strangulated hernia always becomes inflamed if the condition persists for any length of time. Irreducible herniæ are most prone to inflammation, especially the femoral and umbilical varieties. The process results in the production of lymph and fresh adhesions. The sac may become distended with fluid, and obstruction and strangulation may supervene.

Symptoms.—A sense of increased fulness, pain, and tenderness are present. There is usually a slight rise of temperature. There may be vomiting and constipation. If obstruction or strangulation occurs the symptoms of this condition supervene. On palpation there are tenderness and local heat, and the mass may be tense or semifluctuating. Inflamed omentum usually feels hard and nodular.

Treatment.—Rest in the recumbent position and the application of heat or cold. Enemata, but not cathartics, should be used. The pain may be relieved by anodynes.

(*d*) Obstructed Hernia.—An obstructed or incarcerated hernia is one in which the passage of the contents of the intestine is inhibited, but in which the circulation of blood is not interfered with.

Obstruction is more common in irreducible than in reducible herniæ. As it is usually due to constipation, it occurs more often in herniæ containing the large intestine. Hence we find it more often in umbilical herniæ and in large inguinal herniæ in which the contents are the sigmoid flexure or cæcum. As large herniæ are more common and as there is a lack of intestinal tone in the elderly, obstruction occurs most frequently during the period from middle life on.

The determining causes are usually neglected constipation, and the ingestion of indigestible food or food that leaves a large residue.

Symptoms.—The symptoms vary considerably, but are distinguished from those of strangulation by their gradual development. Constipation at first is not generally absolute. The tongue is coated, the breath is foul, and there is complete anorexia followed by vomiting, which is not usually persistent and seldom stercoraceous. There is colicky pain which may be severe, but there is no collapse. Distention is more or less marked. The hernia, if before reducible, becomes irreducible and increases in size. Impulse, however, is obtainable, which serves to eliminate strangulation. The tumor is often doughy and may be dull on percussion, although imprisoned gas may give a tympanitic note. The prognosis is usually good.

Treatment.—The emptying of the bowel is the first consideration, and this should be accomplished by high enemata and by massage of the hernia. Cathartics should not be given until the tumor has decreased in size.

If there be no response to treatment, and if strangulation be suspected, operative interference should be at once instituted, as delay may be fatal. Recurrence of obstruction may be to a large degree averted by proper attention to the food and bowels.

(*e*) STRANGULATED HERNIA.—A strangulated hernia is one containing intestine in which both the passage of bowel contents and the circulation of blood are interfered with. For the time being it is not spontaneously reducible.

This condition is rare in infancy and is most common in middle life and old age. It occurs more often in small than in large, and in old than in recent herniæ; although rarely a hernia may become strangulated on its first appearance. Narrowness of the neck of the sac conduces to it. Hence it is more common in femoral than in other varieties, and in irreducible herniæ when the neck is partially occluded by adherent omentum, as in some umbilical herniæ. According to Berger, the risk of an inguinal hernia undergoing accident is 2.16 per cent., of a femoral 9.02 per cent.

Determining Causes.—Among the more common causes may be mentioned straining, such as occurs in lifting, sneezing, coughing, etc., in all of which acts there is an increase in the intra-abdominal pressure. Consequently all conditions predisposing to such strain, as certain occupations, pulmonary disease, constipation, and obstruction to urination, are all predisposing causes. Trauma from ill-applied trusses, inflammation, and bands in the sac all may produce it. Volvulus of the contained loop may occur.

Mechanism.—Several theories have been advanced as to the manner in which the pressure is brought about and exerted upon the contained bowel. Undoubtedly the exact mechanism varies in different cases, and it is a combination of factors rather than any single one that produces the result. Among the various theories advanced, the following are the more important: 1st. Elasticity of the ring (Richter). 2d. Compression of the efferent by the distended afferent end of the loop (Lossen). 3d. Angulation of the distal end at the margin of the orifice (Scarpa). 4th. Fæcal impaction. 5th. Torsion or volvulus of the loop (de Roubai). Whatever the cause it must first interfere with the return circulation, producing congestion which increases the bulk of the contained gut and thus augments the pressure. The condition thus tends always to increase itself.

Violent peristaltic efforts of the intestine to force its contents onward increase the pressure at the point of constriction. The mesentery becomes swollen with the intestine and at the same time is put upon the stretch by the excessive peristalsis. This stretching of the mesentery may produce interference with the circulation in the mesentery and gut on the abdominal side of the constriction, which accounts for the not infrequent circulatory disturbances observed proximal to the site of constriction. The latter may also be due to the nipping of the mesenteric vessels supplying gut which is not in the hernial sac. Furthermore, volvulus of intestine lying in the abdominal cavity may be caused by the anchoring of a loop in the hernial sac. The intestine in the sac then represents only a portion of that involved.

Anatomical Changes.—The strangulated intestine passes through stages which can be conveniently stated as (1st) congestion; (2d) inflammation; (3d) gangrene. The rapidity of sequence of these stages depends upon the degree to which the circulation is interfered with. As the return circulation is the first to be interfered with, the first change is an engorgement of the vessels. The walls of the intestine become œdematous and change in color, becoming dark red or purple, and black or grayish-black as gangrene supervenes.

The peritoneum loses its glistening appearance and becomes dull and granular as its vitality disappears. At the site of constriction, usually the neck of the sac, there is a deep furrow which is as a rule grayish in color. The intestine becomes cold, loses its power of contractility, and is distended with gas. As these changes progress there is an exudate of serum, later becoming bloody, into the sac; and a migration of pathogenic germs, notably the B. coli communis and varieties of streptococci and staphylococci, takes place through the walls of the gut. The local peritonitis in the sac may extend to the general cavity and produce a spreading peritonitis, or it may be shut off by adhesions. On the other hand, if the vitality of the bowel within the abdomen be impaired, from the causes already stated or from a progressive thrombosis of the vessels, peritonitis may be primarily instituted within the abdomen itself. If the strangulation be due to inflammation of an irreducible hernia, the sequence of events is slightly changed in that the stage of inflammation precedes that of congestion. When gangrene ensues it may occur locally in small patches at the seat of constriction or at the convexity of the loop, or the whole loop may slough. With the gangrene there is an escape of the contents of the bowel. The skin over the sac at first is not involved, but later the tissues covering the sac become infiltrated and œdematous. Finally, an abscess may form and burst and a spontaneous artifical anus result. This is more likely to be the outcome in cases of partial enterocele (Richter's hernia), when only a portion of the circumference of the gut is nipped, and explains the manner in which spontaneous cures may sometimes occur.

The extent of gangrene varies from a portion of the circumference of the bowel to several feet.

The period elapsing between the onset of strangulation and the occurrence of gangrene varies considerably, from four hours to several days, but is rarely less than twenty-four hours. The presence of omentum in the sac delays the onset of gangrene.

Symptoms.—The symptoms of a strangulated hernia are conveniently divided into the general and the local. The general symptoms are practically those of acute intestinal obstruction in contradistinction to those of an obstructed hernia, which are rather those of chronic intestinal obstruction. They are pain, vomiting, complete constipation, and collapse. To these may be added those of general peritonitis.

Pain is of two varieties: a severe colicky pain felt in the region of the umbilicus, which may be constant but more often remittent, and an aching pain at the hernial site. After the onset of gangrene the pain may disappear.

Vomiting is an important symptom. It is as a rule persistent from the moment of strangulation. The contents of the stomach are first expelled, then those of the upper part of the small intestine, and finally the vomitus becomes stercoraceous. It is not accompanied by marked nausea, and is remarkable on account of the quantities expelled. In later stages it becomes regurgitant and there may be hiccough. It may be absent in Richter's hernia, and it may cease on the advent of gangrene. Constipation is complete, no gas or fæces being passed. However, the bowel may be emptied below the seat of strangulation, and if the strangulation is high up in the small intestine a considerable quantity of fæces may be expelled. Also in Richter's hernia, constipation is not the rule and there may even be diarrhœa. The degree of abdominal distention is likewise dependent upon the site of strangulation. If this is located high up in the small intestine it is relatively slight, while if the large intestine is implicated it is great. It is at first accompanied by excessive peristalsis, but later the paralytic meteorism of peritonitis may be present.

Collapse is usually profound, although it may be delayed for several hours. The pulse becomes weak and thready, the temperature is subnormal, the extremities are cold and moist, and the facies abdominis is marked. When inflammation sets in, the temperature usually rises, but it seldom reaches a high level. The duration of life averages from five to seven days. In the aged the symptoms often are not marked, the course presenting an asthenic type in which some of the classic symptoms may be wholly absent. The symptoms at the site of the hernia are pain, irreducibility, loss of impulse, tenderness, dulness, and the absence of gurgling. The hernial protrusion may be so small as readily to escape notice, and it must be remembered that the absence of a history of hernia does not exclude, inasmuch as a hernia may become strangulated on its first appearance. The attention of the patient is usually attracted to the hernia by the presence of pain. The local pain may be masked, however, by the general abdominal pains.

The chief value of irreducibility as a sign of strangulation is in herniæ that have previously been reducible. It may be absolute or relative. Tenseness, dulness, loss of impulse and the absence of gurgling are all due to the same causes, *i.e.*, fixation and swelling of the contents of the sac and the exudation of fluid within it.

In certain forms of strangulated hernia the characteristic symptoms may be masked or modified.

The following classification, slightly modified from that of Eccles,[2] will serve to indicate the sources of ambiguity.

I. Cases in which the peculiarities are dependent upon the contents of the sac.

1. Strangulation of a portion of the bowel.

(1) Partial enterocele (Richter's hernia).

(2) Strangulation of the vermiform appendix.

(3) Strangulation of Meckel's diverticulum (Littré's hernia).

2. Strangulation within the body of the sac.

(1) By bands, adhesions, apertures in omentum, etc.

(2) By kinking or volvulus.

II. Cases in which the peculiarities are dependent upon the sac.

1. Strangulation within a loculus or pouch of the sac.

In cases of strangulation of a portion of the bowel the general symptoms as a rule are not marked, while the local symptoms may be characteristic. On the other hand, the remainder of the classified cases present the usual general symptoms, while the local symptoms may be markedly modified. The differences in the local symptoms are due to the fact that the entire hernia is not necessarily irreducible, and there may be impulse, tympany, and gurgling at a portion of the protrusion.

In the following groups of cases errors of diagnosis as to the site of strangulation, or as to whether it is present or not, may arise (modified from Eccles[2]).

I. Cases with multiple herniæ.

1. Two (or more) herniæ, one irreducible and the other strangulated.

2. Two herniæ, one concealing the other.

3. An inguinal and a femoral hernia on the same side, one strangulated and the other not.

II. Cases with irreducible hernia in which the obstruction or strangulation is within the abdomen and not at the site of the hernia.

In cases of multiple herniæ the local symptoms as a rule are sufficient to determine the site of strangulation. In infants, inasmuch as they are unable to direct attention to the local condition and as they are frequently subject to attacks of vomiting and colic, the diagnosis may be delayed. In them continued vomiting should lead to a thorough examination of all hernial sites. The differential diagnosis lies chiefly between strangulated and obstructed or inflamed hernia. Other conditions which may simulate strangulated hernia are inguinal adenitis, acute epididymitis or orchitis, and severe colic, peritonitis, or the uncontrollable vomiting of pregnancy in conjunction with a hernia.

Prognosis.—The prognosis in untreated cases is uniformly bad, with the exception of the exceedingly few cases that end in recovery with the spontaneous formation of an artificial anus. The mortality following taxis and that associated with herniotomy manifestly cannot be compared, inasmuch as the conditions found in many cases successfully operated upon would absolutely contraindicate the employment of taxis, and also because cases in which taxis proves successful would in all probability be successfully treated by operation.

The statistics of Frickhoffer[1] in regard to cases in which taxis has been apparently successful give in 308 cases of femoral hernia a mortality of 14.9 per cent., and in 518 cases of inguinal hernia one of 7.8 per cent. The statistics of herniotomy show a mortality that varies from 10 per cent. to 12 per cent. in cases in which the strangulation has existed twenty-four hours or less, to 50 per cent. in cases in which it has existed over three days. The risk of herniotomy when the gut is still returnable is comparatively slight. In gangrenous hernia the mortality depends largely upon the method of treatment of the intestine (see Treatment).

In a total of 354 cases of gangrenous hernia, collected by Gibson,[8] 120 were fatal, a mortality of 34 per cent. Of these 354 cases, 96 were of the inguinal variety, with 25 deaths (mortality: 26 per cent.); 188 were of the femoral variety, with 69 deaths (mortality: 37 per cent.); 22 were of the umbilical and 2 of the ventral variety, with 16 deaths (mortality: 67 per cent.); and 7 belonged to the obturator variety, with 6 deaths (mortality: 86 per cent.). By these statistics it will be seen that the mortality of femoral hernia is greater than that of the inguinal form, and the mortality of umbilical hernia is greater than that of femoral hernia.

Treatment.—The treatment of strangulated hernia is by means either of *taxis* or of *herniotomy.*

Taxis is the reduction of the protrusion by manipulation. It is best performed with the aid of a general anæsthetic, and the operator should be prepared to resort at once to herniotomy if his efforts at reduction fail. In inguinal and femoral hernia the parts are relaxed by flexing the thigh on the pelvis and rotating it in an inward direction. Placing the patient in a position of slight inversion, *i.e.*, with the head lower than the pelvis, is permissible.

The neck of the sac is then grasped with the left hand and gentle efforts are made with the right hand to press the contents back. Pressure should be exerted in the direction of the canal; upward, outward, and backward in inguinal and backward and upward in femoral hernia. The efforts should never be prolonged for more than five minutes and roughness is distinctly contraindicated.

Success is determined by the complete disappearance of the hernia, and by the fact that the surgeon can pass his finger through the ring.

Taxis is contraindicated in the following conditions:

1. When it has already failed.
2. When the superficial tissues are inflamed.
3. When there is reason to suppose that the intestine may be gangrenous.
4. When strangulation has existed for twenty-four hours.
5. When the hernia has been previously irreducible.
6. When there is great prostration.

The dangers of taxis are:

1. Injury or rupture of the intestine.
2. The return of gangrenous intestine to the abdominal cavity.

3. The transference of septic fluid from the sac into the general peritoneal cavity.
4. "Reduction *en masse.*"

Reduction *en masse* is rare, is more frequent in inguinal hernia, and is practically the conversion of the hernia into a form of interstitial hernia; the sac and its contents being forced into a position between the transversalis fascia and the remainder of the abdominal wall, while the constriction still remains at the neck (Fig. 2622). The sac may be ruptured and its contents escape into its new position; or only part of the sac may be reduced.

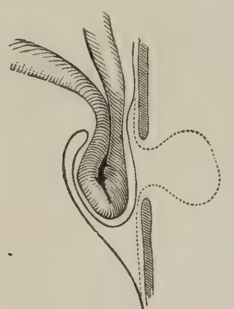

FIG. 2622.

In modern surgery taxis is resorted to with constantly diminishing frequency, most surgeons now performing herniotomy at once.

Herniotomy and *kelotomy* are the terms applied to the operation for the relief of strangulated hernia. This operation possesses the advantage over taxis of avoiding its dangers, of permitting inspection of the intestine, and of affording an opportunity for the radical cure of the hernia.

The steps in the operation are:
1. The exposure of the sac.
2. Opening of the sac and relief of the constriction.
3. Treatment of the contents.
4. Closure of the wound.

The sac is exposed by an incision similar to that which would be employed in an operation for radical cure. The incision should be made in such a manner as to expose well the neck of the sac, and it may have to be prolonged in order to afford room for resection of the bowel. The sac is recognized by its dark color and its gliding over the contents. It is opened by pinching it up with forceps so as to form a fold which can be incised without injury to the contents. When an opening has been made, the fluid which escapes will be clear and odorless, although it may be bloody, if the gut is sound; or it will be cloudy, purulent, or feculent, if the vitality of the gut has become impaired. The interior of the sac and the contents are then thoroughly washed with normal salt solution to lessen the chances of contamination and the constriction is sought for and divided.

Inasmuch as the constriction is usually caused by bands of fascia which lie outside the sac, division is best done from without, and not from within, as was formerly taught by the old school. It may be necessary, however, in some femoral herniæ to divide it from within, which is done by cutting upward with the herniotome or blunt-pointed bistoury or by use of a director. The constriction having been freely divided the gut must be gently drawn out to expose the efferent and afferent portions, especially the latter, in order to observe their condition, since changes in their nutrition may have occurred for a considerable distance within the abdomen. If the condition of the gut is satisfactory it is returned to the abdomen and the wound is closed as in the operation for radical cure of a hernia of the same variety.

The gut is returned if its peritoneal coat is smooth and glistening, if its color is not black or gray, even though it may be dark red or purple, if the fluid in the sac is odorless and clear, and especially if it has retained the power of contractility in all its parts. It must not be returned if the peritoneum has a granular aspect, if the fluid is cloudy and foul, or if the gut is cold and flabby and has lost its contractility. If there is doubt, the constriction having been freely relieved, the bowel may be surrounded with compresses wet in warm normal salt solution, for several minutes, and its condition again noted. In cases of exceptional doubt it may be thus left for twenty-four hours. Very small areas of gangrene may be excised and the edges of the resulting perforation turned in with Lembert sutures.

If the gut is not in a returnable condition, there are two methods of treatment applicable: 1. Resection and immediate reunion. 2. Formation of an artificial anus. In the performance of the latter the gut is either fixed by a few sutures to the margins of the wound and opened to relieve the obstruction, or it is resected and the ends are sutured to the wound.

In the choice between resection and immediate reunion, and the formation of an artificial anus, the operator must take into consideration the condition of the patient and his own skill as an intestinal surgeon. According to Hofmeister,[3] the decision to form an artificial anus is tantamount to the expression that the case is otherwise hopeless.

As the following statistics in regard to gangrenous hernia show, the treatment by primary resection and immediate reunion is the most successful.

Compiler or operator.	ARTIFICIAL ANUS.			PRIMARY RESECTION AND REUNION.		
	Cases.	Deaths.	Mortality, per cent.	Cases.	Deaths.	Mortality, per cent.
Zeidler[4] (1892)..........	287	213	74.22	289	142	49.13
Mikulicz[5].....	94	72	76.6	68	32	47.1
Hofmeister[6] (1900)......	167	101	60.5	214	99	46.0
Petersen (up to 1898)....	17	10	57.0	16	8	50.0
Petersen (since 1898)....	5	5	100.0	12	1	8.3
Petersen[7] (total)........	22	15	68.2	28	9	32.14
Gibson[8] (1900)..........	101	53	52.5	226	58	26.0

Of these series Gibson's are the most comprehensive and argue strongly in favor of resection and reunion. His statistics in regard to the formation of an artificial anus with and without resection of the gangrenous intestine show a very slight advantage in favor of resection. In twenty cases collected by him in which the gangrenous portion was invaginated, three patients died—a mortality of fourteen per cent.

The large mortality following the formation of an artificial anus is due not only to the immediate condition, but also to asthenia if the anus is situated high up in the tract, and to the subsequent measures taken to cure the artificial anus. The mortality of the operation for relief of artificial anus following herniotomy is in the neighborhood of twenty-five per cent.

The chief considerations to be observed in regard to the treatment of gangrenous hernia are: the use of local anæsthesia if feasible; the employment of a large wound (hernio-laparotomy), enabling the operator to return the intestine easily and visibly, thus avoiding kinking; the emptying of the intestine so far as possible; wide resection, the amount removed depending largely on the condition of the mucous membrane; open treatment of the wound by tamponade when peritonitis is present, or if the condition of the returned bowel is still suspicious.

For the technique of intestinal resection the reader is referred to special articles on that subject. A fatal outcome in herniotomy is due to one or more of the following causes: 1. Shock. 2. Return of damaged intestine (insufficient resection). 3. Extension of an existing peritonitis, or one due to leakage (faulty suture). 4. Kinking or twisting of the returned loop. 5. Exhaustion (artificial anus).

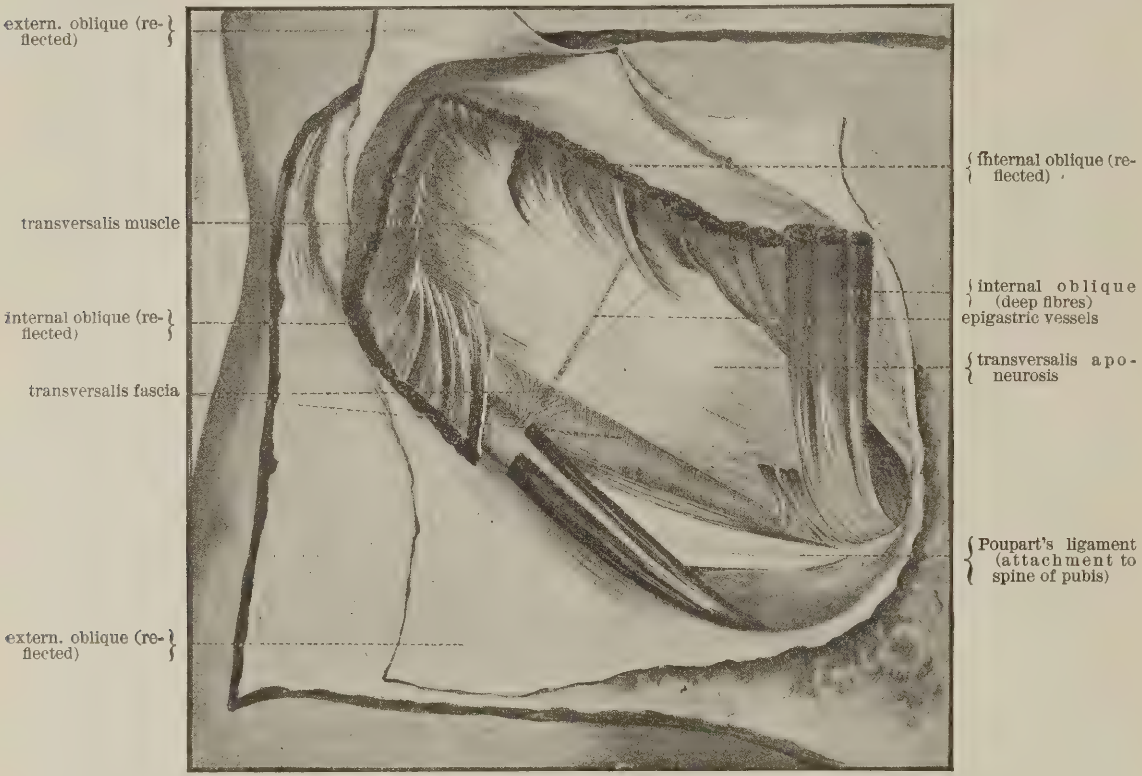
The after-treatment does not differ from that employed after other operations upon the intestinal tract. For the first few days the bowels are best opened by enemata.

ANATOMICAL VARIETIES OF HERNIA.

INGUINAL HERNIA.—This term includes all herniæ into or through the inguinal canal.

Anatomy.—For the detailed anatomy of this region the reader is referred to special treatises. There are, however, certain considerations which are not generally made clear, and which have considerable bearing especially upon the methods of radical cure. In the second month of fœtal life a process, the *processus vaginalis peritonei,* is found evaginated from the peritoneum of the body cavity and accompanying the gubernaculum to that part of the skin of the inguinal region which becomes the scrotum in the male and the labium majus in the female.

Later the testicle descends alongside of this process to the scrotum, and the distal portion of the process forms the *tunica vaginalis testis.* The proximal portion ordinarily becomes obliterated, but if it remains open the tunica vaginalis continues in communication with the peritoneum, and a portion of the abdominal contents may descend through it. Such a protrusion is known as a congenital hernia, even if it does not descend until adult life. If the process remains open in the female it is known as the canal of Nuck.



extern. oblique (reflected)
transversalis muscle
internal oblique (reflected)
transversalis fascia
extern. oblique (reflected)
internal oblique (reflected)
internal oblique (deep fibres)
epigastric vessels
transversalis aponeurosis
Poupart's ligament (attachment to spine of pubis)

FIG. 2623.

Incomplete or partial obliteration of the process gives rise to cystic swellings, known as hydroceles of the cord or of the round ligaments, as may be.

The abdominal wall in this region, omitting the superficial structures, consists of the following muscular and aponeurotic layers from without in: the aponeurosis of the external oblique, the internal oblique and transversalis muscles, and the transversalis fascia. At the mesal part of this region the rectus abdominis is inserted into the pubis on a plane dorsad to the structures enumerated, with the exception of the transversalis fascia, which sends a prolongation over the dorsal surface of the muscle.

The general arrangement of these structures is shown in the accompaning figures (Figs. 2623 and 2624). The inguinal canal, which contains the gubernaculum and processus vaginalis peritonei in the fœtus and the spermatic cord or round ligament in the adult, and through which the testicle passes in its descent, is found between these structures. Its commencement, the internal abdominal ring, is an aperture in the transversalis fascia normally just large enough to permit the passage of the cord. Its termination, the external abdominal ring, is a slit-like aperture in the aponeurosis of the external oblique muscle. The internal ring is situated about 4 cm. laterad to the spine of the pubis and about 1 to 1.5 cm. above Poupart's ligament, being suspended as it were in the transversalis fascia (Fig. 2624), which is developed in curving fibres on its mesal and lower aspect, forming the inguinal ligaments of Henle. It lies thus about half-way between the anterior superior spine of the ilium and the spine of the pubis, and a finger's breadth above Poupart's ligament. The deep epigastric artery passes upward at the mesal border of the ring between the transversalis fascia and the peritoneum. The external ring lies just above and laterad to the spine of the pubis.

The inguinal canal is about 3.5 cm. long and is slightly longer in the female than in the male. At its commencement its ventral wall is formed by the thick fleshy fibres of the internal oblique and the transversalis muscles, and its dorsal wall by the transversalis fascia. At about its middle its dorsal wall is still the transversalis fascia, but the internal oblique and transversalis muscles are above it and its ventral wall is formed by the aponeurosis of the external oblique. At its termination it escapes through the external oblique, and its dorsal wall is here formed by transversalis fascia, which for the last centimetre is strengthened by the conjoined tendon and the triangular ligament. In the final two-thirds of its course its floor is formed by the shelf of Poupart's as it broadens into Gimbernat's ligament. The greater part of the dorsal wall is thus seen to be formed by the transversalis fascia, and the importance of this as a safeguard cannot be overestimated. It is in fact a special development of the transversalis fascia, and by some it has been described as a part of the conjoined tendon, although it is entirely distinct from this structure. Its mesal portion consists of strong vertical fibres, its lateral of the fibres before mentioned as curving about the internal ring. Between these stronger portions is a weaker one, lying as a rule on the mesal side of the deep epigastric artery, and at this part direct inguinal herniæ occur (Fig. 2624). The transversalis muscle is very poorly developed in this region, and consists chiefly of an aponeurosis, the fibres of which pass horizontally across to their insertion in the ventral rectus sheath, and as a rule are wanting for some distance above Poupart's ligament (Fig. 2623). The internal oblique muscle, on the other hand, consists of a thick, fleshy mass of fibres which, unless displaced by a hernia or ill developed, completely protect the internal ring and pass to their insertion with a general direction parallel to Poupart's ligament, only rising sufficiently to allow the cord to pass below them. The conjoined tendon consists of a few fasciculi derived from the opposed surfaces of the internal oblique and transversalis muscles, and passes on the deep surface of the former muscle to be inserted by tendinous fibres to the crest and ilio-pectineal line. This structure is wholly concealed by the internal oblique, and its insertion seldom extends for more than a centimetre laterad to the spine of the pubis.[9] Although given considerable prominence in most text-books, it is a negligible factor in procedures for the radical cure of hernia.

An oblique inguinal hernia is enclosed in the same layers of fascia as the spermatic cord. These layers from within out are: the infundibuliform fascia derived from the transversalis fascia; the cremasteric fascia and muscle derived from the internal oblique; and the intercolumnar fascia derived from the external oblique. These layers must be divided in separating the sac from the cord. The fascial coverings of a direct hernia are the same, with the exception that the transversalis fascia itself is substituted for its infundibuliform process.

FIG. 2624.

The relations of the spermatic cord to the sac are important. The structures of the cord are usually somewhat spread out on the surface of the hernia unless the latter is small or a direct one. The vessels lie on the lateral and the vas deferens on the latero-dorsal aspect of the sac. In a direct hernia the entire cord is on the lateral aspect of the sac. In congenital hernia the cord is more closely adherent to the sac than in acquired herniæ. The importance of the peritoneal fossæ on the internal abdominal wall as etiological factors in the production of hernia seems to the writer to be exaggerated. The presence of muscular or fascial weaknesses or dimples is of far greater importance, inasmuch as the peritoneum is a highly elastic and distensible membrane, and when unsupported by other structures offers little resistance to pressure from within. For the same reason the treatment of the neck of the sac is of minor importance in the operation for radical cure.

Varieties of Inguinal Hernia.—Inguinal herniæ are divided into *direct,* which is always acquired, and *indirect* or *oblique,* which may be congenital or acquired (see Anatomy). In a direct hernia the protrusion is mesal, while in an indirect hernia it is lateral to the deep epigastric vessels. If the protrusion passes through the external abdominal ring into the scrotum or labium majus it is termed a complete or scrotal hernia; if not, an incomplete hernia or bubonocele.

Direct Inguinal Hernia.—Direct inguinal herniæ constitute seven per cent. of all inguinal herniæ. They are more common in men than in women and are seldom seen in children. They are always acquired. They are seldom complete and may usually be recognized by their globular shape and by the fact that they appear to bulge directly through the abdominal wall.

Indirect Inguinal Hernia constitutes the greater part (ninety-three per cent.) of inguinal herniæ. The hernia may descend into the unobliterated processus vaginalis either in the male or in the female, being then called congenital hernia (Fig. 2625, *A*); or its sac may be formed by the protruded peritoneum of the abdomen—acquired hernia. The proportion of congenital to acquired herniæ is difficult to state, as the diagnosis is made only by operation. A study by Bull and Coley[10] of five hundred cases of inguinal hernia operated upon in children under fourteen years of age showed that less than fifty per cent. were congenital.

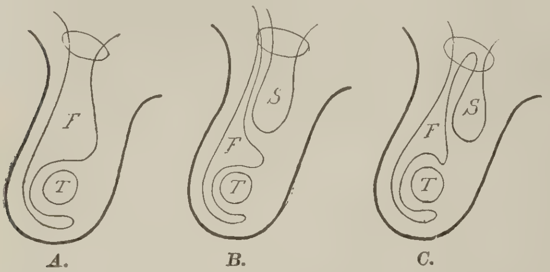

Fig. 2625.—Formation of Sac in Congenital and Infantile Hernia. *A*, Congenital hernia; *B* and *C*, infantile hernia; *F*, funicular process; *S*, sac; *T*, testicle.

A form of hernia known as *infantile hernia*, although always acquired, is sometimes confounded with congenital hernia. The hernial sac in these cases is formed from the parietal peritoneum and is pushed down alongside of an open or partially obliterated funicular process; the different varieties of this form depend upon the extent and the site of the obliteration (Fig. 2625, *B* and *C*). Since the unobliterated funicular process is often spread out over the hernial sac, the latter appears as a sac within a sac; hence the term encysted hernia.

Interstitial Hernia is a form of inguinal hernia in which the protrusion insinuates itself between the layers of the abdominal wall. According to Langdon,[11] the frequency of interstitial hernia is 1 in 1,100. It is relatively more common in females than in males, forming 0.13 per cent. of all inguinal herniæ in males and 0.61 per cent. in females.[1]

Three varieties are recognized. In order of frequency they are: (1) Between the internal oblique and the aponeurosis of the external oblique; (2) between the aponeurosis of the external oblique and the skin; and (3) between the peritoneum and the transversalis fascia (properitoneal hernia). The first two varieties present an external swelling, while no visible or palpable tumor is found in the last variety. In the majority of the cases of the last variety there is also a scrotal or labial hernia. Such an accompaniment is seldom observed in the first two varieties. In fact the sac of a properitoneal hernia is usually a diverticulum of the sac of a complete hernia; and herein lies its danger, since a false idea of security may follow reduction of the complete portion.

The causes contributing to the production of interstitial hernia are efforts at reduction, giving rise generally to the properitoneal form; and errors in development, namely, non-descent of the testicle or incomplete closure of the canal of Nuck. Macready states that in 67 per cent. of the cases in males the testicle was wholly retained or only partially descended. According to Langdon,[11] in 42 cases of interstitial herniæ in males in only 2 were the testicles in normal position in the scrotum.

The second and third varieties may acquire very large dimensions. Inasmuch as it is difficult to prevent the return of an interstitial hernia by a truss, operation is as a rule indicated.

Diagnosis of Inguinal Hernia.—The subjective symptoms are pain, which is present in ninety-six per cent. of all cases in the early stages, and later a sense of fulness and discomfort. The chief objective sign is a tumor, which as a rule disappears when the patient lies down but returns upon his standing, coughing, or crying. Impulse is present in reducible forms, and in complete hernia the contents may be felt to descend by the finger introduced into the canal.

Incomplete hernia or bubonocele must be differentiated from femoral hernia, hydrocele of the cord or canal of Nuck, inflammatory conditions and new growths of the inguinal glands and cord, psoas abscess, and undescended testicle. It is distinguished from femoral hernia by its relation to Poupart's ligament and the spine of the pubis; from hydrocele by the irreducibility, circumscription, and fluctuation of the latter; and from psoas abscess by the presence in the latter condition of a deep-seated swelling above Poupart's ligament, between which and the visible protrusion fluctuation can be obtained.

The conditions most commonly confounded with complete inguinal hernia are hydrocele, hæmatocele, varicocele, and tumors or inflammatory conditions of the testicle or epididymis. The statements of the patient as to the position and growth of the swelling at its incidence, taken with the characteristic signs of the several conditions, will serve, as a rule, to make the diagnosis evident.

Treatment of Inguinal Hernia. (For treatment by truss see "Mechanical Treatment of Hernia.")

Radical Cure of Inguinal Hernia.—The operative methods devised for the cure of inguinal hernia are so numerous, and so many have become obsolete, that the reader must be referred to special treatises for the details of those operations which have a historical interest only.

The success with which radical cure is performed at the present time is due primarily to the almost uniform aseptic healing obtained, and, secondly, to the improvements in technique and method. The aim of present methods is to secure the least possible scar formation, and the production of a muscular contractile barrier against future relapse.

Methods depending upon the use of foreign materials to form an obturator have been advanced in the last few years but have not become popular, largely on account of the inherent difficulties in getting such substances to remain within the tissues of the body without giving rise to trouble.

The methods most commonly in use at the present time and which have given the best results are the following: Bassini's (1888), Halsted's (1890), Kocher's (1892), and Macewen's (1886).

The Bassini operation is the favorite one at present. According to a recent writer,[12] about ninety-five per cent. of all operations for inguinal hernia are being done by this method or slight modifications of it. The steps of the operation are as follows: The incision is made parallel with Poupart's ligament and 2 cm. above it, from a point laterad to the internal ring to a point corresponding to the centre of the external ring. The length of the incision is 7 to 9 cm. in adults and shorter in children.

The incision is carried directly to the aponeurosis of the external oblique, and if properly planned should strike it in the line of divergence of the pillars of the external ring. The superficial structures should not be stripped from the aponeurosis since its vitality is thereby impaired. The aponeurosis is then slit in the direction of its fibres for a distance of 5 or 6 cm. from the external ring, care being taken not to wound the underlying structures. The upper lip of the aponeurosis is then stripped from the surface of the internal oblique and the sheath of the rectus for a distance upward of about 3 cm. This separation is important, as it facilitates the bringing down of the fibres of the internal oblique in the final steps of the operation. The tissues covering the cord and sac are similarly stripped from the lower lip of the aponeurosis until the deep surface of Poupart's ligament is well exposed as far as its insertion to the pubic spine. This clearing of the deep surface of the external oblique is best done by blunt dissection, the instrument being swept toward the middle line in the direction of the aponeurotic fibres.

The sac and cord enclosed in their coverings now lie freely exposed, and the second step of the operation, the isolation of the sac, is commenced. A longitudinal incision is made through the cremasteric and transversalis fascia, exposing the sac at its uppermost part (Fig. 2626). The assistant now catches the sac with two toothed forceps, one at each extremity of the incision, and lifts it upward, while the operator seizing the margin of the fascia nearest to him, *i.e.*, on the outer aspect of the sac, draws it away from the sac. The vessels of the cord now appear and must be freed from the sac by a few light touches of the knife. Just beneath the vessels on the outer side of the sac the vas deferens is recognized and is to be freed in a similar manner. The operator in grasping these structures should use smooth forceps and make very light pressure. As the dissection is carried around the sac the assistant shifts his hold, so that at all times the sac is kept tense. If any vessel is divided in this dissection it should be immediately caught and tied so that the field may not be obscured.

The cord now being isolated from the neck of the sac, the finger is inserted between it and the sac from without inward, and curved about the latter; in this way the remaining attachments of the fascia on the inner aspect of the sac are easily stripped off over the point of the finger and the neck is completely circumscribed. The direction of the encircling finger may now be reversed, and the stripping of the sac can be readily accomplished by pushing the cord away from it with gauze, this being aided by a few touches of the knife.

If this procedure is carried out with extreme gentleness subsequent swelling of the cord rarely ensues.

The fundus of the sac having been freed, it is lifted up, and the internal oblique having been retracted to expose the internal ring, the freeing of the sac is carried upward beyond its neck to the point where it flares out into the parietal peritoneum. On the inner aspect of the neck considerable subperitoneal fat will be found, and in large indirect as well as in direct herniæ this may contain the bladder. In congenital hernia the sac is cut in two, the lower portion being of sufficient size to cover the testicle, over which it is sutured.

The third step of the operation comprises opening of the sac, reduction of its contents, and ligation of the neck. Adherent masses of omentum are treated in the usual manner by chain ligation. Ligation of the sac is done by drawing it down as far as possible, its mouth being kept open, and then transfixing its neck as high as possible with a needle carrying heavy catgut. The ligature is tied around each half of the neck separately and then around the entire neck, and the sac is cut off. If the neck is too large for ligation it must be sutured (Fig. 2627).

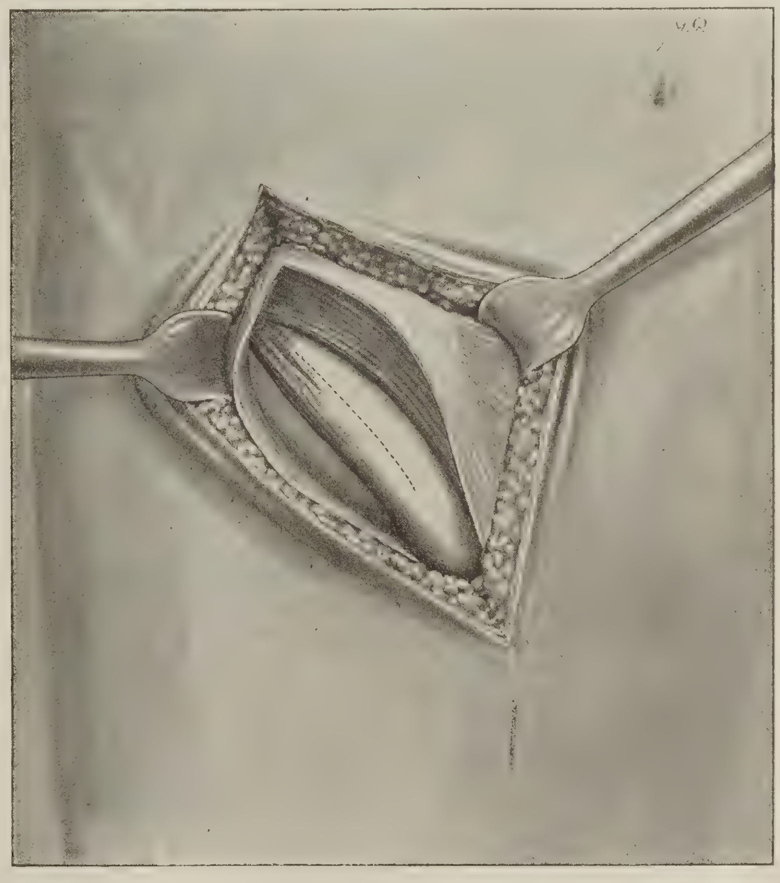

FIG. 2626.—Operation for the Radical Cure of Inguinal Hernia, Bassini's Method. External oblique divided and retracted. Sac in place. Line indicates incision preliminary to separation of cord from sac.

The fourth step is the most important, and herein lies the peculiarity of the Bassini operation, namely, the transplantation of the cord and the suture of the internal oblique* to Poupart's ligament. The cord is first freed from its bed and retracted to the outer part of the incision against the point of origin of the internal oblique from Poupart's ligament.

The first stitch is taken on the inner side of the cord, the needle passing through the whole thickness of the internal oblique 1.5 to 2 cm. from its margin, and then picking up the deep shelving portion of Poupart's ligament. This suture should just touch the cord when it is held at right angles to the wound. Three or four similar sutures are then taken until the spine of the pubis is reached. The last suture takes in the conjoined tendon, and it is often better to include also in it the margin of the rectus, especially when the insertion of the internal oblique does not extend down to the pubic spine (Figs. 2628 and 2629).

The writer, following the example of W. B. Coley, always puts a suture on the outer side of the cord, but he differs from Coley in that he inserts and ties it before the other sutures are introduced, while Coley puts it in last. This suture subserves two purposes: it gives the muscular fibres a lower plane at their origin and it places the point of emergence of the cord at a greater distance from the internal abdominal ring, thus giving the latter additional protection. The sutures should be tied without tension to avoid strangulation of the muscle fibres.

The best suture material is one that will be absorbed in about thirty days. Kangaroo tendon fulfils this condition best, then chromicized catgut. Non-absorbable suture material should not be used, for the tissues sometimes resent its presence and extrude it.

---

* The internal oblique muscle is alone mentioned, since it is practically the only structure sutured to the ligament. See the section on Anatomy.

The next step is the suturing of the external oblique, which is done so as to include the cord between it and the internal oblique. A continuous suture is sufficient (Fig. 2630).

The cutaneous incision is then closed with or without drainage, according to the operator's technique.

In the female the steps of the Bassini operation are carried out as in the male, with the exception that in the description of the procedures the round ligament is to be understood whenever the cord is mentioned.

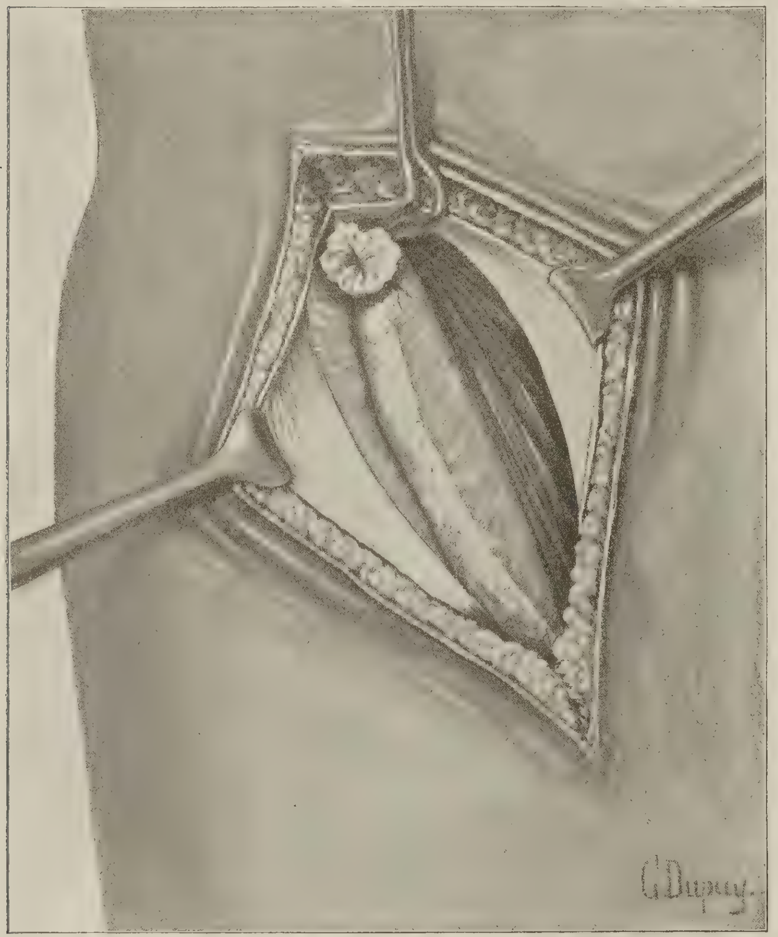

FIG. 2627.—Operation for the Radical Cure of Inguinal Hernia. Bassini's method. The margins of the aponeurosis of the external oblique muscle are retracted horizontally, the internal oblique upward, exposing the site of ligature of sac at the internal ring. The cord lies on the transversalis fascia.

The writer, however, believes it to be a mistake to transplant the round ligament—*vide infra.*

Suture of the muscles without transplantation of the cord has been practised with success by Bull and Coley.[13] The writer has also employed this modification in cases in which the transversalis fascia forming the dorsal wall of the canal was well developed.

Transplantation of the Rectus Muscle.—To meet the condition in which the transversalis fascia forming the dorsal wall of the canal is deficient and the neck of the hernia is very large, Bloodgood[14] devised a most excellent method of transplanting the rectus muscle by slitting its deep or dorsal sheath and drawing it down with the internal oblique to Poupart's ligament. This method is superior to Wölfler's[15] in that the latter operator slits the ventral sheath, thus destroying the insertion of the internal oblique and transversalis at that point. Bloodgood's operation is done in conjunction with the Halsted operation (Fig. 2633). The writer has used his method of opening the sheath, but has stitched the rectus to Poupart's ligament first and brought the internal oblique down in front of it as in the Bassini operation. This procedure is also of value in direct herniæ and when the internal oblique is deficient.

Halsted's Method.[16]—The cutaneous incision, slightly more vertical than the Bassini, having been made, the knife is carried down from the outermost part of the external ring through the aponeurosis of the external oblique, the internal oblique and transversalis muscles, and the transversalis fascia to a point 2 cm. above and slightly lateral to the internal ring. The sac is isolated as high as possible and resected, and the peritoneum is sutured.

The veins of the cord are excised with the exception of one or two. Mattress sutures are then introduced through the entire thickness of the abdominal wall above, with the exception of the skin and peritoneum, and through the transversalis fascia, Poupart's ligament, and the aponeurosis of the external oblique below, the sutures passing beneath the cord, so that when they are tightened the cord lies directly beneath the skin. The sutures are passed so that the distal cut ends of the internal oblique are sutured to Poupart's ligament; thus, as it were, rotating the muscle. Halsted usually employs silver wire (Figs. 2631 and 2632). It is at once seen that there are marked differences between this method and Bassini's. These are: 1. The division of the internal oblique muscle. 2. The transplantation of the cord to a position between cut ends of muscle fibres. 3. The bringing of the cord in a direct line through the entire muscular wall. 4. The excision of the veins. 5. The suture *en masse* of the muscle. These differences are considered by some to be objections.

In fact, in the relapses after Halsted's operation the descent usually occurs along the cord, and in order to obviate this he has lately transplanted the vas deferens alone. The failures of the operation may be attributable to the first three of the points above enumerated. The excision of the veins has, moreover, led to atrophy of the testicle in some cases.

Bloodgood's Method[15] is the same as Halsted's, with the addition, already mentioned, of including the rectus drawn out of its sheath in the lower mattress sutures (Fig. 2633).

The distinguishing features of Kocher's and Macewen's methods consist chiefly in their treatment of the sac.

Kocher's Method.—The aponeurosis of the external oblique is exposed but not divided. The sac is separated from the cord and the separation is carried up to the internal ring where the sac is ligated. A forceps is now thrust through the external oblique aponeurosis above Poupart's ligament and the sac is caught and drawn out of this opening. It is then laid on the surface of the aponeurosis, which is plaited over it with a sort of Lembert suture. These sutures also narrow the canal (Figs. 2634 and 2635).

Macewen's Method.—In this method the sac is folded with a sort of accordion plait by means of a suture, passed from its extremity back and forth through both its walls; the suture is then continued through the transversalis fascia and the muscles above the internal ring in a direction from within outward. The sac thus forms a pad at the ring. The internal ring is then narrowed by suturing the transversalis fascia above it to Poupart's ligament with a mattress suture. Several stitches may be inserted.

The objection to these last two methods is that the sac, when stripped, and especially when ligated, is practically effete material, and it is unsurgical to retain it in the body.

Fowler's Method.—The posterior wall of the canal, consisting of the transversalis fascia and peritoneum, is divided from the internal ring inward to the border of the rectus, and the cord is displaced to this point. The internal ring and the transverse incision are then closed. The incision divides the deep epigastric vessels. The canal may be closed by suture of the internal oblique to Poupart's ligament. This procedure is of particular value in cases associated with undescended testicle, in order to obtain additional length of cord.

Lucas Championnière's Method.—The peculiarity of this method lies in the manner of closing the canal. The muscles and aponeurosis of the upper lip of the wound are brought down over the aponeurosis of the lower lip and retained by mattress sutures, thus producing an overlap.

Remarks.—The chief accidents happening from operations for radical cure are injury of the vas deferens, hemorrhage from omental stumps, to be avoided by including only small masses, pneumonia following the anæsthesia, and sepsis. The occurrence of sepsis largely increases the percentage of relapses.

The mortality is slight. Bull and Coley[17] have found it to be 0.9 per cent. in 10,000 operations performed between 1886 and 1897. In 2,000 later operations the mortality was less than 0.2 per cent. No operations for strangulated hernia are included in these lists.

As a rule children under four years of age and adults over fifty should not be operated upon, inasmuch as many children are cured by the wearing of a truss, and in the aged the hernia can be controlled by truss with less inconvenience than in the younger and more active, while the dangers of operation are greater. Patients with bronchitis should defer operation; but in cases of chronic respiratory diseases, and when the necessity presses, it may be done under local anæsthesia after Cushing's method. As before stated, large irreducible herniæ are not suitable for operation. The best results are obtained in children and young adults.

Choice of Methods.—The most desirable operation is one that combines simplicity with the best results in the hands of a large number of operators.

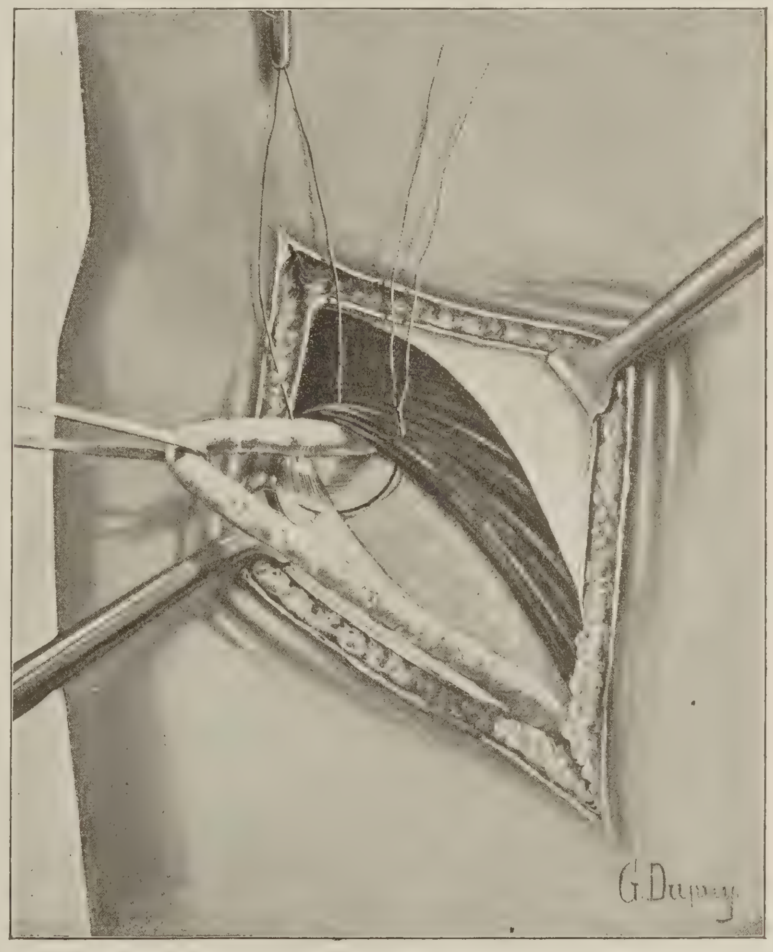

FIG. 2628.—Operation for the Radical Cure of Inguinal Hernia, Bassini's Method. Sac removed, cord drawn aside, and lower fibres of the internal oblique and transversalis muscles stitched to Poupart's ligament from without inward. The transversalis fascia appears at the deepest part of the field of operation.

The Bassini operation seems to meet these requirements better than any other. The percentage of relapses after this operation is probably not greater than 5 in good hands. Coley[18] reports 500 cases traced with 6 relapses only. Galeazzi[19] has collected 1,334 cases operated upon by surgeons out of Italy, with only 2.16 per cent. of relapses. The Halsted method has given 6.5 per cent. relapses, but better results are reported since the veins of the cord have been excised as a routine measure.

The methods of Macewen, Kocher, and Championnière, although each gives as good results in the hands of its originator, have in other hands given much poorer results than the Bassini.

Hernia Associated with Undescended Testicle.—The treatment of this condition is still the subject of considerable controversy. The weight of opinion seems to be that children under ten or twelve years of age should have mechanical treatment if possible, as the truss can be constructed so as to crowd the testicle down. In all cases of operation the testicle should be preserved if possible.

Anchoring of the testicle to the bottom of the scrotum is useless, it should rather be crowded down by passing deep sutures through the deep fascia.

The cord should not be transplanted, as length can be gained otherwise. Possibly Fowler's method would give still greater length.

Operations in children under fourteen years as a rule give the best results, as the testicle is more likely to become scrotal if retained outside the external ring before the changes incident to puberty have taken place.

Post-Operative Treatment.—The patient remains in bed in the reclining position for eighteen days, but is usually able to be up and around on the twenty-first day. This may be stated as the time necessary after operation for any variety of hernia, although sometimes for especial reasons a longer period may be desirable.

Trusses After Operation.—In children and young adults in whom there is good muscular development and the hernia has not been very large, a truss is unnecessary. Each case has to be judged by itself.

Femoral Hernia.—A femoral hernia is one that descends in or alongside the femoral sheath. The most common form is that in which the gut or omentum descends through the crural or femoral canal, which lies at the mesal side of the femoral vein. In rare cases the hernia may descend in front of the vessels or even on their lateral aspect.

Anatomy.—The femoral sheath is formed by the funnel-shaped process of the transversalis fascia, which is prolonged from the abdominal cavity downward dorsad to Poupart's ligament into the thigh to form the sheath of the femoral vessels. The sheath is too large for the vessels at its commencement but contracts at the saphenous opening to enclose them snugly. Thus a space not occupied by the vessels is left on the mesal side of the vein, and is known as the crural canal. Its ventral boundary is Poupart's ligament; its mesal Gimbernat's ligament; its dorsal the ilio-pectineal line, Cooper's ligament, and the pectineus muscle; and its lateral the femoral vein from which it is separated by a septum of fascia. The space is filled with loose areolar tissue, the septum crurale, and a small lymph node (Fig. 2636).

The deep epigastric artery passes up on the lateral aspect of the canal. In about thirty per cent. of cases the obturator artery is given off from the deep epigastric and then is in relation with the crural canal; although it generally passes downward to the obturator canal on the lateral aspect of the crural canal, yet in three per cent. of all cases it passes down on its mesal aspect and is then subject to injury in herniotomy.

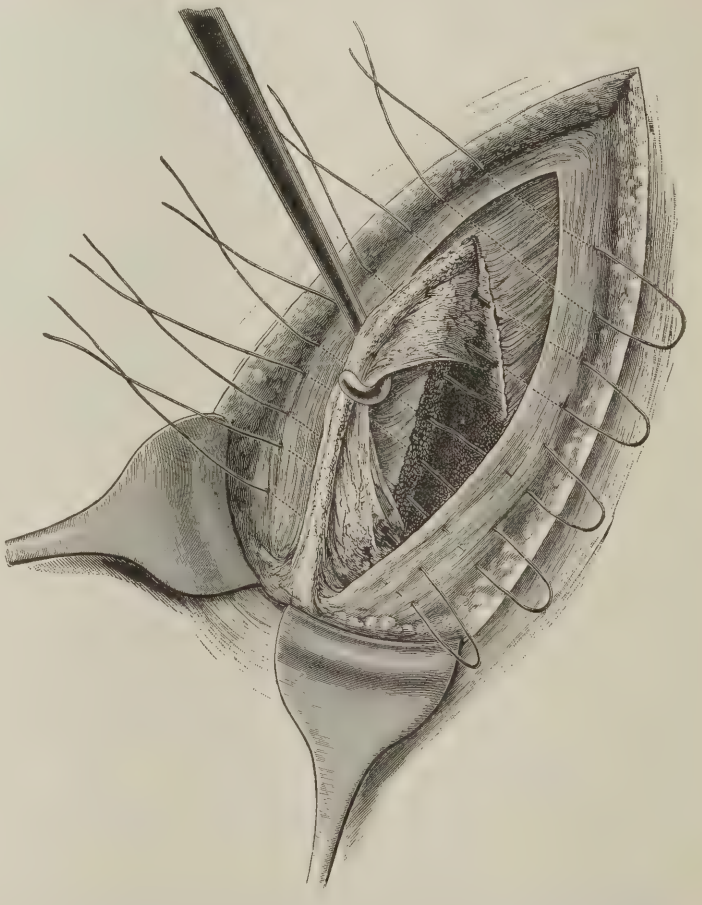

Fig. 2631.—Operation for the Radical Cure of Inguinal Hernia. Halsted's Method. Veins ligatured and resected. Mesocord torn only at its centre. Silver sutures inserted, one above and four below the cord. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

A hernia descending through the crural ring acquires as coverings the peritoneum, the subperitoneal fat which is usually very thick, the septum crurale, the transversalis fascia derived from the femoral sheath, the cribriform fascia, and the superficial fascia and skin.

The protrusion appears in the thigh below the fold formed by Poupart's ligament and below and laterad to the pubic spine. It is usually small and globular or hemispherical in shape. It may extend down the thigh as far as its middle or even farther. Occasionally it turns upward, and passing above Poupart's ligament may be mistaken for an inguinal hernia. Very rarely it may become scrotal or labial. The contents of the sac are more commonly entirely omental than in inguinal hernia. The omentum usually becomes adherent early, especially at the neck of the sac. The intestine is more apt to become strangulated than in inguinal hernia, and gangrene supervenes more quickly.

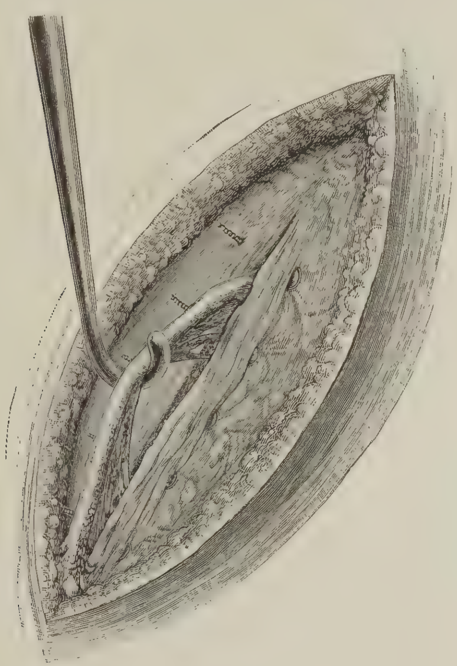

FIG. 2632.—Operation for the Radical Cure of Inguinal Hernia Halsted's Method. Aponeurosis or external oblique closed by silver-wire mattress sutures, ends bent down and buried. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

Occurrence of Femoral Hernia.—Femoral hernia occurs more commonly in women than in men, the ratio being about 3 to 1 in persons under fifty years of age. After this age the proportion of women ruptured decreases so rapidly that the relative frequency in the two sexes is nearly the same. As compared with inguinal hernia the frequency is 1 to 17 according to the statistics of the Hospital for Ruptured and Crippled,[15] according to Macready[1] the ratio is 8 to 92. According to the same author, of 100 men ruptured, 97.5 per cent. have inguinal and 2.5 per cent. femoral hernia. Of 100 women ruptured 60.3 have inguinal and 39.7 per cent. femoral hernia.

As to the period of incidence, it is uncommon in early life, but occurs with greatest frequency in persons between sixteen and fifty years of age.

Causes predisposing to it are weakening of fascia resulting from stretching of the abdominal wall in pregnancy, and the greater size of the crural canal in women.

Diagnosis.—Psoas abscess, inguinal hernia, and saphenous varix may be confounded with reducible femoral hernia, inflammation and new growths of the lymph nodes with the irreducible form. In fat females the diagnosis between femoral and small inguinal herniæ is not always easy.

Treatment.—Unless contraindicated by general considerations, all femoral herniæ should be operated upon for the following reasons: They are more dangerous than inguinal herniæ, they are practically incurable by mechanical means, the operation is simple, and by it permanent cure is nearly always obtained.

Bassini's Method. The sac is exposed by an incision parallel with and slightly below Poupart's ligament. Having been cleared of fat and separated from the canal, the sac is drawn down as far as possible, transfixed, and ligated, after reduction of its contents, and the stump is allowed to recede into the abdominal cavity. Poupart's ligament, the pubic portion of the fascia lata, and the canal having been well cleared of fat, interrupted sutures are now introduced so as to unite Poupart's ligament with the pubic portion of the fascia lata covering the pectineus muscle, care being taken to avoid the femoral vein.

The upper sutures are inserted parallel with Poupart's ligament and pass into the pectineus muscle. The lower sutures unite the falciform process to the pubic portion of the fascia lata. The canal is thus closed (Fig. 2637).

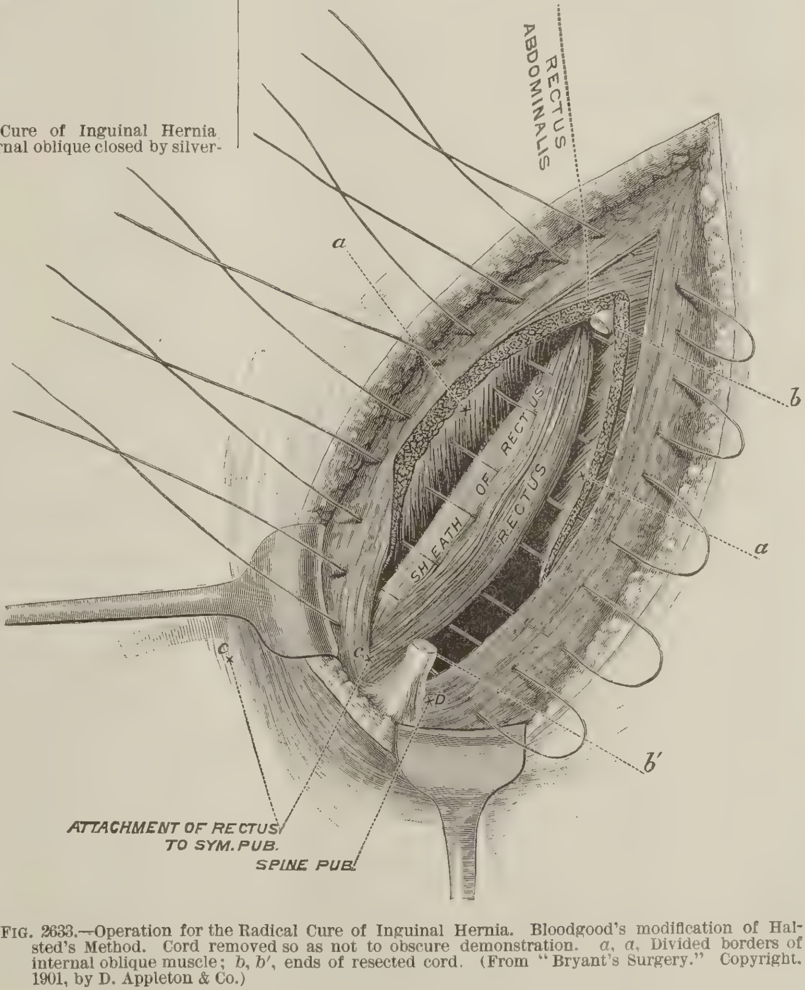

FIG. 2633.—Operation for the Radical Cure of Inguinal Hernia. Bloodgood's modification of Halsted's Method. Cord removed so as not to obscure demonstration. *a*, *a*, Divided borders of internal oblique muscle; *b*, *b′*, ends of resected cord. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

Purse-string Method. The procedure in this method is the same as in the Bassini operation, with the exception that the canal is closed with a single purse-string suture passed in the following manner: A curved needle is introduced through Poupart's ligament and picks up the superficial fibres of the pectineus and its fascia, the falciform process, and finally emerges through Poupart's ligament a short distance from its point of entrance (Fig. 2638). When the canal is very large Bassini's method is preferable.

Gordon's Method. This method has lately been advocated by Bacon.[20] The incision commences 2 cm. above Poupart's ligament and 5 cm. from the pubic spine; it then passes parallel with the ligament to a point opposite the canal, where it turns down over the sac, thus exposing the aponeurosis of the external oblique and the sac. The sac is isolated, its contents are reduced, and then the sac is resected and sutured or ligated flush with the peritoneum. The aponeurosis of the external oblique is split along its fibres, thus opening the inguinal canal, the contents of which are then separated from its lower surface, exposing the deep part of Poupart's ligament. The transversalis fascia forming the femoral sheath is then separated from the ligament, thus opening the femoral canal. All the subperitoneal fat and connective tissue are removed from this region, and the internal oblique is united with mattress sutures to the ligamentum Cooperi and the pectineus muscle in such a manner as to cause its lower margin to be everted.

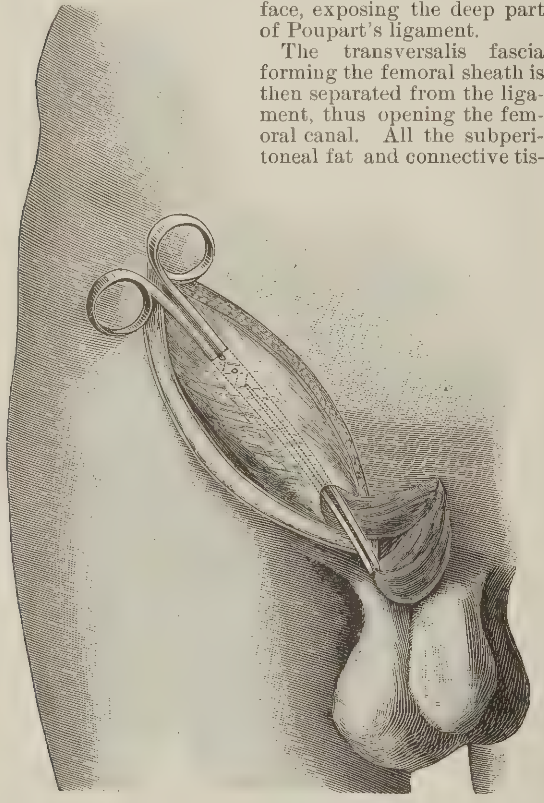

FIG. 2634.—Operation for the Radical Cure of Inguinal Hernia. Kocher's Method. Sac separated and end seized by forceps passed through the transverse incision (*a*) down the inguinal canal. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

The canal is thus closed by muscular tissue. The wound in the external oblique is then sutured and this is followed by closure of the superficial wound.

Results of Operation for Femoral Hernia.—Gordon's operation is so recent that sufficient time for observation has not elapsed and too few cases have been treated to enable one to pass judgment upon it. The far simpler method of Bassini and the purse-string suture have, however, been so efficacious that it seems unnecessary to resort to any other. Bassini reports 54 cases, 41 traced, with no deaths and no relapses. Coley has operated in the same number of cases (by Bassini's and the purse-string methods), most of which have been traced, with no deaths and but one relapse in a Bassini operation in which suppuration occurred.

UMBILICAL HERNIA.—Umbilical herniæ are divided into three classes: 1. Congenital umbilical hernia. 2. Infantile umbilical hernia. 3. Adult umbilical hernia.

Congenital Umbilical Hernia or Hernia of the Cord.—This condition is very rare, occurring according to Lin-

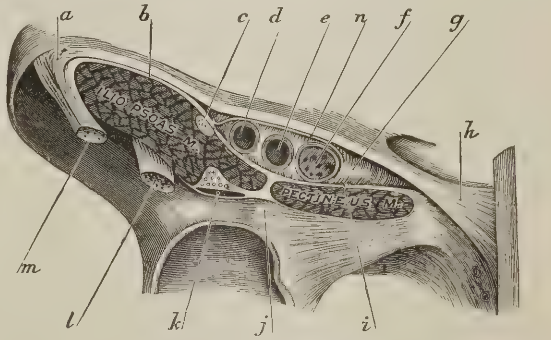

FIG. 2636.—Transverse Section below Poupart's Ligament. *a*, Anterior superior spine of the ilium; *b*, iliac fascia; *c*, anterior crural nerve; *d*, femoral artery; *e*, femoral vein; *f*, septum crurale; *g*, Gimbernat's ligament; *h*, spine of pubis; *i*, pectineal fascia; *j*, ilio-pectineal eminence; *k*, iliac bursa; *l*, rectus femoris muscle; *m*, sartorius muscle; *n*, transversalis fascia. fors[21] once in 5,184 cases. In embryos of 10 mm., and that have not reached beyond the tenth week of development, a portion of the intestine is found in the cavity of the umbilical cord which is continuous with the body cavity. After that period the intestine usually recedes into the body cavity proper and the umbilicus is formed by the union of the visceral plates. However, if development of the abdominal wall be arrested, a varying amount of the viscera may be found in the cord at birth. The term congenital umbilical hernia is erroneous, since no umbilicus has been formed.

The wall of the hernia consists of membrane derived from the same layers that form the amnion. The contents may be a varying amount of intestine alone, the liver alone, or the liver, stomach, spleen, and intestine, *i.e.*, complete eventration. In the latter variety the wall nearly always ruptures at birth and death rapidly ensues. In cases in which the contents can be reduced into the abdominal cavity and the cavity closed, operation gives better results than palliative measures. Of 90 cases collected by H. E. Safford,[22] 64 were treated by laparotomy and suture with 65.6 per cent. recoveries; 1 case by simple ligature, with recovery; 3 cases by percutaneous ligature, with 1 recovery; 5 cases by Olshausen's method, with 100 per cent. of recoveries. Of 15 cases treated expectantly, 47 per cent. recovered.

Olshausen's method consists in separation of the skin around the sac, removal of Wharton's jelly, reduction of the hernia *en masse* without opening the sac, and suture of the skin.

Infantile Umbilical Hernia.—This form occurs in infancy and childhood and is due to weakness in the umbilical cicatrix. Berger[23] places the limit between it and adult umbilical hernia at fifteen years. It is about equally common in males and females, the ratio being 1 to 1.6 according to the statistics of the Hospital for the Ruptured and Crippled. According to Berger[23] it forms 22.42 per cent. of all herniæ occurring in male children and 65.34 per cent. of all herniæ in female children under fifteen years of age. This variety is always reducible and is quite amenable to treatment by a simple pad or truss and does not require operation.

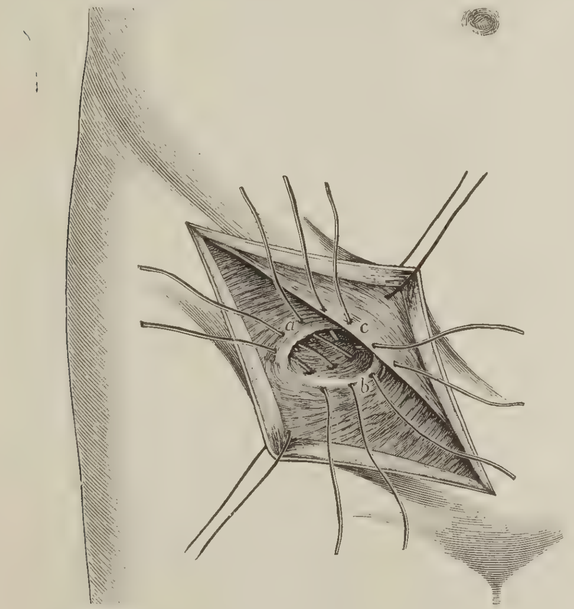

FIG. 2637.—Operation for the Radical Cure of Femoral Hernia, Bassini's Method. *a*, Falciform process; *b*, pubic portion of fascia lata; *c*, Poupart's ligament. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

Adult Umbilical Hernia.—This variety is much more common in females than in males, constituting, according to Berger, 22.16 per cent. of all herniæ in females and 2.5 per cent. of all herniæ in males over fifteen years of age.

Its greatest frequency is during the child-bearing period, and it is the most common of all herniæ in women at the age of forty years.

Two sub-varieties may be recognized, namely, those occurring without diastasis and those accompanied by diastasis of the recti. The first form embraces the greater number of cases occurring in males; the hernia in this case is usually small. The second variety is more common in women, and the tumor may reach an enormous size.

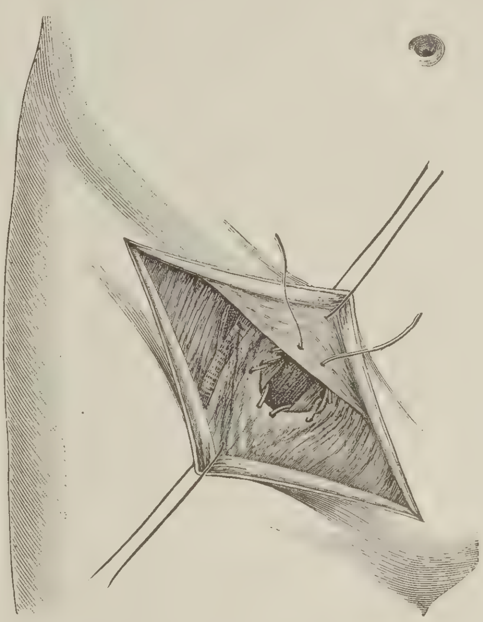

FIG. 2638.—Operation for the Radical Cure of Femoral Hernia. Purse-string suture, Cushing's Method. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

The first form, that occurring without diastasis of the recti, resembles infantile hernia in both symptoms and treatment and rarely requires operation.

Hernia with diastasis is more serious and the symptoms are often most distressing. The hernia is apparently due to the progressive stretching of the abdominal wall from internal pressure or from strains. The umbilicus being the weakest point gives way and the most marked protrusion occurs at this point, although the protrusion may be diffuse and take in a varying amount of the linea alba.

The *coverings* of the sac consist of skin and peritoneum, little or none of the intervening fibrous tissue remaining between them.

The *contents* of the sac consist at first usually only of omentum which soon becomes adherent and irreducible. The transverse colon is found in the sac more commonly than any other part of the intestine.

Symptoms are due to the size of the hernia and to complications, such as adhesions, obstruction, etc. The size of the hernia is an inconvenience and it may ulcerate on account of the poor nutrition of its coverings. It may cause gastric or intestinal symptoms from the inclusion of large amounts of viscera and from the dragging of adhesions. Being commonly associated with loose and pendulous abdominal walls, it is often accompanied by the symptoms of enteroptosis. Pain from adhesions and attacks of local peritonitis are common. Strangulation occurs about as frequently in umbilical as in other herniæ, but the mortality from strangulated umbilical hernia is greater. In gangrenous hernia, according to Gibson,[8] the mortality of umbilical hernia is 67 per cent., of inguinal hernia 26 per cent., and of femoral hernia 37 per cent.

Treatment.—Small reducible umbilical herniæ are best treated by truss. Many of the larger ones can be helped by a well-fitting abdominal support when a pad cannot be worn on account of the irreducibility of the contents.

Many cases of hernia in adults are not suitable for operation inasmuch as this is difficult and often prolonged by adhesions, etc., and because the patients, who are, as a rule, obese women in middle life, bear operations poorly.

In younger women of good fibre, although fat, especially if the protrusion is not too large, operation should be performed, because the hernia tends to increase in size and with the increase in size come the distressing symptoms and complications, and the chance for complete radical cure diminishes. Aside from the risk of operation (the mortality is about 5 per cent. in irreducible cases), the success in regard to permanent cures has not been great. According to Berger,[23] in 30 per cent. of large herniæ and 15 to 20 per cent. of herniæ of moderate size relapse occurs, while in small herniæ the relapses are practically *nil*. In cases in which suppuration occurred, the percentage of relapses was 60.

As would be expected from such poor results, a number of methods of radical cure have been devised. These methods may be classified according to the method of repairing the defect in the abdominal wall. In considering operative methods it must be remembered that in cases of diastasis of the recti the entire abdominal wall becomes thinned and stretched as well as the linea alba, so that the recti muscles may become more than twice their normal width and less than half their normal thickness.

Lineal Approximation of Fascia or Fascia and Muscle (Condamin,[24] Socin, Sanger,[25] Gersuny [26]). After excision of the sac and reduction of its contents, the abdominal wall is sutured layer by layer. In small herniæ the sheaths of the recti may be split and the muscles themselves approximated as well as their sheaths (Socin, Sanger). This method is unsuitable in hernia with diastasis of the recti.

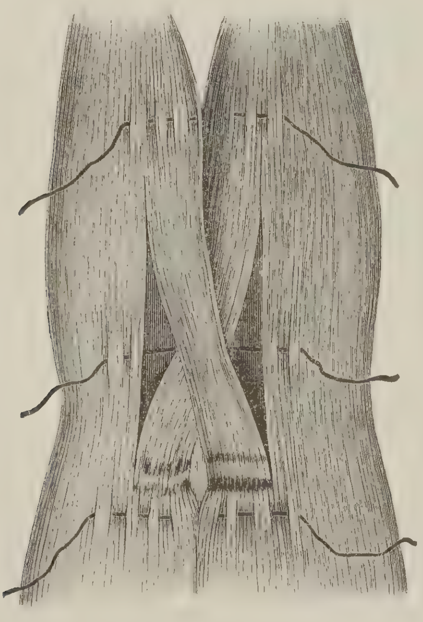

FIG. 2639.—Operation for the Radical Cure of Umbilical Hernia, Dauriac's Method. Muscular segments transferred and united, and sutures laid for closure. (From "Bryant's Surgery." Copyright, 1901, by D. Appleton & Co.)

Interlacing of the Recti (Bacon,[27] Dauriac [28]). In order to fill up the hiatus present after excision of the sac, the inner portions of the recti are split off, and having been cut free at one end are transplanted to the opposite side, thus producing an interchange of portions of the recti following the figure of a cross (Fig. 2639). The chief objection to this method is the impairment of innervation and nutrition in the transplanted muscle.

Involution of Abdominal Wall (Lucas Championnière [29]). The margins of the wound are turned in, thus bringing in apposition the ventral surfaces of the aponeurosis, and retained by means of a series of sutures resembling the Lembert suture. This method is applicable only to cases in which the abdominal walls are very lax.

Flap Operation (Noble,[30] Diakonoff and Starkoff,[31] Heinrich,[32] Hagen,[33] Ferguson [34]). A flap is cut from the ventral sheath of one rectus muscle and is carried across and united to the sheath of the opposite muscle; or a flap is taken from each sheath, the two being joined so as to close the hernial opening. The margins of the flaps may be united or the flaps may be lapped. The flaps are cut so that their attached borders are at the mesal borders of the recti, and when turned in and united their ventral surfaces become dorsal. The chief objection is the lack of nutrition of these flaps.

Lapping of the Abdominal Wall (Mayo,[30] Piccoli,[36] Sapiejko,[37] Blake [38]). This method is particularly adapted to cases with diastasis of the recti and pendulous abdominal walls. It is also suitable to protrusions in the linea alba elsewhere than at the umbilicus.

It consists in the excision of a large elliptical area of skin and fat in either a vertical or a transverse direction, down to and exposing, on one side at least, very completely, the sheaths of the recti. In typical operations done by the writer the incision has included an area from 25 to 40 cm. in length and 15 to 20 cm. in width. The sac is partially or wholly excised and the linea alba is divided for the whole length of the skin incision. The peritoneum is separated if possible from the dorsal surface of one rectus. It is not necessarily opened except at the hernial sac. One musculo-aponeurotic wall is then lapped over the other, as seen in Fig. 2640.

In the writer's cases the amount of lapping has varied from 4 to 10 cm. according to the laxity of the abdominal wall. In one case the greater part of the sac with adherent intestine and omentum was lapped under the opposite rectus. The margin of the underlapping side is sutured to the deep surface of the overlapping side by mattress sutures of chromicized gut which are tied on the superficial surface of the latter. The margin of the overlapping side is tacked with interrupted sutures of the same material to the superficial surface of the underlapping side. The skin wound is then closed without drainage. The results by this method in the hands of the writer and as reported by others have been excellent. Few cases have been under observation, however, for more than two years. Mayo has lapped the walls transversely in some of his cases.

VENTRAL HERNIA.—Ventral hernia is the general term applied to all herniæ of the abdominal wall excepting umbilical and groin herniæ. The herniæ may occur at any part of the abdominal wall. The term therefore includes: (1) Hernia in the linea alba elsewhere than at the umbilicus; (2) diastasis of the recti; (3) hernia in the lineæ semilunares; (4) hernia in the lineæ transversæ; (5) lumbar hernia; (6) traumatic hernia.

Hernia in the Linea Alba.—These herniæ, leaving out umbilical herniæ and those due to diastasis of the recti, occur four times as frequently in males as in females (Macready). They are rare in early life, and most frequent at middle age.

Two varieties occur: 1. Herniæ above the umbilicus—epigastric hernia. 2. Herniæ below the umbilicus.

Epigastric herniæ are usually small and may be multiple and are situated at any point between the xiphoid and umbilicus. They are protrusions through the gaps which are not uncommon between the decussating fibres of the linea alba in this region. They may consist only of properitoneal fat or there may be a well-defined sac with omental or intestinal contents. Symptoms are rarely present. Treatment is indicated when there is impulse or increase in size. They may be retained by truss, but operation is better. The aperture may be closed transversely or vertically.

Herniæ of the linea alba below the umbilicus are often confused with diastasis of the recti. They occur within 5 cm. of the umbilicus, as a rule. They may acquire considerable size. They are best treated by a truss such as is used for umbilical hernia or by operation.

Diastasis of the Recti.—This occurs in childhood and at middle life. In children it occurs as a bulging of the linea alba above the umbilicus, and disappears with the growth of the child.

In adults it occurs practically only in women who have borne children, at or before middle life. It is usually most pronounced below the umbilicus although the whole linea alba suffers. It may be so pronounced that there remains only a thin pendulous bag enclosing a large part of the intestines and sometimes the gravid uterus.

The treatment is by means of an abdominal support. If operation is feasible, that of lapping the abdominal wall (see Umbilical Hernia) will be found peculiarly adapted to these cases.

Hernia in the Lineæ Semilunares.—This is a rare form occurring usually at the level of the semilunar fold of Douglas. About twenty-three cases have been observed. The protruding mass occasionally penetrates only a part of the abdominal wall, resulting in a "masked hernia."

According to some writers direct inguinal herniæ are herniæ of the linea semilunaris, but the writer cannot concur in this, since in these cases the contents of the hernia push forward the transversalis fascia and escape below the insertion of the transversalis and internal oblique muscles.

Hernia in the Lineæ Transversæ.—This is very rare, only seven cases having been oberved at the London Truss Society in sixteen years (Macready).

Lumbar Hernia.—Twenty-six cases of this variety have been collected by Macready, and one has been observed at the Hospital for the Ruptured and Crippled. They occur at or near the tips of the eleventh and twelfth ribs, or at Petit's triangle, between the origin of the latissimus dorsi and that of the external oblique from the crest of the ilium. They occur more frequently in adults than in children and are usually reducible. In six of Macready's cases there was strangulation.

Traumatic Ventral Hernia.—This term includes hernia occurring through scars of accidental or laparotomy wounds. Not infrequently bulgings of the abdominal wall occur at a distance from a wound, which are due to destruction of the innervation of the muscle. Those following laparotomy are more frequent after lateral wounds than after wounds in the median line. They follow most frequently wounds that have healed by granulation, as for instance suppurating appendicitis wounds. Long wounds are more apt to be weak than short ones. The so-called "through-and-through suture" is responsible for many. More careful methods of making and closing abdominal wounds have lessened to a marked degree the frequency of this distressing condition which is a blot upon the page of abdominal surgery.

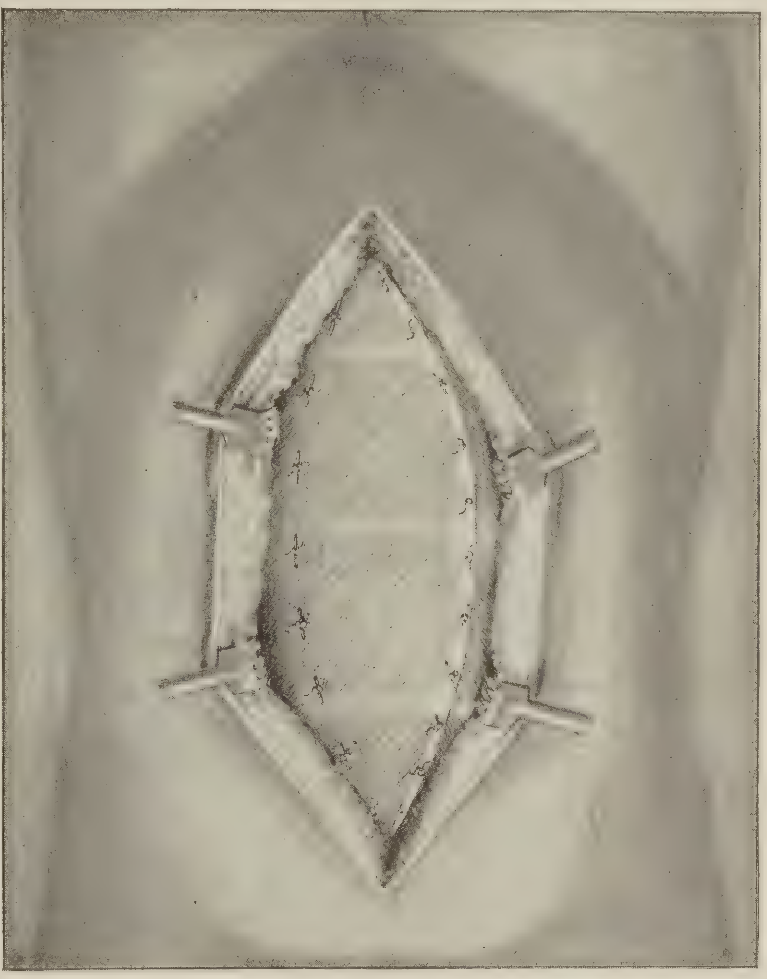

FIG. 2640.—Operation for the Radical Cure of Umbilical Hernia. Method by overlapping of abdominal wall. The right rectus muscle is lapped in front of the left.

The treatment is largely prophylactic and consists in fitting an abdominal support to all weak laparotomy wounds. Most herniæ of this variety are best treated by operation. The muscular and aponeurotic layers should be carefully isolated and separately sutured. The sac may be resected and the peritoneum sutured, or in some cases the peritoneum may not have to be opened. Troublesome adhesions are usually present in those cases in which there has been intra-abdominal drainage for suppurative conditions.

In cases in which the gap was very large, obturators of silver wire netting have been introduced (Phelps[39]).

OBTURATOR HERNIA.—This rare form of hernia passes through the obturator canal, which opens at the mesal and anterior part of the obturator membrane for the passage of the obturator vessels and nerve. The vessels and nerve as a rule lie on the dorso-lateral aspect of the sac.

The protrusion has for its coverings the peritoneum of the upper part of the pelvis or the broad ligament, the subperitoneal fat, and the deep pelvic fascia covering the obturator internus muscle. It may pass beneath the fibres of the obturator externus or take a more superficial course beneath the adductor brevis and pectineus muscles. It is accessible to palpation from the inner aspect of the thigh behind the adductor longus. The contents of the sac are always intestine.

This form of hernia occurs more frequently in women than in men, in the proportion of ninety-three to seven. It occurs in advanced life, the average age being over sixty (Macready).

Symptoms are not as a rule marked until strangulation supervenes. Many herniæ probably become strangulated as soon as protruded. Pain in the course of the obturator nerve has been noticed in forty-two per cent. of the cases. After strangulation tenderness and pain on movement of the thigh become marked. The tumor is not so easily seen as palpated. The neck can often be felt by means of vaginal or rectal examination. The size is usually small, although cases have been seen in which the hernia was the size of an orange.

Treatment.—As mechanical treatment is impossible, all cases should be operated on unless age or disease contraindicates. Most cases are not recognized until strangulation has occurred. The mortality in strangulated cases is high—84.4 per cent. (Macready).

The protrusion can be reached from without by an incision along the border of the adductor longus and between it and the femoral vein. The pectineus and adductor brevis are thus separated, exposing the sac. Or better, especially in strangulated cases, it can be approached by the abdominal route. This allows of better treatment of the intestine, which is important since the average duration of strangulation before operation is long (seven days, according to Macready).

Ischiatic Hernia.—The few instances of this hernia have been imperfectly described. The protrusion escapes at the great sacro-sciatic foramen either above or below the pyriformis muscle. Of seventeen cases collected by Macready the hernia appeared in seven in infancy or at birth. The sexes seem to be equally affected. The contents may consist of intestine, omentum, or some of the pelvic organs as the ovary or bladder. The hernia is usually small, but may extend into the thigh below the glutei or pass over the trochanter toward the groin.

It may be confounded with cysts, abscesses, new growths, or hæmatoma.

Treatment.—The abdominal route or a combined operation would probably be the best way of attacking this variety.

Hernia of the Pelvic Outlet.—This group comprises several varieties in which the abdominal contents escape through the floor of the pelvis. They are much more common in the female. In the male the hernia is into the ischio-rectal fossa or the perineum. In the female it may be into the ischio-rectal fossa, the vagina, or the labium majus. They are named from their superficial location, *ischio-rectal*, *perineal*, *vaginal*, and *pudendal* or *labial herniæ*. Very few have been dissected, so their deep relations are not understood. In some cases the protrusion has occurred at the recto-vesical pouch and in others at the pouch of Douglas. These herniæ are usually small, but may reach enormous proportions containing nearly the whole of the abdominal contents. As a rule they are easy of diagnosis, but a vaginal hernia may be mistaken for a fibroid, polypus, cystocele, or abscess. They seldom become strangulated. Many cases can be treated with a pessary or special truss, although some surgeons advise operation in all cases.

Varieties Depending upon Nature of Contents.—*Vesical Hernia.* The bladder may be protruded through a hernial opening. The condition is four times more common in inguinal than in femoral hernia, and very rare in other varieties of hernia, although it has been observed in ventral and in pelvic herniæ. It is most common in elderly males.

Laxity of the tissues, the pull of the hernia on the peritoneum, and distention of the bladder have been advanced as causes.

Three anatomical varieties are recognized: 1. Extraperitoneal, in which the bladder protrudes alongside of the sac of an ordinary hernia or independent of any sac. 2. Intraperitoneal, in which the bladder appears in the sac covered with peritoneum. 3. Paraperitoneal, in which a portion of bladder only is covered with the peritoneum of the sac. The latter form is the most common.

Of 192 cases collected by Cheesman[40] up to 1901, symptoms were noted in 30. The most constant symptom is the presence of a hernial tumor which disappears on micturition, or pressure upon which causes a desire to urinate or even expels urine from the urethra.

The chief importance of the condition lies in the danger of wounding the bladder in an operation for radical cure. Of the 192 cases quoted, in 47 the bladder was recognized during operation and avoided, and in 93 cases it was wounded, chiefly unintentionally. The presence of the bladder may be suspected if there be an undue amount of fat at the neck of the sac, or if muscle fibres are seen. It may be identified by the passage of a sound in the bladder or by a feeling as of two surfaces rubbing together produced by grasping the mass.

Treatment.—If the bladder is wounded it should be sutured with catgut, preferably in two rows. Catheterization should be frequently performed or a catheter may be left in the urethra for two or three days. The wound should be drained, and if no leakage occurs, the final steps of the radical cure can be completed in a few days. Fifty-five of the ninety-three cases collected by Cheesman were treated by suture, with a mortality of 20 per cent. There was a total mortality of 25 in the 93 cases, but Cheesman attributes the fatal result in 9 cases only to the bladder injury *per se*, a mortality of about 10 per cent.

Hernia of the Large Intestine.—The sigmoid flexure, cæcum, or a portion of the transverse colon may be found in the sac of a hernia.

Especial interest is centred in the cases in which the sigmoid or cæcum is found in the sac of an inguinal or femoral hernia. When the protruded part has a free mesentery the cases do not differ materially from other enteroceles, but in a certain number the bowel is only partially covered with peritoneum, so that a portion of gut is outside of the sac. This condition is known as *slipped* or *sliding hernia ; hernies par glissement* of the French.

According to Coley,[18] sliding herniæ occur as often in children as in adults, although the general belief is that they are more common in middle-aged or elderly males. However, statistics on this point as yet are insufficient. The sliding form is more common in inguinal hernia and when the protrusion is on the right side.

Unless the condition is recognized during the operation the intestine is very liable to be injured. Furthermore reduction is often difficult. The writer has found in his experience that the gut is generally loosely attached to the abdominal wall and can be pushed back *en masse.* Attempts to fashion a peritoneal coat for the bowel should not be made. The redundant sac should be sutured. It will rarely or never be necessary to resect the bowel as has been done by some.

Relapses are more common in these than in other forms of inguinal hernia, for the reasons that the neck of the protrusion is generally very large, and that it cannot be tied off flush with the abdominal wall. Transplantation of the rectus should help in these cases.

Hernia of the Appendix Vermiformis.—The appendix is not uncommonly found in right inguinal or femoral hernia. It may occur alone in the sac, more commonly in femoral hernia. The cases of especial interest are those in which the appendix becomes inflamed (appendicitis in a hernial sac). These cases simulate strangulation and can be differentiated only by the absence of the signs of obstruction. The condition is probably more common than the number of reported cases, sixteen only,[41] would indicate.

Hernia of the Ovary.—On account of error in development the ovary may descend alongside the canal of Nuck into the inguinal canal or even the labium. This condition, *ectopia of the ovary*, is found more commonly in young children, and there is reason to believe that in many cases the organ returns at or before puberty to its normal position. According to Macready,[1] hernia of the ovary occurs in 1.2 per cent. of inguinal herniæ in the female. When there is double ectopia the uterus and tubes are as a rule defective in development, and they may be so in single ectopia. In some cases the tube and even the uterus may be drawn into the sac. Associated with this condition there may or may not be a hernia of the intestine, either congenital into the open canal of Nuck, or into another sac. In most cases the canal of Nuck is open.

In some cases the ovary is reducible and the hernia can then be treated by truss. Other cases should be treated by operation, the ovary being excised or, if its connections can be preserved, returned to the abdomen.

Cases in which the ovary is found with other viscera in otherwise ordinary herniæ are of no particular interest.

Diaphragmatic Hernia.—A protrusion of the abdominal viscera may take place through a wound or through portions of the diaphragm that are deficient. The places where the muscular fibres of the diaphragm are normally deficient are "Larrey's space" between the costal and sternal attachments, and on either side at the lateral portions of the external arched ligaments. A hernia may occur through the œsophageal opening. Finally there may be a congenital defect in the diaphragm. These herniæ are classed as true when the peritoneal sac is present and as false when the viscera lie free in the pleural cavity. The latter form is more common, since the hernia is generally due to trauma.

The protrusion usually occurs on the left side on account of the position of the liver. Varying amounts of the abdominal contents may escape into the thorax. The stomach is the most commonly protruded, although any of the viscera with the exception of the genito-urinary organs may be displaced into the thorax.

The symptoms may be those of pneumothorax, the heart may be displaced, there may be marked interference with respiration, and there may be symptoms of strangulation.

MECHANICAL TREATMENT.—The mechanical treatment of hernia consists in the application of a truss or apparatus to the protrusion. With few exceptions this treatment can be applied only to reducible hernia. Special forms of apparatus have been devised for some forms of irreducible hernia in which operation is contraindicated; such, for instance, is the hinged cup truss for irreducible inguinal hernia.

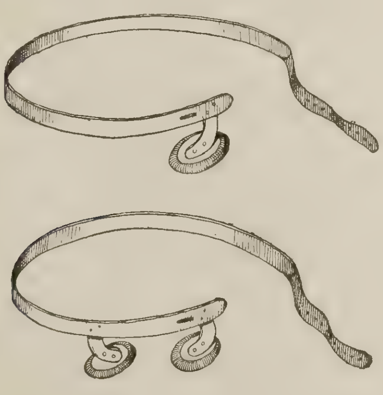

FIG. 2641.—Single and Double Knight Trusses.

For inguinal and femoral hernia three principal varieties of truss are used, namely the "cross body" or Knight truss (Fig. 2641), the frame or Hood truss (Fig. 2642), and the "same side" or French truss.

The chief desiderata in a truss are perfect fit, so that pressure is evenly made on all parts of the pelvis which it comes in contact with; a good spring, the best material being steel, as it combines lightness and durability; and a pad so arranged as to make pressure at the point of exit of the hernia, *i.e.*, over the internal ring in inguinal hernia, and not on the pubic bone.

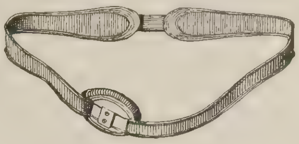

FIG. 2642.—Frame Truss.

The pad is best made of some smooth non-absorbent material as celluloid, hard-rubber, or wood. Sometimes a pad of wood covered with leather is serviceable.

When the pressure of a hard pad is unbearable, as it sometimes is in large herniæ, the elastic water pad can be used.

In adults trusses may be removed at night, as a cure is rarely attainable, but in children, in whom the descent of the hernia would preclude all chance for a cure, the truss should be worn day and night.

It is impossible in so brief an article to give the indications for the use of different trusses, and the methods of application. These points are largely learned by practical experience.

For umbilical hernia special forms of truss have been devised, but for most cases the best apparatus is a well-fitting abdominal support with a pad of suitable size to control the protrusion and of a thickness equal to that of the subcutaneous fat.

For umbilical hernia in children a broad strap of zinc oxide rubber plaster with a wooden button over the hernia makes a very efficient apparatus.

Results of Mechanical Treatment.—*Inguinal Hernia.* According to Coley by far the greater majority of cures are obtained in the first year of life. The best results are obtained with the spring truss in infancy, it being far superior to the "worsted" or "skein" truss.

In children cures are more often obtained in girls than in boys, the reverse being true in adults. About two-thirds of the cases of inguinal hernia can be cured in childhood. Cures are seldom attained in patients over twenty years of age.

Femoral Hernia is practically incurable by mechanical means.

Umbilical Hernia. In the infantile form a cure is nearly always obtained. In adults the most that can be hoped for is limitation of the size of the protrusion.

HEROIN, diacetyl-morphine [$C_{17}H_{17}.(CH_3CO)_2.NO_3$], is one of the group of morphine compounds to which belong codeine, dionin, and peronin. It occurs as an odorless and slightly bitter, white, crystalline powder, insoluble in water, and soluble in dilute acids. The hydrochloride, the salt generally used, is freely soluble in water and alcohol, insoluble in ether, and incompatible with alkalies.

Experiments show that heroin is not absorbed by the unbroken skin, and has but slight effect on mucous membranes. It tends to cause dryness of the throat and slight irritation of the gastro-intestinal tract as manifested by nausea, vomiting, and diarrhœa. These effects are, however, uncommon. In therapeutic doses the circulation is unaffected, though heart failure may follow a large dose. The main action of the drug is upon the respiratory organs, as it tends to diminish bronchial secretion, while it slows and increases the depth and strength of respiration. Dreser demonstrated that a smaller amount of oxygen was used by the system and less carbon dioxide eliminated; in other words, that metabolic processes were retarded. On account of this diminished tissue-activity there is a slight temporary lowering of body-temperature. In very few cases has any hypnotic or analgesic effect been noted. Heroin is a very powerful remedy, the maximum dose being one-twentieth that of codeine. Observers agree that the dose of 0.01 gm. (gr. $\frac{1}{6}$) should not be exceeded. Though not very common, cases with unpleasant sequelæ are met with by every user of the drug. Therapeutic doses have been followed by dryness and irritation of the pharynx, nausea, vomiting, constipation, diarrhœa, languor, and, rarely, excitement or delirium. A case of the writer's always became greatly excited after a dose of morphine or heroin, but never after codeine. Some writers advise adding potassium iodide to prevent dryness of the throat, and cascara or calomel for the constipation. A dose of 0.015 gm (gr. $\frac{1}{4}$) given by mistake to an asthmatic patient was followed by prostration, cyanosis, amaurosis, restlessness, pulse of 40, feeble heart action, spasm of the legs, persistent nausea, subnormal temperature, and a semi-comatose condition.

Among the large number of published reports most authorities agree that heroin is valuable in the treatment of bronchitis, bronchial asthma, pulmonary tuberculosis, and whooping-cough, while opinions differ as to its efficacy in neuralgia, angina pectoris, cardiac dyspnœa, etc. The writer used it in over one hundred cases of tuberculosis, and found it of distinct use, but inferior to codeine in allaying the cough, irritability, and pain, and in promoting sleep. Heroin had little, if any, effect on the pain, dyspnœa, or night sweats. Loewenthal employs it in infantile diarrhœa and colic, the maximum dose for a child of one month being 0.0002 gm. (gr. $\frac{1}{300}$), of six months 0.00027 gm. (gr. $\frac{1}{220}$), and of five years 0.0024 gm. (gr. $\frac{1}{25}$). Heroin has not proven of any special value in diabetes, and so far as known does not create a drug habit. Indeed it is recommended as a substitute for morphine on the withdrawal of the latter drug for morphinism.

W. A. Bastedo.

HERPES.—The term herpes (from ἕρπειν, to creep), formerly employed to designate a large number of diseases of the skin of varying etiology, is restricted at the present time to a class of affections whose distinguishing clinical feature is a grouped vesicular eruption seated upon an inflamed and slightly swollen base. If the term is used in this restricted sense there are practically but two varieties of the disease, viz., simple herpes, of which there are a number of regional forms which differ but little from one another in their clinical characters; and herpes zoster, which clinically and etiologically is quite distinct from the first-named variety. The herpes iris of some authors properly belongs to erythema multiforme; herpes gestationis is one of the forms of the dermatitis herpetiformis of Duhring; while the herpes circinatus and herpes tonsurans of some continental authors are parasitic affections, much more frequently characterized by erythematous and squamous eruptions than by vesicular lesions.

The appearance of the herpetic eruption is preceded for a variable period, usually short, by a sensation of burning, pricking, or slight itching; after a few hours an erythematous, slightly swollen patch appears upon which small papules arise which are speedily transformed into a group of vesicles with clear serous contents, each group containing from three or four to a dozen or more lesions. The vesicles, at first discrete, later become more or less confluent through increase in size, often forming small blebs. After from twenty-four to forty-eight hours the contents of the vesicles become cloudy, then purulent, and yellow or brown crusts form, which after a week or ten days fall off, leaving a slightly reddened patch which lasts but a few days and disappears without leaving any trace of its existence.

Herpes Simplex.—In the great majority of cases the eruption of simple herpes is situated upon the face, usually the lower half; hence it is also spoken of as facial herpes. The parts of the face most frequently attacked are, in the order of frequency, the lips, the lower oftener than the upper lip, the cheeks, and the alæ of the nose. It sometimes occurs upon the external ear and still less frequently upon other parts of the cutaneous surface. It usually begins quite abruptly with a sensation of heat or itching; the skin over a limited area becomes red and slightly swollen, and upon this area a group of small papules appear which in a short time become clear vesicles. The vesicles, discrete in the beginning, enlarge slightly for a short time after their appearance and frequently coalesce, forming blebs that vary in size from that of a pea to that of a dime; but when the lesions are very small and few in number, they usually remain discrete. At the end of a day or two the contents of the vesicles become purulent; they then dry up, forming yellow or brown crusts, which fall off in a few days more, leaving slightly red, or occasionally transiently pigmented stains, the entire attack lasting from four or five days to two weeks.

The eruption is not always limited to the skin, but may appear upon the adjoining mucous membranes, even the larynx in rare instances being invaded. When the eruption occurs upon mucous surfaces it presents marked differences from that upon the skin. Owing to the moisture with which the affected parts are constantly bathed, the vesicles appear as white opaque elevations which are soon transformed into shallow erosions through spontaneous rupture. Herpes of the mucous membranes is, in the great majority of cases, associated with similar lesions upon the skin, although pharyngeal herpes may occur alone; the mucous membranes attacked being usually those of the lips, the cheeks, and the pharynx.

In a considerable proportion of cases the appearance of the eruption is preceded or accompanied by sensations of chilliness and some elevation of temperature; hence the popular terms "cold sore," "fever blister," applied to these eruptions.

In many individuals there is a marked tendency to recurrences, and this continues for years, the eruption appearing with the slightest derangement of the general health, or following slight irritations of the skin.

Although, as a rule, there are usually but two or three groups of vesicles, and often but one, each containing a moderate number of lesions, it happens in rare instances that the eruption is much more extensive, covering, it may be, almost the entire cutaneous surface. Such extensive cases have been most frequently reported by French observers, Rendu having only recently described a case of generalized herpes produced by the ingestion of uncooked shell-fish. It seems to me, however, that such eruptions are very closely allied to, if not actually examples of, bullous erythema multiforme, rather than true herpes.

Facial herpes frequently occurs in febrile diseases of various kinds, such as pneumonia, in which it is quite common, in typhoid fever, in the malarial fevers, and in cerebro-spinal meningitis, a favorable prognostic significance being attributed to it. In the malarial fevers it may occur with each febrile paroxysm, or in exceptional cases it may replace it, as has been noted by several writers.

Under the name herpetic fever, various authors have from time to time described an endemic affection in which, after marked constitutional disturbances, such as chills and elevation of temperature, an herpetic eruption appears upon the face or other parts of the cutaneous surface. A remarkable endemic of this kind has been reported by Savage in which, in an institution for boys, thirty-nine cases of herpes occurred. In this outbreak the eruption was preceded by chills, nausea, and elevation of temperature varying from 102° to 104.5° F., and was accompanied by sore throat and swollen glands, the attack lasting four days.

Herpes Genitalis.—The genital organs of both sexes are frequently the seat of herpes, the eruption occurring, in men, upon the margin of the prepuce or upon its inner mucous surface (herpes præputialis, herpes progenitalis), upon the glans, and, much less frequently, upon the skin of the shaft of the penis; in women the parts affected are the vulva, the mucous surfaces of the labia majora, the labia minora, the clitoris and the prepuce, and the mucous membrane about the meatus urinarius. The appearance of the eruption is preceded by more or less burning or stinging, which is shortly followed by redness, œdema, and the formation of groups of vesicles which are usually quite small. When the skin surfaces are attacked the vesicles after a day or two dry up into brownish crusts which fall at the end of a week, leaving a slightly reddened, or, it may be, pigmented patch. When the eruption occurs upon the mucous surfaces, as the inner side of the prepuce, the glans, or the labia minora, the vesicles rupture almost immediately, forming shallow erosions, the bottoms of which are often covered with a whitish or gray membrane. Occasionally the eruption appears in successive crops separated by intervals of some hours or a day or two, thus prolonging the attack greatly. Fournier has observed a case in which the disease was thus prolonged for five weeks; but this is altogether exceptional. When the affected parts are irritated by violence or by the application of caustics, as not infrequently happens, the inflammation may be considerable and may be attended by marked induration of the base of the vesicles; this induration being especially apt to occur upon the glans in the region of the sulcus. In such cases the glands in the groin may be noticeably swollen. In rare cases the eruption occurs upon the urethral mucous membrane, giving rise to ardor urinæ and, in the male, to a serous discharge. Although, as a rule, subjective symptoms are limited to slight burning or itching, it occasionally happens that the pain is severe, even neuralgic in character.

In women the eruption is sometimes quite extensive, covering the cutaneous surface of the vulva, and the labia majora and minora with numerous groups of vesicles and erosions, and at times extending down upon the inner surface of the thighs. The pain and burning in such cases are severe, and with the marked swelling which is commonly present walking is difficult and at times impossible. Superficial ulceration may occur with the formation of vegetations, producing an appearance much like that of a syphilitic mucous patch; indeed, according to Fournier, it is sometimes impossible to make a positive differential diagnosis until after the lapse of a considerable period of time.

Of all the forms of herpes the genital is most apt to recur, the interval between the attacks varying from a few weeks to several months. In a considerable proportion of cases each coitus in the male and each menstrual period in the female is followed by an attack, the recurrences continuing for years. On the other hand there may be but a single attack.

Simple herpes is in many cases, no doubt, a local manifestation of a general toxæmia. Its frequent association with such general diseases as pneumonia, typhoid and the malarial fevers, epidemic cerebro-spinal meningitis, and other maladies of an infectious nature, lends strong support to such a view of its etiology. In a considerable proportion of cases, however, it must be regarded as due to local conditions associated with a special predisposition. In genital herpes excessive irritations and congestions, physiological or pathological, such as coitus and the menstrual period, play important rôles in the production of the affection. Uncleanliness and previous venereal disease are potent etiological factors. As Unna and Fournier have pointed out, prostitutes are especially liable to suffer from herpes of the genitalia.

The herpetic eruption is the result of a peripheral neuritis of an acute transitory character, the consequence of a direct or reflex irritation of the terminal nerve branches distributed to the skin. Unna, who had the opportunity to examine lesions from three cases of genital herpes, found a fibrinous inflammation of the epidermis, the primary changes affecting the more superficial prickle cells. The entire epidermis was lifted from the papillary layer of the corium, forming a blister whose walls and contents had undergone coagulation necrosis. Beneath the vesicle the entire cutis was œdematous and the blood and lymph vessels were markedly dilated. A striking histopathological difference between the vesicle of simple herpes and that of herpes zoster is the absence of the so-called "ballooning" of the epithelial cells in the former.

The *diagnosis* of simple herpes is usually made without the slightest difficulty. The purely vesicular character of the lesions, the grouped arrangement of the eruption, its localization upon the face, in most cases about the mouth, or upon the genitalia, and the acute course of the disease are features so characteristic that there is little chance for error. When, however, the eruption is seated upon the mucous membranes, particularly those of the genitalia, the erosions which follow the vesicles may be mistaken for venereal ulcers or the initial lesion of syphilis. The herpetic lesion is superficial and does not tend to extend like the chancroid; it exudes an abundance of serum instead of pus, which, as Leloir has pointed out, may be much increased by squeezing the lesion between the thumb and finger; its borders are apt to present a festooned or polycyclic outline; and lastly, there are often groups of well-defined vesicles in the neighborhood. It is to be distinguished from the initial lesion of syphilis by its brief duration and the absence of the peculiar induration characteristic of the chancre. It should not be forgotten, however, that the herpetic lesion, under the influence of irritants, may present an indurated base much like that seen in the chancre, and that in such cases there may be swelling of the inguinal glands. Fournier has called attention to the fact that the chancre may be preceded by herpes; and it is always wise, in view of the very serious results which may follow an error in diagnosis, to be very guarded in expressing an opinion in doubtful cases until sufficient time has elapsed to make the diagnosis certain.

In the *treatment* of simple herpes all irritant applications should be avoided. Frequent applications of ninety-five-per-cent. alcohol in the early stages of the eruption will sometimes partially abort it. If there is marked burning, a saturated aqueous solution of boric acid will be found very useful in relieving this symptom; or a solution of resorcin, from eight to ten grains to the ounce of water, may be even more effective. A lotion containing twenty grains each of sulphate of zinc and sulphide of potassium, as recommended by Duhring, is also a useful remedy.

In genital herpes the parts should be kept scrupulously clean, and nothing better for this purpose can be used than a saturated solution of boric acid, which should be freely and frequently mopped upon the affected parts. When the mucous surfaces are the seat of the eruption, they should be kept apart by pieces of gauze wet with the boric acid solution; or, after careful cleansing, they may be covered with a dusting powder of talc and oxide of zinc, to which, if there is annoying pain, from ten to twenty per cent. of acetanilid may be added, or the acetanilid may be used alone. The resorcin lotion above referred to will often be found a very soothing and cleansing application. Lotio nigra may be employed in many cases with good results. If suppuration occurs, weak solutions of bichloride of mercury should be applied several times a day, but this remedy must be used cautiously as it sometimes proves irritating. As a preventive measure, circumcision has been recommended in recurrent herpes genitalis; it is, however, an uncertain remedy. Arsenic given internally for a considerable period exercises a decided influence in preventing recurrences in many cases, and should always be tried when other remedies have failed. *Milton B. Hartzell.*

HERPES ZOSTER.—Herpes zoster, also known as zona, zoster, shingles,—this last probably being a corruption of the Latin *cingulum*,—names all having reference to the girdle-like arrangement which the eruption often exhibits, usually begins with pain, commonly of a neuralgic character, varying in degree from mere discomfort and soreness to the severest neuralgia, and situated in the regions presently to be the seat of the herpetic eruption. Exceptionally in the beginning of the attack there is some elevation of temperature with slight malaise. After a prodromal period, varying from a few hours to several days, groups of papules seated upon a reddened and slightly swollen base appear in the painful areas, and in the course of a few hours they become vesicles with transparent contents. With the appearance of the eruption the pain may diminish, but there are frequent exceptions to this rule. The vesicles, for the most part discrete, tense, and showing no tendency to spontaneous rupture, vary in size from a hemp seed to a large pea, and are arranged in variously-sized groups from one or two to a dozen or more in number, separated by areas of normal skin, and situated over the distribution of some nerve usually at points where branches are given off to the skin. The several groups of vesicles do not appear simultaneously, but new ones continue to form for some days, the last-formed groups often containing many papules which do not develop into vesicles, and imperfectly developed vesicles. After a day or two the vesicular contents become turbid, then purulent, and later brown or black crusts form which fall off at the end of from ten days to two weeks, leaving transiently hyperæmic patches, or slight pigmentation, and frequently permanent scars. The duration of the entire attack is from ten days to three weeks; but when the inflammation is unusually severe, or when complications, such as suppuration and gangrene, occur, it may last much longer.

The amount of pain present varies within wide limits. In children and young adults it is often entirely absent, or so slight as to cause little or no complaint; but in elderly subjects it is commonly severe, often demanding large doses of powerful narcotics for its relief, and sometimes continuing for weeks or even months and years.

In an overwhelming majority of the cases the eruption is limited to one side of the body, although it is not at all uncommon to see a group of vesicles extend some distance beyond the middle line. While it may occur over the course of any peripheral nerve, it is much more frequently situated upon the trunk than upon the extremities In one hundred cases in which the location of the eruption was specially noted by Crocker, it was observed to occur upon the trunk fifty-four times.

Variations from the ordinary type of zoster occur in a small proportion of cases. The vesicles may be filled with blood instead of serum, giving the eruption a blue or black appearance. In this variety, known as *zoster hæmorrhagicus*, the pain is as a rule extremely severe, and ulceration more or less deep is prone to occur.

In cases of unusual severity suppuration may take place, and in rare instances gangrene of the skin occurs, either after the appearance of the vesicles or before these have had time to develop. As the result of the severe and at times deep-seated inflammation, extensive and indelible scarring follows, which later may become the seat of keloid.

As *zoster gangrenosus hystericus* Kaposi has described an atypical form of zoster that occurs in hysterical women. This variety of the malady is characterized by repeated attacks separated by intervals of a few weeks or some months, the eruption being unilateral or bilateral. Gangrene of the skin at the base of the vesicles occurs, and keloid-like cicatrices follow. This disease is certainly closely related to, if not identical with, the multiple hysterical gangrene of the skin of other authors; and while it is mentioned here, I think it is doubtful if it properly belongs to herpes zoster.

While almost invariably limited to one side of the body, the eruption may be bilateral. According to Hyde, bilateral zoster is most apt to be seen in those suffering from syphilis or in those taking arsenic.

Colombini has reported a case in which the eruption was universal, groups of vesicles occurring over the branches of all the cutaneous nerves. The disease in this instance was most likely of malarial origin, as the patient had had repeated attacks of malarial fever, and the eruption appeared shortly after one of them.

Second attacks of zoster are rare, although not so infrequent as formerly supposed. In recurrent zoster the same region may be affected several times, or new regions may be invaded with each new attack. Recurrences are most likely to be observed in those cases in which the disease is of traumatic origin; as in one under my observation some years ago in which the sciatic nerve was injured by a fracture of the femur. In this case there were many attacks preceded and accompanied by severe pain, most of them in the region of the distribution of the sciatic nerve and its branches. While the pain usually diminishes with the appearance of the eruption and ceases entirely with its complete involution, it may persist for a considerable period, especially in elderly subjects, after all other evidences of the disease have disappeared. Other sequelæ are local paralyses, and various disturbances of sensation, either alone or associated with trophic changes.

The principal local varieties of herpes zoster, named according to the region in which the eruption is situated, are Z. capillitii, Z. frontalis, Z. facialis, Z. ophthalmicus, Z. colli, Z. brachialis, Z. pectoralis, Z. abdominalis, Z. femoralis. In these several local varieties the disease presents practically the same clinical features, particularly so far as the eruption is concerned, but it may vary considerably as to extent and the severity of the inflammation and pain which accompany it.

In Z. frontalis the eruption follows the distribution of the supraorbital branch of the fifth pair, extending over the lid, one-half the forehead, and up into the scalp. This form is sometimes followed by marked scarring resembling the pits produced by variola.

In Z. ophthalmicus, in which the branches of the fifth pair distributed to the eye are affected, the pain is often of the severest character, and the various structures of the eye may be inflamed, the inflammation being in rare cases so severe as to cause destruction of this organ. Fatal meningitis has been known to result in this variety of zoster.

In Z. facialis the second branch of the fifth pair is concerned, the eruption occurring on the cheek, the side of the nose, and one-half of the upper lip. In exceptional cases it also occurs upon the mucous membranes of the cheek and pharynx. Loss of the teeth and necrosis of the jaw have been noted as rare complications.

The supraspinous portion of the scapula and the upper arm are the regions affected in Z. brachialis. The forearm and the fingers are not often involved. This is usually a mild form of the malady.

Z. pectoralis is the variety oftenest seen, and the one from which the disease gets its various names signifying a girdle. Groups of vesicles extend from the spine forward to the sternum. In many cases the eruption consists of but two or three groups, one close to the spine, a second in the axillary line, and a third, often composed of imperfectly developed lesions, near the anterior middle line. In severe cases the groups of vesicles may coalesce, forming a continuous half-girdle. In this variety of zoster the pain which sometimes precedes the appearance of the eruption may be mistaken for a pleurisy.

In Z. femoralis the eruption is situated upon the anterior surface of the thighs, the external genitalia, and upon the buttocks. The legs and feet are only rarely attacked.

Etiology.—Zoster occurs much more frequently in the young than in the old, but old age is by no means exempt. In three-fourths of the cases observed by Crocker the patients were under twenty years of age. Although infrequent in infancy cases have been reported in infants from four days to several months old. The sexes appear to be equally liable. Cold, damp, and other climatic influences seem to play some part in its production since it occurs most frequently in winter and spring.

It sometimes occurs in connection with such diseases as influenza, malaria, and tuberculosis. Winfield has reported a number of cases in which the presence of the plasmodium malariæ was demonstrated; and it has been observed often enough in the subjects of tuberculosis to suggest the possibility of a causal relationship between the two maladies.

As was first pointed out by Hutchinson, and afterward confirmed by other observers, arsenic when given in large quantities for a prolonged period may produce zoster by setting up a neuritis. Other toxic substances, such as carbonic oxide gas, have also produced the disease. In a considerable number of instances the eruption has been observed to follow injuries to nerves. Occasionally it seems to be of reflex origin, as is shown by a case reported by Jewel in which a crural zoster resulted from disease of the uterus; and in other cases it has seemed to be due to irritation in the alimentary canal caused by the presence of tapeworm. Lastly, it is very probable that in a considerable proportion of cases it is the result of a specific infection, although the infectious agent is as yet unknown. Its occurrence in epidemics, its undoubted occasional contagiousness, its self-limited course, and the rarity of second attacks are features of the malady which are strongly in favor of such a view. From the foregoing brief summary it is evident that there is no one cause of herpes zoster, but that it may be produced by any agent capable of setting up a neuritis.

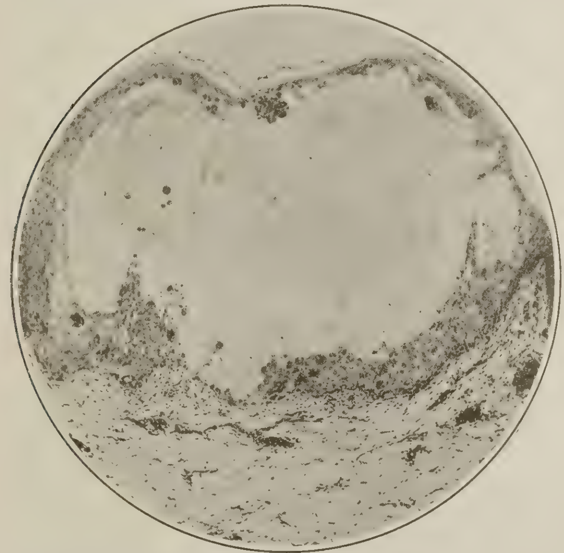

FIG. 2643.—Vesicle of Zoster. Upon the bottom of the vesicle are numerous cells which have undergone alteration like that shown in Fig. 2644. (Author's own case.)

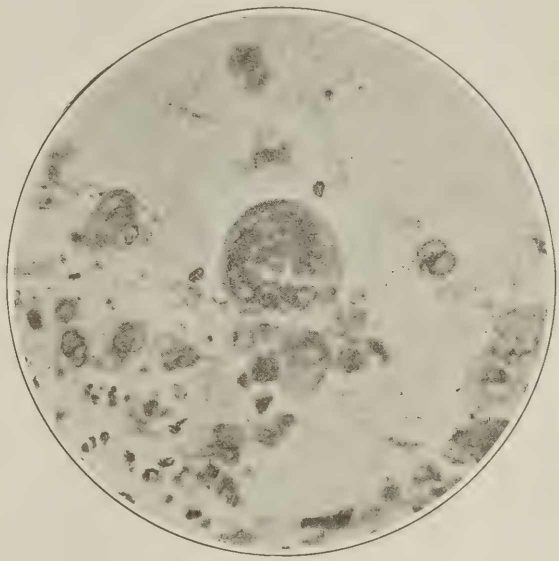

FIG. 2644. — Epithelial Degeneration; Large Protozoön-like Cell. (From author's own case of herpes zoster.)

Pathology and Pathological Anatomy.—Proof of the neuritic character of the disease was first furnished by Baerensprung, who found that there was inflammation of the ganglia and the nerves distributed to the area occupied by the eruption. The ganglia do not always share in the inflammatory process, as Baerensprung supposed, but the inflammation is sometimes limited to the peripheral parts of the nerve. The pathological alteration of the nerve is not always of an inflammatory character, but may be the result of hemorrhage, the pressure of new growths, or traumatism.

The zoster vesicle lies deeply within the epidermis, the bottom being formed by the papillary layer of the corium upon which lie masses of altered epithelium. The most striking feature is the peculiar alteration which many of the epithelial cells have undergone, by which they have been transformed into bodies resembling more or less closely protozoa. These bodies were regarded by Pfeiffer, who was one of the first to describe them, as parasites, and were believed by him to be the cause of the disease; but the later investigations of Unna, Torok, myself, and others have clearly demonstrated their epithelial character. These altered cells are often enormous in size, round, oval, or balloon-shaped, with a double-contoured wall or capsule within which are from two to a dozen or more large round and oval nuclei which often present a peculiar beaded limiting membrane. The cavity of the vesicle contains a few free epithelial cells, a small number of leucocytes, and fibrin. The papillæ and that part of the corium immediately beneath the papillary layer are abundantly infiltrated with leucocytes, and there is dilatation of the blood-vessels.

Diagnosis.—The clinical features of zoster are, in the great majority of cases, so well defined that the diagnosis is usually easily made. The two diseases with which it is most likely to be confounded are vesicular eczema and simple herpes.

It may be distinguished from eczema by the grouping of the vesicles over the course of known nerves, by the accompanying neuralgia, by the absence of itching and discharge, and by the vesicles, unlike those of eczema, showing no tendency to spontaneous rupture.

It differs from simple herpes by its unilateral distribution, by the pain which precedes and accompanies the eruption, and by the infrequency of second attacks. Simple herpes is most apt to occur about the mouth and upon the genitalia, regions seldom invaded by zoster.

Prognosis.—The prognosis is in most case favorable, the disease usually terminating in from ten days to three weeks. In severe attacks, however, or when ulceration, deep-seated inflammation, or gangrene occurs, the duration may be greatly prolonged beyond the usual period. In elderly subjects, less frequently in the young, persistent neuralgia of a severe type may follow, lasting for months or years. In exceptionally severe cases of ophthalmic zoster disfiguring, scarring, loss of an eye, and even death may result.

Treatment.—In mild cases of herpes zoster only the simplest treatment is required. The vesicles should be protected from the friction of the clothing by covering them with two or three thicknesses of gauze or a thin layer of absorbent cotton, having first freely applied a simple dusting powder, such as equal parts of starch and oxide of zinc, to which, if there is burning or pain, camphor or morphine may be added. Internal remedies administered with the view of aborting or controlling the eruption are of more than doubtful efficacy. Phosphide of zinc, in doses of from one-sixth to one-third of a grain given every three hours, is recommended by Thompson and Bulkley for the relief of the pain and the control of the eruption, but other observers have not found it reliable. In cases in which the pain is severe, antipyrin, phenacetin, or acetanilid may be given in doses of from five to eight grains every three or four hours; when these fail to afford relief morphine, given hypodermatically, may be employed. Locally frequent application of ninety-five-per-cent. alcohol is often very useful; or, instead of simple alcohol, alcoholic solutions of resorcin fifteen grains to the ounce, or a solution of carbolic acid five to ten grains to the ounce, or of menthol ten grains to the ounce, may be used. Such lotions should be mopped on gently every three or four hours with a soft cloth, care being taken not to rupture the vesicles. Duhring specially recommends a lotion containing from twenty to sixty grains each of sulphate of zinc and sulphide of potassium to the ounce of water; he finds it very useful in relieving pain and drying up the eruption. Collodion, either alone or with one or two grains of morphine to the ounce added, may be painted over the eruption for the purpose of favoring its absorption and alleviating the pain. For the relief of persistent neuralgia, galvanism is perhaps the most useful remedy, mild currents being more useful than strong ones. Crocker finds repeated blistering over the root of the affected nerve very efficacious in some cases. An abundance of easily digested, nutritious food, and cod-liver oil are also indicated.

HIGHLAND SPRINGS.—Lake County, California.

Post-Office.—Highland Springs. Hotel and cottages. These excellent springs are found within the edge of the mountains, about four miles from Kelseyville and seven miles from Lakeport. They are reached by the Southern Pacific Railroad, on the south to Calistoga, and thence by stage; also by the Northern Pacific road on the southwest to Cloverdale, and thence by stage. The drive from Calistoga or Cloverdale is exceedingly picturesque. The road leads through a romantic mountain region until an elevation of 3,200 feet is gained. Here a grand panorama is revealed. As far as the eye can reach in every direction are mountains and valleys, peaks upon peaks, mountain streams and brooks, forest and shrubbery. The most picturesque of all is the view northward over Clear Lake and Lake County. This is a magnificent sheet of water twenty-five miles long and six to eight miles wide. It has an elevation of 1,200 feet above the Pacific Ocean, and lies peacefully smiling in the embrace of the mountains on every side, with the towering head of "Uncle Sam" above them all. The bright, cultivated fields appear like a checker-board in the valley below. The gigantic oaks, the largest in the State, are scattered here and there to lend variety to the enchanting picture. The descent to the springs is made in much less than half the time it takes to make the ascent, and the resort is soon seen lying in a level sequestered spot surrounded by hills and by trees of many years' growth. At Highland we find a commodious hotel and many elegant cottages built with a view to health and pleasure combined. A large, pure mountain stream which is well supplied with fish runs past the hotel. The usual mild, genial climate of Lake County prevails here. The altitude is about 1,700 feet, and it is claimed to be an excellent place for consumptives. There are about twenty springs at Highland, five of the most important having been examined by Anderson in 1888. These analyses show results practically identical with those of Professor Rising in 1882, except in the case of the "Neptune" spring, which seems to have lost greatly, especially in calcium salt, in the course of six years. The principal springs are the "Magic," the "Neptune," the "Seltzer," the "Dutch" or "Ems," and the "Diana" spring. The waters are chiefly of the alkaline-saline type, most of them containing a well-marked proportion of iron. Following are the analyses of two of the representative springs:

THE SELTZER SPRING.

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	0.67
Sodium carbonate	2.06
Sodium bicarbonate	12.72
Potassium bicarbonate	.50
Magnesium bicarbonate	33.95
Calcium bicarbonate	52.25
Manganese bicarbonate	Trace.
Ferrous carbonate	1.43
Silica	5.13
Alumina	1.75
Organic matter	Trace.
Total	110.46

Free carbonic acid gas, 98.41 grains.
Temperature of water, 60.4° F.

The water is antacid, laxative, and diuretic, and has been used with much satisfaction in dyspepsia, neuralgia, kidney and bladder troubles, calculi, etc., and in rheumatism, gout, and skin diseases.

THE "DUTCH" OR "EMS" SPRINGS.

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	1.76
Sodium bicarbonate	17.50
Sodium carbonate	2.45
Potassium bicarbonate	.78
Magnesium bicarbonate	66.55
Magnesium carbonate	1.63
Calcium bicarbonate	57.32
Manganese bicarbonate	Trace.
Ferrous carbonate	1.53
Silica	7.22
Alumina	.12
Organic matter	Trace.
Total	156.86

Free carbonic acid gas, 58.90 grains.
Temperature of water 77° F.

This water is more diuretic and laxative than the Seltzer. The Highland bathing water is artificially heated.

It is also an alkaline-saline fluid with considerable carbonic acid gas and some iron. The baths are used for rheumatism and joint affections. *James K. Crook.*

HIGHLAND SPRINGS.—Androscoggin County, Maine. Post-Office.—Lewiston. Cottages.

Highland Spring is located in Highland Park, comprising over sixty acres of elevated and wooded land, about two miles from Lewiston station. The spot offers exceptional advantages to persons wishing to camp during the summer. The waters of this spring have enjoyed a considerable reputation for a long time past. They are bottled and sold extensively for table purposes. The following analysis was made by Richard C. Stanley, Ph.D., State assayer of Maine:

One United States Gallon Contains:

Solids.	Grains.
Iron carbonate	1.10
Iron oxide	.31
Potassium and sodium carbonate	.83
Magnesium carbonate	1.23
Potassium and sodium sulphate	.31
Sodium chloride	1.00
Total	4.78

This is an excellent, palatable water and possesses the properties of a mild ferruginous tonic.

James K. Crook.

HIP-JOINT.—The development of the pelvic limbs into organs for support and propulsion has given to the joints by which they are articulated with the trunk a peculiar character of strength and solidity. While movement is free in every direction, and the femur can be circumducted as well as rotated, yet these movements are much less extensive than at the shoulder. The head of the distal bone is more completely enclosed, and the capsular ligament is stronger and narrower at its distal insertion, so as to offer a resistance to luxations. Besides this, certain modifications have been caused by the strain and pressure occasioned by the erect position. It would naturally be supposed that in a ball-and-socket joint the surfaces of contact would be perfectly spherical, and, indeed, the head of the femur is usually described as presenting from two-thirds to three-fourths of the surface of a sphere fitting closely the acetabular cavity. Aeby[1] and Schmid[2] have, however, shown that this is not quite correct, as there is a slight flattening of the surfaces and a thickening of their encrusting cartilages where they are subjected to the greatest pressure. This is more marked in the adult.

The liability of the articulation to disease and injury is considerable, both on account of its size and of the pressure upon the surfaces. It is therefore important to determine its precise position and relations—and this is by no means easy, as it lies buried under thick masses of muscle. In front is the reflected tendon of the ilio-psoas, a bursa (*B. subiliaca*), which sometimes communicates with the joint cavity, intervening. Above, the reflected tendon of the rectus femoris and the gluteus minimus are firmly united with the capsule (see Fig. 2645). Internally lies the pectineus above, also united with the capsule, and the obturator externus below. The tendon of this latter muscle also lies posteriorly, together with the obturator internus, the gemelli, the pyriformis, and the quadratus femoris.

All these form an immediate investment for the joint, and are themselves partially covered by a second mass composed of the tensor vaginæ femoris, the gluteus maximus and medius behind and externally, the biceps group behind, and the adductor group internally.

Over these muscles there stretches the fascia belonging to the different groups, and in several situations this notably strengthens the joint capsule, especially where the iliac fascia comes down from the ilio-psoas, where the pectineal fascia passes outward upon the capsule from the pectineus, and, externally, where a strong process passes inward between the tensor vaginæ femoris and the rectus femoris.

The depth at which the articulation lies makes it difficult to obtain any positive knowledge as to the condition of the joint by direct manipulation, but a fairly accurate notion of its situation may be had by noting the surface forms and bony points of the region. As to the bones, note first the anterior superior spine of the ilium, always marked even in the fattest subjects; then the spine of the pubis, which can easily be found by abducting the thigh and then running the finger along the strong tendon of the adductor longus which starts up. Joining these two points is Poupart's ligament, which may easily be felt. The muscular prominence on the outer side of the leg is caused by the tensor vaginæ femoris, on the inner by the abductor muscles, and the triangular interval between, which reminds one distantly of the axillary space, is the *fossa subinguinalis*, or Scarpa's triangle. It is through the middle of this that the great vessels pass down the thigh, and the beating of the femoral artery, which lies nearest the joint, may be felt by pressing just below Poupart's ligament. The joint is about half an inch external to this, and in a very lean person (easier in cadaver) the head of the femur may be felt rolling under the fingers by pressing deeply here while an assistant extends and rotates the limb. This is impossible, however, when the subject is even moderately fat. A fulness and tenderness here are noted in the early stages of hip dis-

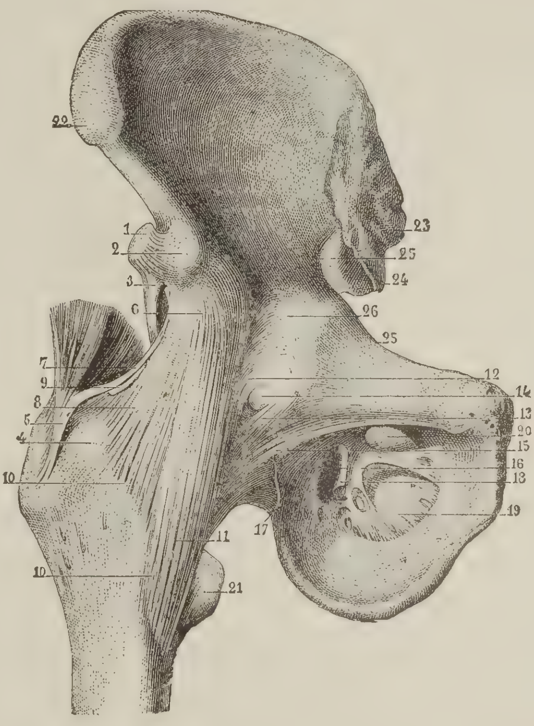

Fig. 2645.—Front View of the Hip-Joint. (From Sappey.) 1, Tendon of rectus femoris, cut; 2, its attachment to the antero-inferior iliac spine; 3, reflected portion of the tendon; 4, tubercle of the trochanter major; 5, tendon of the gluteus minimus; 6, the attachment of the ilio-femoral ligaments to the antero-inferior iliac spine; 7, fibrous union of the capsule with the tendon of the gluteus minimus; 8, superior ilio-femoral ligament; 9, section of a very thin fibrous lamella which covers over and crosses the ligament obliquely; 10, 10, thinner portion of the capsule between the two ilio-femoral bands; 11, anterior ilio-femoral ligament; 12, 13, thin portion of the capsule arising from the ilio-pectineal eminence, and from the horizontal ramus; 14, orifice in the capsule communicating with the bursa beneath the tendon of the ilio-psoas; 15, pubo-femoral ligament; 16, 17, 18, 19, fibrous bands relating to the obturator membrane; 20, the obturator foramen or subpubic canal; 21, lesser trochanter; 22, antero-superior iliac spine; 23, postero-superior iliac spine; 24, postero-inferior iliac spine; 25, ilio-pectineal line; 26, ilio-pectineal eminence.

ease, when there is effusion into the joint. Pus forming around the joint is always confined, and burrows extensively along the lines of fascia above mentioned. An abscess pointing below Poupart's ligament, and external to the vessels, usually comes from the joint.

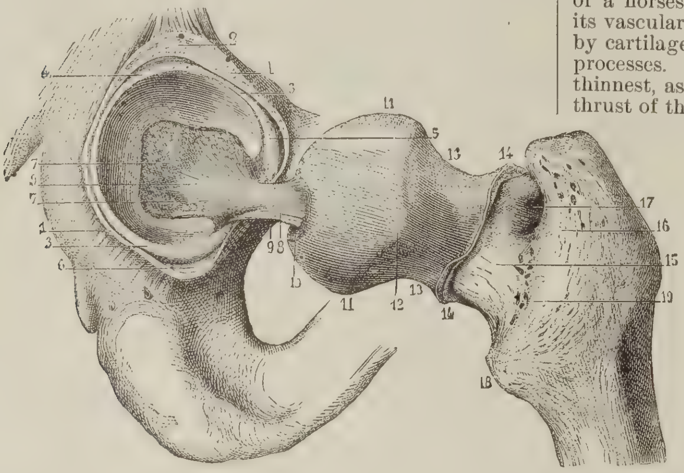

FIG. 2646.—The Hip-Joint Opened. (From Sappey.) 1, 1, Transverse section of the capsular ligament, showing its variations in thickness; 2, section at the situation where it is strengthened by the ilio-femoral bands; 3, 3, free edge of the cotyloid ligament; 4, 5, 6, semilunar interspaces which separate that ligament from the capsule; 7, 7, pad of fat at the bottom of the acetabulum; 8, 9, the ligamentum teres; 10, the umbo, or depression on the head of the femur; 11, 11, head of the femur; 12, farthest extent of the articular surface behind; 13, 13, that portion of the neck behind that is invested with synovial membrane; 14, 14, oblique line where the synovial membrane is reflected; 15, that portion of the neck behind that remains without the capsule: 16, great trochanter; 17, digital fossa; 18, lesser trochanter; 19, posterior intertrochanteric line.

Two other bony points should be noted. First, the tuberosity of the ischium, which is the part upon which the weight of the body rests in sitting. In the erect posture it is concealed by the gluteal fold behind, but may readily be made out by palpation. Second, the great trochanter, which is situated on the outer part of the upper thigh, about four inches below and behind the anterior superior iliac spine. The top of it is on a level with the pubic spine, and about three-fourths of an inch below the head of the femur. When the leg is abducted the trochanter will be found at the bottom of a depression; when adducted and rotated inward it makes a prominence. The anterior superior iliac spine, the tuberosity of the ischium, and the pubic spine are all about equally distant from the bottom of the acetabulum. A line connecting the first two is known as Nélaton's line. It grazes the great trochanter and passes directly over the middle of the acetabulum when the thigh is slightly flexed. By noting the extent of displacement of the trochanter with reference to this line, much can be made out as to dislocation or fracture. Upon rotating the femur the trochanter will be seen to describe the arc of a circle, with a radius equal to the length of the head and neck; in case of fracture the arc is much less, the bone rotating merely upon the axis of the shaft. The patient being in the recumbent position, a fracture of the neck may also be detected by noting the displacement of the trochanter toward a line dropped vertically from the anterior superior spine of the ilium (Bryant).

Of the articular surfaces the acetabulum is the more liable to disease, because it is composed of a greater variety of elements. The three primitive bones, the ilium, ischium, and pubis, which unite to make the innominate bone, all participate in the formation of the cavity. Up to the age of puberty the component bones are separated by a Y-shaped strip of cartilage. It is probably on account of the unusual activity required by the osteogenic process here that the joint is so prone to disease in childhood, hip disease rarely occurring after ossification is completed. The primitive divisions of the cavity are still indicated in the adult by notches on the edge of the acetabulum. The lower part of the cavity is not covered with cartilage, but offers a rough depression filled in with fat and processes from the synovial membrane, in which vessels pass to supply the joint (Haversian gland) (Fig. 2646). It results from this that the part of the joint covered with cartilage has somewhat of a horseshoe shape. The lower part, both because of its vascularity and on account of its want of protection by cartilage, is usually the first attacked by inflammatory processes. It is also in this situation that the walls are thinnest, as it is necessary to buttress above against the thrust of the femur in the erect position. The thinness here explains the ease with which inflammatory processes may be propagated, an arthritis giving rise to a pelvic cellulitis, and a pelvic abscess occasioning inflammation of the joint. Perforation of the acetabulum is not very common, as the pressure is but slight.

Within the pelvic cavity the situation corresponding to the acetabulum is covered in part by the obturator internus. When the perforation occurs it must therefore be in one of three positions—either upon the muscle, behind it, or in front of it. In the first instance the pus passes out with the tendon of the muscle at the lesser sciatic notch, and points upon the nates. When the perforation occurs behind, the pus goes into the ischio-rectal fossa, and discharges through the perineum or into the rectum. When it occurs in front, the pus passes upward along the sheath of the obturator vessels and makes its appearance in the groin.[3]

The acetabular cavity is not quite an inch in diameter and does not comprise an entire hemisphere. This deficiency is made up by fitting to the rim an elastic structure of fibro-cartilage called the cotyloid ligament. This is triangular on section and spans over the notch at the bottom of the cavity, being there known as the transverse ligament. The cavity thus deepened, is somewhat more than a hemisphere. The cotyloid ligament is applied closely to the surface of the femur, and helps to retain it in position—acting, however, as a valve, as it is easily stretched sufficiently to disarticulate the bones. Both the head and the neck of the femur should be regarded as taking part in the articulation, the first by actual contact, the second by its inclusion in the capsule. The articulating surface of the head has been estimated at nine and a half square inches, and when to this is added the surface of the acetabulum and capsule, there are about twenty square inches of synovial surface subject to inflammation.[3] It is not, therefore, surprising that

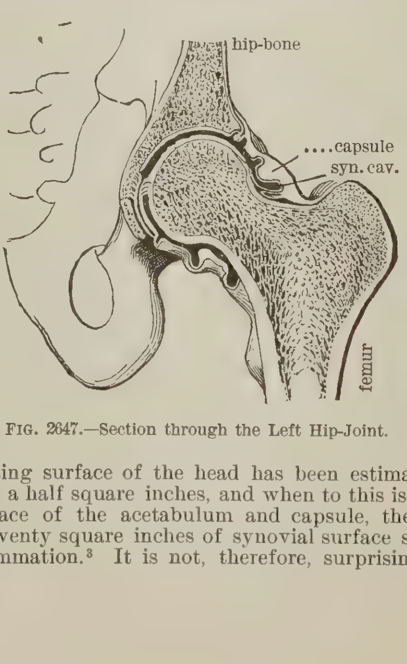

FIG. 2647.—Section through the Left Hip-Joint.

the joint should be susceptible to injury. The cartilaginous covering extends farther from front to back than from side to side, indicating the direction of the greatest excursion of the articular surface. A short distance below the summit of the head, and a little nearer the posterior than the anterior surface, there is a slight depression, termed the umbo, for the insertion of the ligamentum teres (see Figs. 2646 and 2647). The neck is obliquely set upon the shaft at an angle which varies according to the age of the individual, but not so much as is generally supposed, being about an average of 131° for the child and adult, and 128° for the aged.[4] Individual variations are more pronounced, lying between 121° and 144°, or more. The angle is less in females than in males. These facts explain the greater frequency in women and aged people of fracture from shocks delivered upon the neck in a vertical direction, as the nearer the angle between the neck and the shaft is to a right angle the greater would be the shearing stress under such circumstances. The compact tissue is mainly at the lower part, where the most bracing is required. Caries, therefore, works much more rapidly upon the upper surface.[3]

An apparatus connected with the synovial membrane of the joint is the so-called ligamentum teres, or round ligament—which is not round, nor, properly speaking, a ligament, being a flattened band quite similar to the synovial processes with which it is united at both ends (see Fig. 2646). It passes from the fossa at the bottom of the acetabulum to the umbo upon the head of the femur. It does not, like interosseous ligaments, extend in the shortest direction from one bone to the other, but is in a manner rolled around the lower part of the head (Fig. 2647). It is composed of loose connective tissue and contains vessels.

Various surmises have been made as to its use. It was formerly held to be for the purpose of limiting outward rotation and adduction during flexion [5], [6], [7]. It has been shown, however, that if the capsule is left intact, these motions are more closely limited than when it is severed, and the strain comes alone upon the ligamentum teres. Tillaux[4] thinks that it tends to break shocks delivered by the femur upon the top of the acetabular cavity in jumping, etc. Sappey[8] supposes that its principal function is the protection and conveyance of vessels to nourish the head of the femur; but Hyrtl[9] finds that, upon careful injection of the arteries, only the round ligament and the fatty cushion at the bottom of the acetabulum become reddened, and that at the insertion of the round ligament upon the femoral head the capillary arteries loop back and unite with veins. An injection of the superior nutrient artery, on the contrary, fills the capillaries of the cancellous tissue of the head. This explains the well-known pathological fact that an intracapsular fracture of the femoral neck is likely to be followed by non-union of the fragments, notwithstanding that the ligamentum teres may be left intact. Langer,[10] however, finds that, in young subjects, vessels of considerable size pass through directly into the proximal epiphysis of the femur, and suggests that its function is connected with the nourishment of that epiphysis. When this becomes united, its vascular system is connected with that of the nutrient artery, and the branches received through the ligament gradually atrophy, until in old age they are almost entirely wanting.

Welcker[11] has made a careful examination of this ligament in the animal series, as well as in human embryos, and considers it a process of synovial membrane originating as a fold at the side of the articular surface, and gradually detached by the twisting of the limbs. In some animals quite near man, as the orang (occasionally also in man), it is wanting, but it may be said to be generally present when there is much differentiation of the hind limbs. In the tapir it is reduced to a process attached only at the side, a condition occasionally found in the human shoulder-joint.

One of the most interesting views as to the nature of this puzzling structure is that of Sutton,[12] who thinks it a vestige of a tendon, probably a former attachment of the pectineus. The ambiens muscle of ostriches, homologous with the pectineus, carries its tendon into the joint to the head of the femur. In the lizard *Sphenodon*, the pectineus has two heads, one going to the femur, the other to the pubic bone, reminding one of the biceps brachialis. In the horse the ligamentum teres has two parts, one of which is continuous with the pectineus.

The capsule of the joint is much stronger and thicker than that at the shoulder, and confines the bones more closely. It is united above just beyond the base of the outer edge of the cotyloid ligament, and to the transverse ligament. Upon the femur it passes considerably beyond the articular surface, taking in a portion of the neck. In front it reaches to the anterior intertrochanteric line, while behind, because of the numerous muscles coming to be inserted into the trochanter, it does not reach the posterior line, but covers only about the inner two-thirds of the neck. It follows from this that all fractures of the neck are intracapsular in front, that they are intracapsular in front and behind when situated at the internal half, but when at the external half they may be intracapsular in front and extracapsular behind. Tillaux[4] notes that the synovial membrane is reflected within the capsule somewhat in advance of the fibres of the capsule, and shows that a fracture might be intracapsular and still not involve the synovial membrane. He therefore proposes that the fractures of the neck be divided into intra- and extra-articular.

The innermost layer of the capsule, not including the synovial membrane, is a thin layer of circular fibres. These become more apparent behind and at the lower part, where they are known as the zona orbicularis. This is the weakest part of the capsule, and, consequently, the point where pus usually bursts through, and where spontaneous dislocation takes place in hip disease. A blow on the great trochanter forcing the head of the bone downward and backward is apt to occasion dislocation, especially when the thigh is flexed so as to make the head of the femur press against this weak part. The circular fibres are not confined to this spot, but are found intermingling with others in all parts of the capsule. They undoubtedly exercise a restraining influence against dislocation of the bone by constricting the capsule at its femoral insertion.

In those situations where special stress occurs, longitudinal bundles of considerable strength have been formed upon the surface of the capsule. These form four tolerably distinct bands. Two of these are caused by the necessity of supporting the trunk in the erect position. They pass from the anterior inferior spine of the ilium downward, diverging from each other like the branches of an inverted **Y** (**⅄**), one going to the base of the trochanter major, the other to just above the trochanter minor. They have usually been described collectively as the ilio-femoral ligament, ligament of Bertin, or **Y** ligament of Bigelow. Welcker[11] has, however, suggested that, as the two bands are distinct and perform different physiological functions, they should receive separate names, and proposes to call them the superior and anterior ilio-femoral ligaments. They are both exceedingly strong. It is because of this that, in the barbarous punishment of "drawing" a criminal, by means of four horses attached to his limbs and proceeding in opposite directions, the separation at the hip-joint had usually to be completed with a knife, the ligaments resisting after several hours of trial—as was the case at the execution of Ravaillac, the assassin of Henry IV., and of Damiens, who attempted the life of Louis XV.

The superior ligament is perhaps the strongest ligament in the body, being from one-fourth to one-half an inch thick (7 to 14 mm. Welcker), and stronger than the tendo Achillis. Its action is to limit the extension of the femur upon the pelvis. In the erect position the weight of the body falls behind the hip, and the pelvis is accordingly tilted backward, putting this band on the stretch, and it then sustains the whole weight of the trunk, head, and arms, a great economy of muscular force being thus effected. It also limits outward rotation and adduction.

The anterior ligament is also very strong, being nearly one-fourth of an inch thick (4 to 5 mm.), and the longest strengthening band of the capsule. It assists the superior ligament in limiting extension, but not in the same plane, the plane of limitation for the superior ligament being nearly parallel to the axis of the femoral neck, that of the anterior with the axis of the shaft.

The two ligaments are but slightly developed before the erect position is attained. Indications of them are found early, but they increase with the growth. In animals that can stand partially erect, such as apes and some marsupials (kangaroo), the ligaments are strong; in others slight.[13]

They have an important influence in determining the deformity which results from dislocations of the femur, and may be used as a fulcrum in reducing them.[14] Thus, it is the superior ligament which holds the neck fixed, and hence causes the inward turning of the toes in dislocation backward. In thyroid dislocation the anterior ligament causes in a similar way an eversion of the toes.

Another strengthening band of the capsule is the pubofemoral ligament, which stretches from the pectineal eminence of the pubic bone to the lesser trochanter. It is from 2 to 3 mm. thick, and limits abduction. The ischio-femoral band is of about the same size, and stretches in a similar way from the tuberosity of the ischium to the digital fossa of the great trochanter, along the line of the tendon of the obturator internus, with which it is somewhat blended. It limits rotation inward. It is sometimes described as ending upon the capsule, and therefore called ischio-capsular (Henle); but Welcker and others find the arrangement described the usual one.

The action of these four bands is such that in passing from the flexed to the extended position they wind around the neck in such a way as to shorten the capsule, which, being closely united with the zona orbicularis, is drawn up against the edge of the acetabular cavity and surrounds the lower part of the head as with a ring. It may be said that the contraction is such that dislocation is impossible in the extended position.

The brothers Weber made the discovery that the head of the femur is held in position by atmospheric pressure, the amount of weight thus lifted being somewhat greater than that of the limb. This greatly economizes the muscular force required for walking. The closely fitting cotyloid ligament assists this greatly, and dislocation is very unusual, if not entirely impossible, without injury to it. Men and animals that ascend mountains to a height where the air becomes sufficiently rarefied to be of less effect in upholding the weight of the limbs suffer from weakness in the joints. Hyrtl[9] states also that mountaineers, who have trained their muscles by long use in a rarefied atmosphere, are somewhat inexpert in the use of their legs when they descend to the valleys.

The arterial supply to the joint is, as has been stated, through the notch in the lower part of the acetabulum, some collateral circulation being imperfectly effected by means of capillary branches from the nutrient artery of the femur. The capsular ligament is remarkable for the number of vessels and nerves which ramify in it.

The joint is usually said to be supplied with nerves from the sciatic and from the obturator trunks, but recently the nervous supply has been carefully reinvestigated by Chandelux, who finds it to be as follows: In front, a twig from the musculo-cutaneous branch of the anterior crural is given off a short distance from the point where the nerve is lost in the pectineus. This passes behind the sheath of the femoral vessels, and reaches the capsule at its antero-internal portion. It supplies the internal half of the anterior part of the capsule Behind there is a branch of somewhat variable origin, but always emanating either directly or indirectly from the sacral plexus. It descends upon the posterior part of the articulation, reaches the capsule behind and above, and is distributed to the internal half of the posterior portion. No nerve was found from the obturator trunk.

It is believed that this distribution explains certain phenomena connected with coxalgia. In certain forms the propulsion of the head against the acetabular cavity by percussion upon the knee is hardly felt, although a direct pressure upon the internal part of the femoral head in front is very painful, as are also forced movements of outward rotation. In this case it is supposed that there is a coxalgia of capsular origin.

Again, the characteristic attitude is also explained. Often adduction of the leg is accompanied by inward rotation, but in some patients outward rotation occurs. As the anterior articular nerve is only a bifurcation of the branch going to supply the pectineus, it may easily be imagined that a neuritis, arising perhaps from the synovial membrane, affects the pectineal branch and causes the muscle to act.

The pain in the knee, which is an almost constant symptom in hip disease, has usually been considered to be caused by the reflex action through the articular branch from the obturator nerve. It may, however, be caused by a neuritis extending to the internal saphenous nerve, or, as is more likely, by the pressure which the effusion into the joint makes upon the obturator nerve where it lies upon the anterior part of the capsule.[8]

Frank Baker.

HIP-JOINT, CONGENITAL DISLOCATION OF THE.—Congenital dislocation of the hip-joint, or perhaps more properly misplacement, is by far the most common and the most important of this class of disability.

It is much more common in females than in males, as is illustrated by the following statistics: In 671 cases collected from different sources by Lorenz 589 (87.8 per cent.) were in females and 82 (12.2 per cent.) in males. Of 1,039 cases seen at the Polyclinic in Milan, 867 (83.4 per cent.) were in females, 172 (16.6 per cent.) in males. In 500 cases recorded at the Hospital for Ruptured and Crippled, 413 (82.6 per cent.) were in females and 87 (17.47 per cent.) in males.

The dislocation is more often unilateral than bilateral. In Lorenz's series of 671 cases, 421 (64.4 per cent.) were single; 225 of the right, 196 of the left side. In 245 cases (36.6 per cent.) the displacement was bilateral. In the statistics of the Hospital for Ruptured and Crippled 353 (71.3 per cent.) were unilateral; 135 of the right and 218 of the left side; 136 (27.87 per cent.) were bilateral.

The dislocation at the time when the patients are brought for treatment is usually posterior, upon the dorsum of the ilium. In other instances it is anterior, the head of the bone lying below the anterior superior spine. Occasionally the displacement appears to be a subluxation due to laxity of the capsule; in such cases it may be directly upward, supracotyloid. This form is more often seen in infancy, and it represents possibly the primary displacement of a much larger proportion of the total number, which changes to the ordinary form under functional use.

Pathology.—The degree of abnormality of the joint and of the surrounding parts varies with the age of the patient and with the strain and friction to which the displaced parts have been subjected. At birth it may be assumed that the head of the bone lies in close proximity to a somewhat rudimentary actetabulum. At a later time, when the joint is exposed at operation at the age of four years or more, the rudimentary acetabulum may be partly filled with cartilage, fat, and fibrous tissue. As a rule, however, a well-marked ridge indicating its posterior and upper margin can be made out and in many instances it appears to be of fair size and depth, but always misshaped to a greater or less degree, smaller and shallower than normal, and in older subjects contracted at its upper margin to a somewhat triangular form.

The capsule is elongated to accommodate the upward dislocation of the femur. It is hypertrophied, especially where it covers the upper part of the head of the bone, and it is often drawn into a shape like an hourglass; the upper part contains the head of the bone; the anterior wall is drawn tightly across the acetabulum, forming at its upper border a narrow, slit-like communication, through which the ligamentum teres passes, if it be present. The interior of the capsule is in part lined with synovial membrane, and it often contains more synovial fluid than is found in the normal joint.

The ligamentum teres, although probably present at birth in a large proportion of the cases, becomes attenuated and ribbon-like with the increasing elongation of the capsule, and after the age of five years it is usually absent or very rudimentary.

A shallow depression formed in part by the direct pressure of the head of the bone through the adherent capsule, and in part the result of irritation of the periosteum is usually found upon the ilium, but as it is not often of sufficient depth to assure a secure support for the head of the femur its upper margin gradually recedes or two distinct depressions may be formed one above the other. The upper extremity of the femur is usually somewhat atrophied. The neck is often shorter than normal, its angle may be lessened and in many instances its forward inclination is increased (anteversion). The head of the bone may be nearly normal, although usually it is somewhat flattened on its inner and under surface, or it may be somewhat conical, or again compressed from side to side to an almond shape or otherwise distorted.

There are also secondary changes in the bones of the pelvis. In unilateral dislocation the pelvis is usually somewhat atrophied on the affected side, and a lateral inclination of the spine may be present. The final changes in the pelvis caused by the bilateral dislocation are more important; its inclination is increased, the lumbar lordosis is exaggerated, the sacrum is forced forward and downward so that the antero-posterior diameter is lessened; the tuberosities of the ischia are everted and the transverse diameter of the pelvic outlet is increased.

The long muscles of the thigh are shortened, while those attached about the trochanter are changed in direction and are usually lengthened. There is also a slight general muscular atrophy that is particularly marked on the gluteal group. The changes become more marked with increasing age, and in some of the adult specimens but little resemblance to the normal parts remains.

As a rule, congenital dislocation of the hip is not accompanied by defective development or deformity elsewhere; although cases are sometimes seen in which a general laxity of ligaments is present or in which the dislocation may be one of a series of deformities and malformations.

Etiology.—Nothing positive is known of the etiology of the dislocation. In a small proportion of the unilateral cases it may be due to violence at birth, but the fact that nearly eighty-five per cent. of the patients are females indicates that the primary cause can be neither injury nor disease.

Hereditary influence can be established in a few instances and the displacement may be present in more than one of the same family. The writer has examined three female children, in a family of nine, in each of whom there was dislocation of the left hip, the order being the third, eighth, and ninth child; also twins, one having single and the other double dislocation. In but two instances in a large number of observations, was it certain that congenital displacement was present in the mothers of the patients.

Of the various theories that have been advanced to account for the condition, the most reasonable seems to be defective development either of the entire acetabulum or of its posterior margin. This defective development may be primary or it may be secondary to a fixed position of the limb in adduction and flexion.

Heusner has endeavored to explain the greater liability of females to the dislocation by disproportionate laxity of the capsule which he thinks is characteristic of the sex. It is probable that the dislocation in many instances is at birth a subluxation only and becomes complete through muscular action and by the use of the limb in standing and walking.

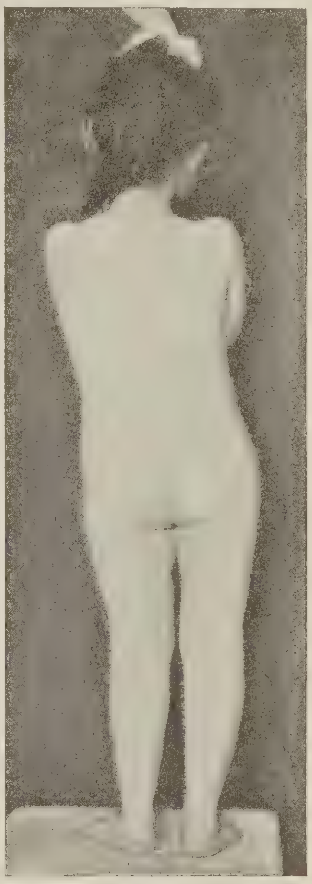

Fig. 2648.—Unilateral Dislocation Showing the Inclination of the Body Toward the Shorter Limb.

Symptoms.—The displacement does not as a rule attract attention until the child begins to walk; although in some cases the mother may have noticed a peculiar breadth of pelvis, or a "lump" on the buttock, or a "snapping" about the hip-joint, or a peculiar attitude of the limb before this time.

Unilateral Dislocation.—If the displacement is of one side, a limp is immediately apparent, and this becomes more noticeable as the child grows older. The limp is characteristic of the affection, for the limb is not only shorter than its fellow but owing to the elasticity of the capsule it becomes still shorter when weight falls upon it. Thus in walking there is a peculiar lunge of the body toward the affected side. In most instances the dislocation is upon the dorsum of the ilium, the head of the femur being displaced upward and backward. In compensation the pelvis is tilted toward the short leg and its inclination is increased. It is also rotated forward so that the anterior superior spine lies on a lower plane, and in advance of that of the opposite side.

When the child begins to walk the shortening of the limb is from one-half to three-quarters of an inch. In adolescence it is from one and a half to three inches or even more, the shortening increasing as the capsule elongates under pressure.

Other signs are the flattening of the buttock and the elevated and prominent trochanter which may be seen or felt as an abnormal lateral projection, on a level with the anterior superior spine, which is, as has been stated, somewhat tilted downward.

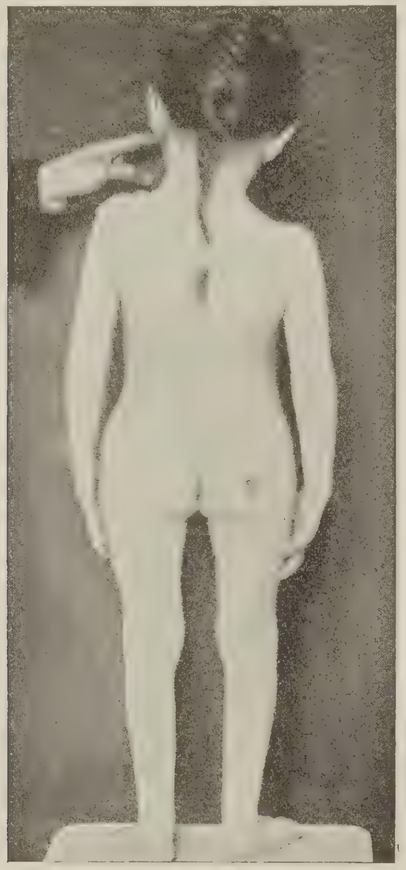

FIG. 2649.—Bilateral Dislocation Showing the Relative Shortening of the Lower Limbs and the Apparent Broadening of the Pelvis.

In childhood the attitude of the limb is practically normal and motion is unrestricted. There is, in fact, an abnormal mobility that may be demonstrated by alternate traction and upward pressure on the limb. As the femur becomes larger and the upward displacement increases, the mobility is restricted; the range of abduction in particular is much diminished and not infrequently the limb becomes permanently adducted and flexed, thus adding the apparent shortening of adduction to that caused by the dislocation.

Bilateral Dislocation.—When the dislocation is bilateral the shortening of the limbs is, as a rule, equal or nearly so, and as both femora are displaced backward the pelvis is tilted forward. In compensation the hollow of the back is increased, the abdomen protrudes, the buttocks are flattened, the pelvis appears to be abnormally wide, and the thighs are separated by a considerable interval. The limp characteristic of the single displacement is replaced by an exaggerated waddle, a "sailor gait."

In early childhood there may be no symptoms other than the physical signs that have been described, but as the child becomes more active it usually complains of discomfort after exertion. It is easily fatigued and at times it may suffer actual pain. These symptoms are of course more marked in the double than in the single displacement, because in the latter case the normal joint is capable of bearing more than its share of the strain. The symptoms often increase during adolescence, but they may become less troublesome in adult life if a permanent resting-place on the pelvis is secured. This security is often assured, however, by a corresponding limitation of the range of motion. The physical signs of course persist and the individual is, as compared with the normal standard, more or less disabled and deformed. Fortunately the great majority of the patients are females, and because of the less laborious occupations and the distinctive dress, the disability and its effects are less serious than if the displacement were more equally divided between the sexes.

The symptoms of the anterior dislocation in which the head of the bone lies beneath the anterior superior spine, are less marked because the relation of the pelvis to the femur is nearly normal, so that secondary deformity is slight. The shortening is less and the resistance of the tissues attached to the anterior superior spine is sufficient to assure a more secure support than in the ordinary form so that the limp is less noticeable. In bilateral anterior dislocation there is a swaying backward of the body, but the exaggerated lordosis is absent.

DIAGNOSIS.—The diagnosis offers no difficulty. The history of the limp, at once apparent when the child began to walk, yet not accompanied by pain or preceded by injury or disease, is in itself sufficiently distinctive. If the displacement is of one side measurement demonstrates the shortening as compared with the other limb, a shortening that is explained by the prominence and the elevation of the trochanter above Nélaton's line. Traction and upward pressure on the leg will demonstrate the abnormal mobility of the displaced head; and finally if the thigh be flexed and adducted to its extreme limit, the neck and head of the femur can be easily distinguished moving under the gluteal muscles when the limb is rotated. Thus it may be differentiated from depression of the neck of the femur (coxa vara), in which although the trochanter is elevated, the neck and head of the bone cannot be felt, and in which the abnormal mobility, characteristic of the dislocation, is absent. Again, coxa vara is almost never a congenital affection, therefore the history itself would practically exclude it.

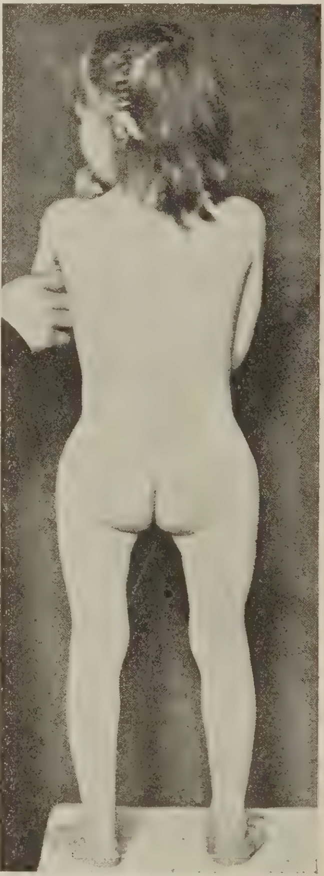

FIG. 2650.—Bilateral Dislocation Showing the Separation of the Thighs.

Upward displacement of the femur not infrequently follows infectious epiphysitis in infancy or early childhood. In such cases a part of the upper extremity of the bone is usually destroyed so that the head cannot be dis-

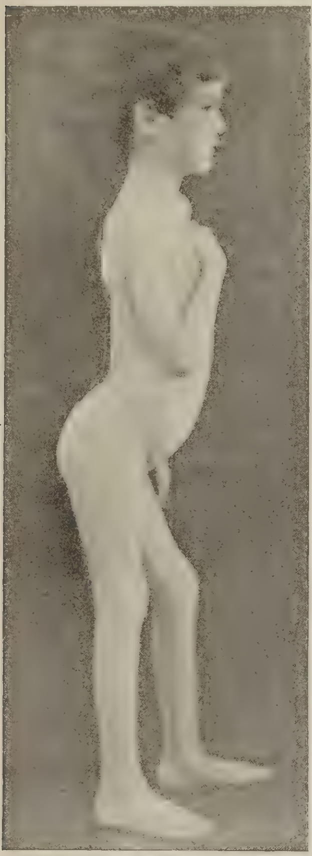

FIG. 2651.—Bilateral Dislocation Showing Habitual Flexion of the Thighs and the Increased Inclination of the Pelvis.

tinguished on palpation. Although the other physical signs are similar to those of the congenital displacement, the scars about the joint show the evidence of former disease and the history is almost always available for diagnosis, so that as a rule such disabilities as well as traumatic dislocations or other results of injury or disease are readily excluded.

Certain of the minor symptoms of congenital dislocation may be simulated by other affections, but these may be excluded readily by the physical examination.

In doubtful cases a Roentgen picture will demonstrate the character of the disability.

TREATMENT. — The principles of the treatment are simple, since it is evident that the only cure of a dislocation must be replacement of the displaced part. The application of these principles is difficult, however, because of the congenital or acquired abnormalities that may interfere with reduction or with the functional ability of the limb after treatment.

There are two methods of treatment by which cure or palliation may be attained. The first is forcible reduction without cutting, of which the most practicable method is that advocated by Lorenz, although this treatment was first advocated by Paci.

The Lorenz treatment is based upon the theory that if parts about the joint can be sufficiently stretched to allow the head of the bone to be brought into direct contact with the rudimentary acetabulum, and if it can be held for a sufficient time in this position, the weight of the body in walking, constantly forcing the bone against the substance that partly fills it, will gradually enlarge it to its normal capacity. Thus he calls it the "functional weighting" method, and this is its essential and vital distinction from the forcible correction of Paci, with which it is often confounded.

The steps of the operation are: 1. Elongation of the Limb. The trochanter must be brought down to the level of Nélaton's line or lower. This may be accomplished by preliminary traction in bed with heavy weights or by manual force at the time of operation, the latter means being efficient in young subjects. The child having been anæsthetized, a folded sheet is passed between the legs, the two ends of which are held by the assistant above the shoulder of the side to be operated on, or the assistant may clasp his hands about the perineum and thus fix the pelvis. In most instances counter-traction on the sheet by one assistant and fixation of the pelvis by another will be necessary. One then seizes the thigh and begins a series of alternate stretchings and relaxations, using gradually increasing force for from ten to twenty minutes, or until the resistance of the tissues is entirely overcome. The leg is then as long or longer than its fellow and lies limp in an attitude of abduction.

For this preliminary extension Lorenz often uses a powerful machine attached to the leg by means of a band about the ankle, but I am inclined to think that the manual method is to be preferred if one does not object to the labor that it involves.

2. Reposition. One now attempts to force the head of the femur over the ridge that represents the posterior margin of the acetabulum and through the opening in the contracted capsule.

The thigh is flexed to about ninety degrees in order to relax the capsule, and while the pelvis is fixed by an assistant, the limb is gradually and forcibly abducted; the resistance of the muscles being overcome by forcibly kneading the tense adductors with the ulnar border of the hand, as well as by the direct traction. During this manœuvre reduction often takes place, but in most instances this is facilitated by upward traction of the flexed limb with one hand, direct pressure being exerted on the trochanter with the thumb of the other hand. The limb is at the same time abducted, and the head of the bone is drawn and lifted over the posterior rim of the acetabulum. This partial reduction is accompanied as a rule by a distinct thud and shock, the limb remaining fixed; a position from which it may easily be displaced by reducing the abduction or flexion.

One now endeavors to make the reduction more stable by enlarging the capacity of the articulation. The forcible abduction is continued, the limb being forced outward until it is parallel with the table, or even behind the plane of the body. It is then forcibly rotated outward and inward. Finally, the patient is turned upon the sound side and the limb is moved up and down (like a pump handle), while strong pressure is exerted on the

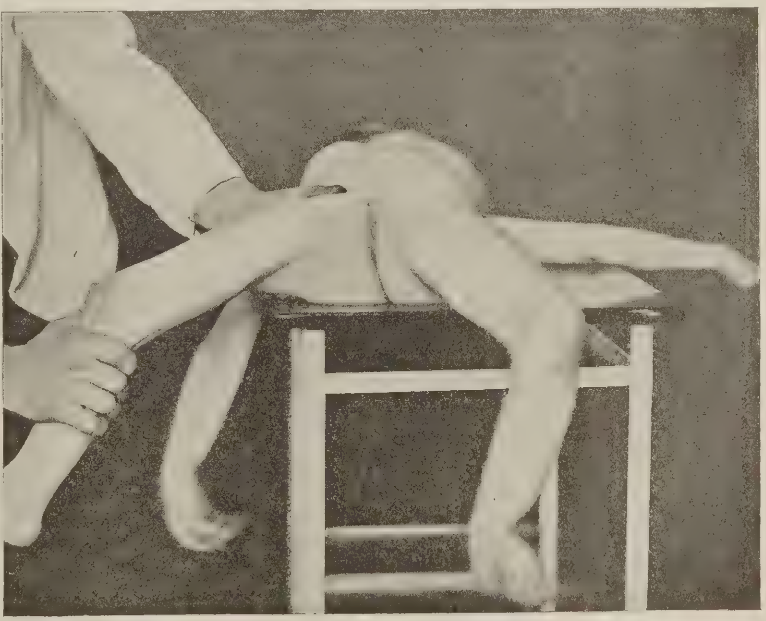

FIG. 2652.—The Typical Position in which to Fix the Limb After Reduction.

trochanter, the aim being to drive the head of the bone forward and inward completely within the capsule and to stretch its anterior wall which was drawn over, and was partly adherent to the acetabulum. The next step is to fix the limb in a position in which reluxation is impossible, the typical position being that already described of over-abduction from the original attitude of right-angled flexion of the thigh on the body. This position Lorenz describes as one of extreme abduction, extension and outward rotation, a description which is somewhat less intelligible to most readers than that adopted. In this attitude the head of the bone should be felt directly under the femoral artery, and it often forms a distinct prominence beneath Poupart's ligament. A short plaster spica bandage is then applied reaching to the knee where it is cut out sufficiently behind to allow flexion of the leg on the thigh. The body part of the spica may be of the usual form or made after the Lorenz method by figure-of-eight turns about the pelvis so that the iliac crests are firmly fixed. This pelvic portion, which is made at least one-half inch in thickness, is then cut out as in the illustration so that it does not restrict greatly the movements of the trunk. If greater fixation is required, as when it is difficult to hold the head of the femur in the acetabulum, the bandage may be extended below the knee, and as the neck of the bone is usually somewhat anteverted it is well at the same time to rotate the thigh slightly inward. When the reduction can be made easily and when the joint is evidently fairly secure, as in certain cases treated at an early age, it is unnecessary to exaggerate the normal range of motion, but it is better to fix the limb in an attitude of moderate flexion and abduction.

In the ordinary class of cases or up to the age of about four years, the reduction in the manner described is not especially difficult. In older subjects preliminary traction in bed until the muscular shortening is in great part overcome is indicated. In certain cases of this class preliminary tenotomy of the hamstrings, of the adductors, and of the muscles attached to the anterior superior spine is advocated by Lorenz, and when reduction is difficult he places a padded block under the trochanter in order to increase the leverage. In this older class, in which great force is necessary to accomplish reduction, a number of accidents have been recorded; for example, fracture of the neck of the femur, paralysis due to forcible stretching of the nerves, necrosis of soft parts, and several deaths from shock. As a rule, however, in the cases operated on within a reasonable limit of age, surprisingly little discomfort is experienced. There is usually some discoloration and swelling of the adductor region and discomfort lasting for several days, after which no complaint is made by the patient, who soon attempts to walk. If the limb is fixed in the ordinary position, that is drawn up to about a right angle with the trunk; a shoe with a cork sole two or three inches in height should be worn on the operated side. This first bandage should be kept in place for several months; in younger subjects as long as it is reasonably clean and efficient. When the second bandage is applied, if it is evident that the femur is still in place, the forced attitude is somewhat lessened, the limb is advanced slightly in front of the plane of the body and at the same time lowered to a moderate degree, the height of the shoe being correspondingly reduced.

In certain of the cases in which the foot can be brought to the floor, the high shoe may be removed, the pelvis being tilted downward to accommodate the attitude; thus more direct pressure is exerted upon the rudimentary acetabulum.

The second period of fixation corresponds to the first in time. Practically speaking, the limb is to be fixed in an attitude to guard against reluxation for from eight months to a year according to the character of the case. The fixation bandage is then removed. In successful cases the attitude of abduction and outward rotation often persists for a time. Massage and exercises, with the aim of strengthening the extensors and abductors of the thigh, are of service in the after-treatment.

By this method of treatment applied in a proper manner, a certain number of absolute cures may be attained (in nearly fifty per cent. of the cases Lorenz claims). This proportion is according to general experience far too large, and perfect cure in twenty-five per cent. of selected cases—that is, in patients five years of age or less—is perhaps nearer the true proportion.

In most instances what is really accomplished is a transposition, the head of the femur being forced forward to a position below the anterior superior spine. In many instances this failure is not apparent until the limb is brought to an approximately normal position, in others it is evident on removal of the first bandage. The reasons for failure, even when all the details of the treatment are carried out, are apparent:

1st. Failure to force the head of the bone through the constricted capsule.

2d. The very common anteversion of the neck of the femur that is practically always present in anterior displacements and in a large proportion of the other forms. Thus in the normal attitude the head of the bone cannot be retained in the acetabulum.

3d. Such deformity or non-development that adaptation of the parts is impossible.

The limit of age within which this operation may be

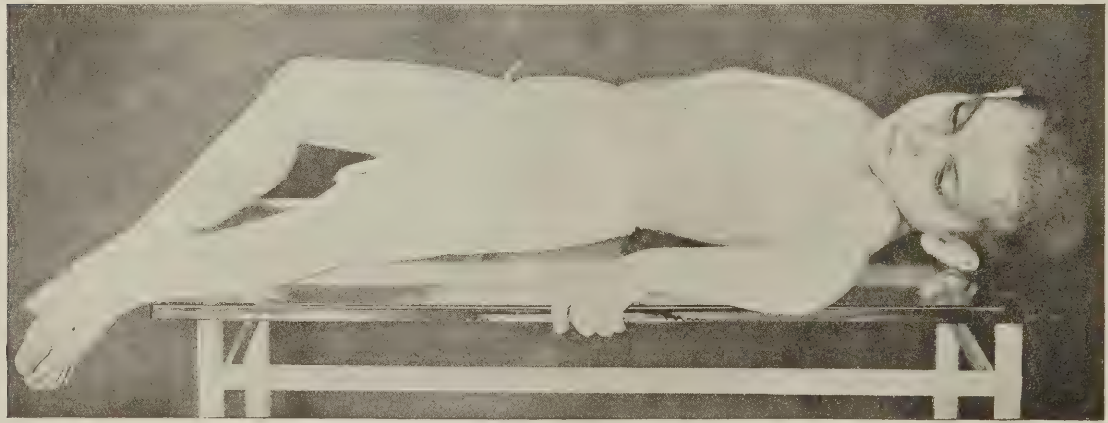

FIG. 2653.—The Lorenz Spica Bandage Illustrating the Typical Position During the Second Stage of the Treatment.

successful cannot be stated with certainty. It is evident, however, that the earlier it is undertaken the greater the chance of success. After the age of five years the difficulty of the manipulation is greatly increased and the chances of success are correspondingly lessened. It may be performed, however, as a preliminary to the open operation, even if the chance of success is small or with the aim of transposing the head of the femur and thus improving the condition of the patient. For such transposition which lessens the shortening and replaces the head of the femur in a relatively normal position, may be classed as a half cure.

The bilateral dislocation is far less favorable for treatment than the unilateral, because the chance of success is in any event lessened by half and because the congenital abnormalities appear to be more marked than in the unilateral class of cases. In young subjects both hips may be operated on at one time, although the resulting attitude is very awkward and walking is practically impossible. In older subjects on this account it is better to treat one hip at a time.

As has been stated, anterior displacements are practically always accompanied by a forward twist of the neck of the femur, anteversion. In such cases the limb must be fixed in an attitude of abduction and inward rotation, the distortion to be corrected later by osteotomy.

THE OPEN OPERATION.—As has been stated, one of the chief obstacles to successful reposition is the interposition of the capsule between the head of the femur and the acetabulum, the failure in other words to force the head through the constriction of the capsule.

In such cases or whenever the simple reposition has been unsuccessful the next step must be the open operation.

If the details of the Lorenz operation have been followed no preliminary treatment is required, but if the open operation is the primary procedure, all shortening of tissues must be overcome either by traction in bed or by forcible manipulation before the parts are exposed.

An incision is made from a point about half an inch to the outer side of the anterior superior spine, and is extended downward and slightly backward for about four inches; the fascia is divided and the line of junction between the tensor vaginæ femoris and the gluteus medius muscles is found. These muscles are then separated and are drawn to either side by retractors, exposing the capsule of the joint. The ilio-psoas muscle which often covers its anterior surface is separated from it, and the capsule is caught with a sharp hook and it is freely opened by an incision parallel to the neck of the bone. The finger is then passed through the opening down upon the rudimentary acetabulum. A strong cervix dilator is then inserted and the contracted capsule is thoroughly stretched. If the ligamentum teres is present it is removed. If on examination the acetabulum appears to be of sufficient size, the head of the bone is placed within it, the capsule is united, and the wound is closed with catgut sutures. A long plaster bandage is then applied and the further details of the ordinary noncutting method are carried out, except that if anteversion of the neck is present the limb must be rotated inward as well as abducted. In such cases when the first dressing is changed, or at a later time, an osteotomy of the shaft of the femur must precede the return of the limb to the normal attitude.

Osteotomy.—In order to control the head and neck of the femur a long drill is inserted through the trochanter and to a sufficient distance in the neck to fix it firmly. The child is turned upon the sound side and a sand bag is placed between the thighs. A small sharp osteotome is then inserted on the outer aspect of the thigh at a point just below the trochanter minor, and the femur is divided. The upper fragment being fixed in its place by the drill, the shaft of the femur is rotated outward until the normal relation is restored. In this attitude the plaster bandage is applied about the projecting drill. This is drawn out when the new position is assured, that is, at the expiration of a week or more.

The Open Operation with Enlargement of the Acetabulum (the Hoffa-Lorenz operation).—This operation is in principle that originally devised by Hoffa and modified by Lorenz, as the operation of routine for congenital dislocation, but which is now reserved for cases in which the simple reposition has failed or in which arthrotomy seems unlikely to be successful.

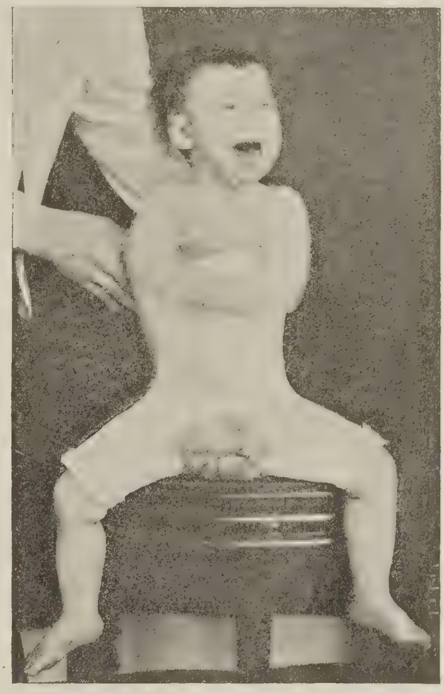

FIG. 2654.—Bilateral Dislocation, Showing the Less Extreme Attitude of the Limbs.

If when the joint is opened in the manner described the acetabulum is manifestly inadequate, it may be enlarged by removing with a strong sharp spoon the contents of the rudimentary acetabulum and deepening it to the normal size.

The head of the bone is then replaced and the stability of the articulation is tested by moving the limb in various directions. The wound is then closed or it may be temporarily packed with gauze according to Hoffa's method. A long plaster bandage is then applied, the limb being extended and slightly abducted. If anteversion of the neck is present the femur should be rotated inward and secondary osteotomy must be performed at a later time in the manner described. At the end of eight weeks a short spica bandage is substituted on which the child is allowed to walk about.

As might be expected, this operation is often followed by limitation of motion and by pain on manipulation, symptoms explained by the traumatism of the operation. In such cases, and in fact in the majority of cases, there is a strong tendency to distortion of the limb toward flexion and adduction. It is therefore in this class far safer to fix the limb in a proper attitude by means of the plaster bandage or other appliance until this tendency is overcome, in some cases for a year. In other instances the support may be dispensed with in a much shorter time. A removable apparatus which will allow massage, the use of hot air, and the like, is of course preferable.

When all the symptoms of discomfort have disappeared forcible movements under anæsthesia are sometimes of service in breaking up adhesions and increasing the range of motion. Special exercises to strengthen the weak extensors and abductors are of course indicated in all cases.

The advantages of this operation are that immediate replacement with comparatively small danger of reluxation is assured, while the limb remains in the normal attitude. The disadvantages are the limitation of motion or even ankylosis that may result.

Ankylosis following the operation in unilateral displacement, provided there is no distortion of the limb, is a marked improvement on the original dislocation, but bilateral ankylosis would practically disable the patient. For this reason one should await the result of the operation on one side before treating the other.

Ankylosis is, however, the exception, and in many instances practically normal, or at all events a sufficient range of motion remains. The degree of final disability depends in great part upon the after-treatment. If deformity is prevented, and if the muscles are strengthened by massage and by exercises, a practical cure may be attained, although in most instances a slight limp will persist even in favorable cases.

The danger of the open operation is slight in the hands of competent surgeons, less even than it is in the other method when great force is required to reduce the displacement, as in the treatment of older children.

In conclusion it may be said that the prospect of success in the treatment of congenital dislocation of the hip stands in direct relation to the age of the patient, since the extent of the pathological changes that make cure difficult or impossible depends in great degree, as in acquired dislocations, upon the duration of the disability. Consequently treatment should be applied as soon as the displacement is discovered, and there is little excuse for not making the correct diagnosis as soon as the child begins to walk. The treatment of selection before the age of six years is the functional weighting method of Lorenz. By this means a certain proportion of the cases may be cured, and in all instances the posterior may be changed into an anterior displacement, which makes the after-treatment much easier. If this treatment is ineffective it should be followed by the open method. In the younger patients simple incision and forcible stretching of the capsule may be sufficient, if the acetabulum is well formed; if not, it will be necessary to enlarge it to a sufficient size. Osteotomy may be necessary to correct anteversion of the neck of the femur whichever method is employed to reduce the displacement.

The treatment of congenital dislocation of the hip is not likely to be successful beyond the age of ten years, although in favorable cases it may be attempted. In exceptional cases at the age of adolescence or in adult life, the discomfort attending the dislocation may necessitate excision of the hip. In other instances adduction and flexion deformity may require osteotomy to correct practical shortening.

Other Congenital Dislocations.—Congenital misplacements at other joints are quite insignificant when compared with that at the hip, and in only two situations is the disability of sufficient importance to require especial consideration. These are the shoulder and the knee.

Congenital dislocation at the shoulder may occur in two forms, one in which there is actual misplacement before birth, and the other in which a dislocation is caused by violence at birth. In either case the displacement is almost always backward upon the dorsum of the scapula (subspinous). Thus the arm is abducted and rotated inward and there is the characteristic limitation of motion.

True primary displacement of either variety is rare. Many of the reported cases were apparently subluxations, secondary to the relaxation of the capsule of the joint and to the muscular atrophy caused by anterior poliomyelitis, or to the habitual malposition due to obstetrical paralysis.

Treatment.—The only treatment of a dislocation is replacement of the displaced bone if it be possible. If the displacement were discovered in infancy it might be possible to reduce it by manipulation and, unless the glenoid cavity were undeveloped, it might be retained in proper position. As a rule, however, the cases are not seen until later childhood when the accommodative changes are marked.

Phelps, of New York, has reported several cases of congenital dislocation of the shoulder, caused apparently by injury at birth, as they were accompanied by paralysis. In one case, that of a boy eight years of age, the joint was opened by a posterior incision along the border of the deltoid muscle. The head of the scapula was found to be atrophied, and the posterior margin of the glenoid cavity broken away. This, together with the contraction of the tissues on the anterior aspect of the joint, made it necessary to cut away a part of the head of the bone in order to replace it. The secondary depression on the scapula was excised and the redundant capsule was removed. The immediate result of the operation was very favorable. Phelps states that he has operated in two similar cases, but a final report of the results has not been presented.

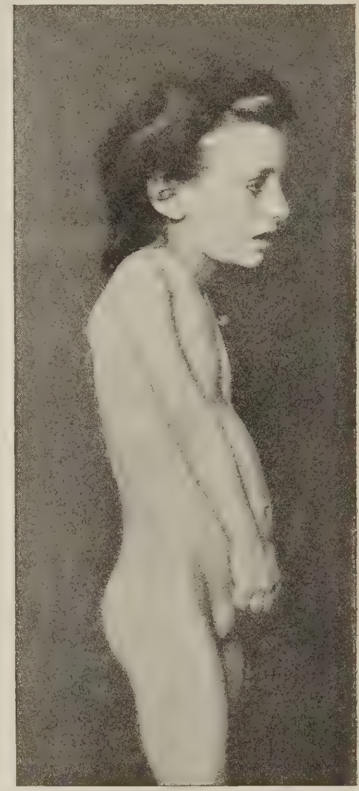

Fig. 2655.—Congenital Dislocation of the Right Shoulder.

It would seem, however, that as in a posterior displacement the contracted tissues must be those in front of the joint, an anterior rather than a posterior incision would be preferable. In all cases the open operation should be deferred until after the contracted parts have been stretched by manual force in the manner described in the treatment of congenital displacement of the hip.

Cases of congenital displacement in other directions are recorded, but these are so rare as to be of little practical importance.

Congenital Genu Recurvatum, or Anterior Displacement of the Tibia.—The most common of the congenital deformities at the knee is the so-called genu recurvatum, in which the knee is bent somewhat backward, or, in other words, the leg is hyperextended on the thigh. The deformity is often classed as an anterior dislocation, but there is no actual displacement, except in the extreme cases in which the tibia may be turned directly forward on the femur, even to a right angle or less. In the ordinary cases the range of extensionis merely exaggerated, while flexion is limited or checked, principally by adaptive shortening of the quadriceps extensor muscle.

The appearance in well-marked genu recurvatum is very peculiar; it is as if the patient's limb were reversed, the popliteal depression having become a prominence, the range of overextension representing apparently normal flexion. In such cases the leg may be brought to the straight line, but greater flexion is resisted by the retracted tissues, and when the pressure of the hand is removed the leg is drawn back to the deformed position by the contraction of the quadriceps extensor muscle.

Genu recurvatum is not infrequently accompanied by varus or valgus deformity at the knee, more often by the latter, and by laxity of the ligaments. In many instances the patella is absent or is rudimentary and not infrequently deformity is accompanied by malformations or defective development of other parts.

Etiology.—The deformity in cases of simple recurvatum may be explained by an abnormal and fixed position in utero, and in cases seen soon after birth the mechanism is clearly shown by the habitual attitude. The thighs are sharply flexed on the body, the dorsal surfaces of the hyperextended knees are in relation to the abdomen, while the feet may be brought into contact with the face or trunk according to the degree of deformity. The retarded development of the quadriceps extensor muscle explains the rudimentary patella which is often an accompaniment of the deformity.

Treatment.—The treatment of the hyperextended knee is very simple. It consists in massage of the atrophied and contracted muscle, combined with more or less forcible manipulation in the direction of flexion. If, as is often the case, the leg seems to be drawn forward by spasmodic muscular action, the methodical massage should be combined with the use of a simple posterior splint.

In the more extreme cases manual force may be applied under anæsthesia, and the deformity may be overcome at one or several sittings according to the resistance of the contracted parts. The leg is then fixed in a flexed position until the tendency to recurrence has been overcome. When the child begins to walk a light lateral brace may be necessary to insure perfect functional use of the joint, as in many instances laxity of ligaments and muscular weakness may persist for a time.

Rudimentary or Absent Patella.—As has been stated, a rudimentary patella is a frequent complication of genu recurvatum, or of any congenital defect or deformity of the knee or limb that involves imperfect development of the quadriceps extensor muscle. In many cases of this type it is impossible to distinguish the patella during the early months of infancy, but later a minute patella appears that slowly increases to an approximately normal size.

Absence of patella under the same conditions is less frequent, although Potel collected one hundred cases from literature.

Treatment.—The treatment of rudimentary patella is included in the massage and stimulation of the atrophied or rudimentary muscle with which it is usually associated, and the support that the weak or deformed knee may require.

Royal Whitman.

HIPPOCRATIC OATH.—The ancient Greek writings commonly called "The Works of Hippocrates of Cos" were judged even by ancient Greek critics to be really by various authors. The truth of this conclusion is plain to modern scholars. These writings have probably existed as in some sort a collection since the early days of the Alexandrine library near the beginning of the third century B.C.; and the composition of the several writings may safely be referred to the fifth or fourth century. Which of them are truly works of the famous physician whose name they bear is quite uncertain, as no direct contemporary testimony exists. Modern critics can only sift internal evidence, and compare the views of earlier critics, ancient, perhaps, but often naïve or biassed. Many writings in the collection, however, are plainly as old as Hippocrates, if not older. He was born in 460 B.C.; died, probably, in 377 B.C.; and was a worthy of the great period often styled that of Pericles. There is no proof, however, that Hippocrates was ever at Athens, though he was known there; and scarcely anything is known of his life with certainty.

One of the most famous writings of the Hippocratic collection is that entitled "The Oath." It is probably at least as ancient as Hippocrates, but that he composed it can neither be affirmed nor denied. Traces of its widespread influence occur in history; and by means of it modern physicians still hand down the traditions of their calling to those about to receive a medical degree. The ancient words do not accord with the changes wrought by twenty-two centuries in men, beliefs, and manners; but no modern words can be nobler, and the ancient thoughts are vital to the modern oath. The following translation of the Greek original into English is by the present writer:

THE OATH.

I swear by Apollo the Physician, and Æsculapius, and Hygeia, and Panacea, and all the gods and all the goddesses—and I make them my judges—that this mine oath and this my written engagement I will fulfil so far as power and discernment shall be mine.

Him who taught me this art I will esteem even as I do my parents; he shall partake of my livelihood, and, if in want, shall share my goods. I will regard his issue as my brothers, and will teach them this art without fee or written engagement if they shall wish to learn it.

I will give instruction by precept, by discourse, and in all other ways, to my own sons, to those of him who taught me, to disciples bound by written engagement and sworn according to medical law, and to no other person.

So far as power and discernment shall be mine, I will carry out regimen for the benefit of the sick, and will keep them from harm and wrong. To none will I give a deadly drug, even if solicited, nor offer counsel to such an end; likewise to no woman will I give a destructive suppository; but guiltless and hallowed will I keep my life and mine art. I will cut no one whatever for the stone, but will give way to those who work at this practice.

Into whatsoever houses I shall enter I will go for the benefit of the sick, holding aloof from all voluntary wrong and corruption, including venereal acts upon the bodies of females and males whether free or slaves. Whatsoever in my practice or not in my practice I shall see or hear, amid the lives of men, which ought not to be noised abroad—as to this I will keep silence, holding such things unfitting to be spoken.

And now if I shall fulfil this oath and break it not, may the fruits of life and of art be mine, may I be honored of all men for all time; the opposite, if I shall transgress and be forsworn.

The best Greek text (from which the foregoing translation was made) is that of E. Littré, "Œuvres complètes d'Hippocrate" etc., tome 4, Paris, 1844, pp. 628 to 632.

Many commentaries have been published upon the oath. Among these, special mention is deserved by Littré's Argument, *l. c.*, pp. 610 to 625; and by the notes of C. Daremberg, "Œuvres choisies d'Hippocrate," seconde édition, Paris, 1855, pp. 1 to 11.

The following matters require discussion, more or less brief:

Hygeia and Panacea were daughters of Æsculapius.

The distinction between "precept" and "discourse" (*παραγγελίης τε καὶ ἀκροήσιος*) has not been explained satisfactorily.

"Suppository" is perhaps as nearly equivalent as possible to the Greek word *πεσσός*, which doubtless means, in the oath, a sort of medicated pledget to be withdrawn after a longer or shorter time. Many formulæ for making such, for various purposes, are given in the Hippocratic collection.

The words "destructive suppository" (*πεσσὸν φθόριον*) refer to abortion. A parallel and fully developed phrase, viz., "a wine destructive to embryos" (*φθόριος ἐμβρύων* *οἶνος*) occurs in the Materia Medica of the later Greek physician Dioscorides, of the first century A.D. (Lib. v., cap. 77, ed. Sprengel, vol. i., p. 734). Although abortion is abjured without qualification in the oath, there were probably Greek practitioners of the time of Hippocrates who made a distinction similar to the modern one between justifiable and criminal abortion; for methods of emptying the uterus are frequently and quite simply referred to in the Hippocratic collection, though often expressly aimed at embryos styled "dead" or "livid" or "motionless" or "stricken" or "apoplectic."

But there is also good reason to believe that, in Hellas, the accepted line between guilt and innocence in the matter of abortion did not always coincide with that drawn nowadays. The clear recognition of the fact that the early embryo is from the instant of conception a human being, truly alive and possessing the right to live, even before the "quickening,"—this doctrine is entrenched in a maturer knowledge of physiology than the ancients could command. In the ideal State discussed in Plato's dialogue of "The Republic," certain embryos irregularly begotten were to be made away with before birth (ed. Stephanus, p. 461c). Plato was a younger contemporary of Hippocrates, and Plato's pupil, Aristotle, was born a few years before the death of the great physician, and was himself an Asclepiad, *i.e.*, a physician's son. Aristotle, in his "Politica," expressly recommends abortion in order to limit the number of children, but enjoins the procuring of it "before the advent of sensation and life." The presence of these he formally makes the criterion of "the hallowed" and the reverse in this matter (Politica, vii., cap. 16, ed. Ac. Boruss., p. 1335, b 19 to 26).

In the embryological treatise "On the Nature of the Child" in the Hippocratic collection, the author, who may not have been of Cos, but possibly an adherent of the rival school of Cnidos, describes a certain case as one of abortion at the sixth day deliberately procured by himself. The circumstances are given in detail, and plainly stamp the case as criminal according to modern ideas; but the author relates it without a trace of guilty consciousness, adhering, one may conjecture, to the doctrine of morals set forth by Aristotle (Hippocrates de Nat. Pueri, § 13, ed. Littré, vii., p. 488). The following striking passage both shows us "strict constructionists" of the Hippocratic oath nearly five hundred years after the death of Hippocrates, and sets forth explicitly, as current eighteen centuries ago, a view of the morals of abortion closely akin to that of modern physicians. The Greek gynæcologist Soranus of Ephesus was a practitioner at Rome under the emperors, not far from the time when Juvenal was scourging its vices with his satires in the earlier years of the second century A D. Referring to abortion, Soranus writes:

> There is a disagreement; for some reject destructive practices, calling to witness Hippocrates, who says, "I will give nothing whatever destructive," and deeming it the special province of Medicine to guard and preserve what Nature generates. Another party maintains the same view, but makes this distinction, viz.: that the fruit of conception is not to be destroyed at will because of adultery or of care for beauty, but is to be destroyed to avert danger impending at parturition, if the uterus be small and cannot subserve the perfecting of the fruit, or have hard swellings and cracks at its mouth, or if some similar condition prevail. This party says the same thing about preventing conception, and with it I agree. (Translated by the present writer from the Greek of Soranus, Gynæciorum Lib. i., cap. 19, ed. Rose, p. 229).

The abjuration of lithotomy in the oath contains the only mention thereof made in the Hippocratic collection. The ancient practitioners of medicine freely practised operative surgery; and no certain cause can be assigned for their refusal to cut for the stone. It has been shrewdly guessed, however, that the cause lay simply in the formidable dangers of a rude and uncertain procedure.

As the Hippocratic oath still plays a part in medicine worthy of its character and history, it has been thought proper to end this article with one of the modern adaptations. At the annual commencement of Columbia University in the City of New York, the following oath is administered to the graduating class of its College of Physicians and Surgeons:

Candidates for the Degree of Doctor of Medicine:

You do solemnly swear, each man by whatever he holds most sacred:

That you will be loyal to the Profession of Medicine and just and generous to its members;

That you will lead your lives and practise your art in uprightness and honor;

That into whatsoever house you shall enter, it shall be for the good of the sick to the utmost of your power, you holding yourselves far aloof from wrong, from corruption, from the tempting of others to vice;

That you will exercise your art solely for the cure of your patients, and will give no drug, perform no operation, for a criminal purpose, even if solicited; far less suggest it;

That whatsoever you shall see or hear of the lives of men which is not fitting to be spoken, you will keep inviolably secret.

These things do you swear? Let each man bow the head in sign of acquiescence.

And now, if you shall be true to this, your oath, may prosperity and good repute be ever yours; the opposite, if you shall prove yourselves forsworn.

In this oath, the words "that you will be loyal to the Profession of Medicine, and just and generous to its members," are from a formula at one time in use at the above-named medical school; for the rest of the foregoing adaptation the present writer is responsible.

John G. Curtis.

HIRUDINEA.—Among the Annelida or segmented worms the leeches form a well-marked order. The body of the leech is elongated, usually flattened dorso-ventrally, and provided with a prominent terminal or subanal sucker, while many forms possess also an anterior or oral sucker. The bristles all but universally present in annelids are here wanting save in a single genus, and the metamerism of the body presents a poorly marked external aspect although actually highly developed. The rings which appear in external view are mere surface markings, and are variably related to the true somites. Of the latter there are always thirty-four (thirty-five), of which those in the central portion of the body possess the typical number of annuli, while the first few and last few manifest ordinarily a reduction from that number. Prominent papillæ may usually be observed on the dorsal surface in the form of six or eight longitudinal rows; these are metameric sense organs known as sensillæ, and the eyes which vary in number in different forms are anterior units in certain of the rows. The annulus bearing the sensillæ is now generally regarded as the central one of the typical three- or five-ringed somites, and is the only one present in case of those somites manifesting the extreme of reduction. The leeches are hermaphroditic and the two sexual pores lie in the midventral line, the male in front of the female orifice.

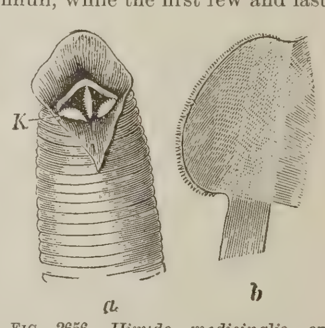

FIG. 2656.—*Hirudo medicinalis*, or European Leech. *a*, Ventral aspect of anterior end, showing an open mouth at the bottom of which the jaws, *K*, are visible; *b*, one of the jaws isolated, showing marginal denticles and muscles. (After Claus.)

The family of the Gnathobdellidæ, or Round-jawed Leeches, is characterized by three saw-toothed jaws in a simple pharynx (Fig. 2656); the typical somite has five annuli. Among the fresh-water leeches (Natantia), which have an eyeless ring between the third and fourth pairs of eyes, only the monostichodont forms (*i.e.*, those with a single row of teeth in each jaw) are important, and of these only two genera need be noticed here.

Hirudo L.—Either one hundred and one or one hundred and two rings with twenty-six metameres between the first pair of eyes and the sucker of which the first six and the last four are abbreviated. Buccal and post-buccal rings fused below; only three annuli in somite XXIII. Each jaw has from fifty to one hundred sharp-pointed teeth. Male genital pore between annuli 30 and 31, female between 35 and 36. First pair of nephridial pores ventral in ring 13, last in ring 93; seventeen in all.

Hirudo medicinalis L.—*Sanguisuga medicinalis* Savigny 1820, *S. officinalis* Savigny 1820, *H. officinalis* Derheims 1825. Length 100 to 200 mm.; breadth 10 to 30 mm. Jaws large, each with 80 to 90 teeth. Color variable, darker above than below, dirty yellowish-brown in tone with tendency to gray or green; at the margin a bright yellow or brown band with black margins; on the back three more or less prominent red longitudinal bands spotted with black (Fig. 2657).

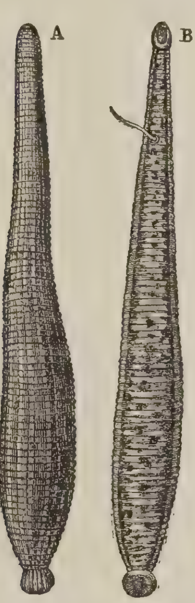

FIG. 2657.—*Hirudo medicinalis*, or European Leech. *A*, Dorsal aspect; *B*, ventral aspect. (After Railliet.)

This species is native in Europe, northern Africa and southwestern Asia, but at present is extinct in many regions and obtained by artificial culture or through importation only. Among the very numerous color varieties, as many as sixty-four being recorded by Diesing, two have been recognized as sub-species or varieties:

The Gray Leech, var. *medicinalis s. str.*, back greenish-gray with three russet-red lines on each side, of which the middle one, and often the inner also, shows a black spot on each metamere. Ventral surface greenish-yellow and spotted with black.

The Green Leech, var. *officinalis*, back darker green, often with black pigment more prominent, though red specimens also occur. Ventral surface almost entirely unspotted. A series of intermediate forms makes a distinction even between these two varieties difficult in many cases.

The leech sucks from four times its volume of blood for the young to three times in an adult, or from 6 to 15 gm. If, however, the sucking leech be cut in two by the shears close behind the pharynx, the blood streams out in pronounced pulsations and, as the sucking action is not interfered with, a stronger or rather longer-continued blood extraction is caused. During the ordinary operation of sucking a leech gives off a large quantity of clear fluid which exudes from the skin in drops. It is not blood serum, as often supposed, but the secretion of the nephridial canals. While this exudation ceases at the end of ten days, the assimilation of the stomach contents of the leech demands from twelve to eighteen months. At the end of two months, however, the animal manifests willingness to bite, but its full appetite is not yet restored. On the other hand, the leech can fast for two years or more and may be kept indefinitely without food in suitable leech jars. A fast of from six to eight months is necessary before re-employment; but the latter is not advisable. Before the third year of their growth leeches are not used for medicinal purposes, and from eighteen to twenty years has been put as the probable length of life. For the method of using leeches, see *Blood-letting*.

At one time the enormous demand for leeches reached, for example, 7,000,000 per year in London alone, but in recent years their use for therapeutic purposes has greatly diminished, no doubt largely as the result of occasional fatal cases and in spite of certain evident advantages for local affections. Fatal bleeding has been known where the bite opened a large vessel (*vena cruralis* or *jugularis*), or in internal organs where the leech, by careless application at the nasal fossæ, vagina, or rectum, has penetrated or been drawn too deeply into the organ. In order to guard against this leeches should be fastened in such cases by a thread passed through the middle of the posterior sucker. Several authors have investigated the reputed transmission of disease, particularly bacterial, by leeches, but uniformly with negative results. So far as bacteria are concerned, the species studied were rapidly digested in the stomach of the leech, and the entrance into the wound of such as may be upon the lips at the start appears difficult under the circumstances of the blood flow.

Where native, these, like other large leeches, attack men and animals invading swamps and pools, and in recorded instances with fatal results to children or young animals.

Hirudo troctina Johnson 1816, often confused with the medicinal leech, is distinguishable by its smaller size, 80 to 100 mm. in length by 12 to 18 mm. in breadth, and especially by the scantier number of teeth, about seventy, in each jaw. It is native in northern Africa and Spain, perhaps also Italy and Sicily, and is exported in large numbers to France, England, and America. In power to extract blood it is much inferior to *H. medicinalis*.

Hirudo nipponica Whitman 1886, also smaller in size than *H. medicinalis*, is common about Tokyo, Japan, and in other parts of the island. Its habits and use conform closely to those of the continental species. Other species of similar habit are reported from different regions of the Orient; they are, however, only poorly known.

The genus *Limnatis* may be distinguished from *Hirudo* by the papillæ on the jaws and by the ventral furrow traversing the entire length of the anterior lip of the oral sucker. One species, *Limnatis nilotica* Sav., demands brief notice. It is native in the circummediterranean region, and in some places is so abundant as to become a veritable pest. Especially the young, described by Moquin-Tandon as *Sanguisuga ægyptiaca*, are often swallowed accidentally in drinking and may remain for a long time fixed in pharynx, choanæ, œsophagus, trachea, or even stomach. The species plays accordingly an important rôle in diseases of man and domestic animals in northern Africa during the hot season. European soldiers in garrison, and even natives, in spite of their precautions, suffer from the leech, which evokes by its presence both local and general symptoms of serious character if assistance is not speedily afforded. With the removal of the worms rapid and complete healing of the wounds and disappearance of secondary symptoms occur almost immediately and without exception. The removal may be accomplished by instruments from those organs where the leech can be seen; in deeper locations copious application of salt water is said to be efficacious. This leech can pierce only the mucous membranes of higher animals, and its inability to penetrate the external skin, even of children, has often been demonstrated. Other species of this genus have a more powerful bite, and are used especially in the East for medicinal purposes, even though they take up less than half as much blood as *Hirudo medicinalis*. In this country *Macrobdella decora*, one of the large native leeches, is employed in some places for blood-letting; it may be recognized by the following description:

Macrobdella Verrill 1872. Cephalic lobe smaller than in *Hirudo*. Annuli 103; at least four in somite XXIII.

Neither buccal nor post-buccal annuli united on the ventral side. Both genital orifices in somite XI., and behind them a group of prominent copulatory glands.

Macrobdella decora Verrill.—*Hirudo decora* Say 1824, *H. decora* Leidy 1868. Jaws with about sixty-five teeth, copulatory glands opening by four pores in a quadrate figure on the last annulus of XIII. and the first two of XIV. The first annulus of XXVI. is divided marginally and sometimes also dorsally into two annuli.

This species is widely diffused in fresh waters of the United States, having been reported from Maine to Minnesota and from Pennsylvania to Kansas. It is frequently used instead of imported leeches by physicians and is said to be equally efficacious, although its capacity is somewhat smaller, only about 5 gm. It is so powerful, however, that serious results have followed its attacks upon the legs of children wading in its haunts.

Among the land leeches which form a special section, Reptantia, of this family, and are distinguished by the absence of an eyeless ring between the third and fourth pair of eyes, a few forms deserve brief mention.

Hæmadipsa Tennent. Body almost round, sucker separated only by a slight constriction. Near the sucker auriculæ with the pores of the last pairs of nephridia. Typical metamere with five annuli.

Hæmadipsa zeylanica Moq.-Tand.—*H. japonica* Whitman. Length 20 mm., or in extended form 60 mm., diameter of body behind 6 mm., in front 2 mm.; sucker 5 to 7 mm. in diameter. Annuli ninety-seven; male genital pore between annuli 30 and 31, female between 35 and 36. In each jaw ninety incurved teeth.

The animal, when gorged, has the form of a flask of about 10 mm. in diameter at its largest part, while the neck measures only 2 or 3 mm. in thickness. The color is exceedingly variable, and yet five or six varieties may be recognized, one of which, var. *japonica* Whitman, known in Japan as the mountain leech, is common in the entire Indomalayan region, China, and Japan. It has long been known on the island of Ceylon, where it forms a veritable pest to natives and Europeans alike. The leeches appear in immense swarms, particularly in moist regions and during the rainy season, and at all levels from the coast up to 4,000 feet, although they occur even as high as 15,000 feet in the Himalayas. During the dry season they hibernate in the earth; at other times they live in moss among stones and on shrubs and trees. The approach of large animals brings them out in myriads; they move with surprising activity, and springing on the unfortunate passer-by they suck often for hours before falling off. No clothing is close enough to protect man from their attacks, and during army manœuvres they have inflicted large losses on European troops, attacking the soldiers even when asleep. Accounts of travel in Ceylon abound in narratives of the ferocity of these pests, and recent writers from the Philippines comment on their activity in that country in equally forcible terms. It is probably this species, and very likely the variety *japonica*, which is reported by Blanchard as abundant in the Philippines, to which the trouble is due, although other species of *Hæmadipsa* manifest, no doubt, similar habits of life.

The bite is not poisonous, as often maintained, but the large number of wounds and careless treatment afford abundant opportunity for secondary infection of a serious character. Among the natives of Ceylon one may see many deformities induced by these leeches, which are accordingly feared more than serpents and carnivores.

An allied form, *Phytobdella Meyeri* R. Bl., is also recorded from Luzon.

The family of the Rhynchobdellidæ, or proboscis leeches, is characterized by a protrusible pharynx, while the typical metamere consists of three annuli and jaws are lacking. Few of these forms are able to penetrate the human skin, but among those of sufficient power are especially American forms, which appear as occasional parasites of man and in some regions are used for therapeutic purposes. The two species of importance are both members of the following genus, which is restricted to the warmer regions of the American continent:

Liostoma Wagler 1831—*Hæmenteria* de Fil. 1849. Body broad and flattened; back covered with many prominent papillæ; the first and third ring of each somite from VI. to XXII. inclusive split on the ventral surface so that on the ventral surface the space occupied by five pseudo-annuli corresponds to that occupied by the three adjoining dorsal annuli. Male genital pore between annuli 26 and 27, female between 28 and 29. Two pairs of eyes so closely set that they appear as a single pair.

Liostoma Ghilianii R. Bl.—*Hæmenteria Ghilianii* de Fil. 1849. Length of alcoholic specimen 190 mm., breadth 100 mm., corresponding to a probable length while living of 350 to 400 mm. Annuli seventy, together with three preocular; the first seven annuli form the oral sucker.

This giant form inhabits the basin of the Amazon and the swampy regions of Guiana. Blanchard reports that it attacks horses and cattle, and a few individuals are sufficient to kill even a full-grown animal.

Liostoma coccineum Wagler 1831—*Hæmenteria officinalis* de Fil. 1849, *H. mexicana* de Fil. 1849, *Glossiphonia granulosa* Jimenez 1865. Length 80 mm., breadth 22 mm. Annuli seventy, with two preocular; the first six annuli form the oral sucker (Fig. 2658).

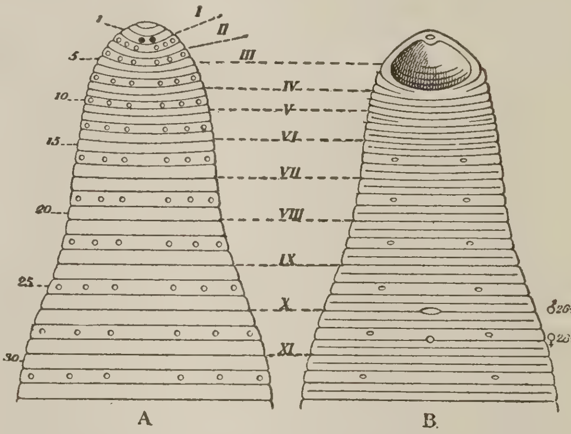

FIG. 2658.—*Liostoma coccineum*, or Mexican Leech. Diagrammatic view of anterior somites, *A*, from dorsal surface with eyes and sensillæ, *B*, from ventral with nephridial and sexual pores. (Modified from Blanchard.)

The range of this species extends from Mexico to Paraguay through Central and South America. In Mexico it is universally used as the medicinal leech. In some instances, however, its bite appears to be accompanied by serious results. There are noted almost immediately a feeling of general lassitude and an unpleasant itching and twitching, succeeded soon by general urticaria, and in a short time apoplectic symptoms are manifested; but cases occur in which the cerebral congestion or the urticaria is wanting. Most authors incline now to the belief that these symptoms are due to the salivary secretion poured into the bite by the leech, and yet it seems also clear that some predisposition on the part of the individual is also a prerequisite. Brandes suggests that the symptoms of poisoning are manifested only in persons exhibiting hyperæsthesia, and attributes the rare cases of serious illness following the application of *Hirudo medicinalis* in Europe to the same sensitive constitution. (Compare in this connection the effects produced by the bite of *Argas*, as reported by Brandes and noted in the article *Arachnida*, Vol. I., p. 437.)

In spite of these accidents this is actually the only species used for medicinal purposes in Mexico, sufficient evidence of its generally satisfactory character. In some provinces (Guadalajara) the leech is regularly cut in two after it has taken hold in order to measure definitely the quantity of blood extracted. *Henry B. Ward.*

HISTOLOGICAL TECHNIQUE.—METHODS OF STUDYING LIVING AND FRESH TISSUE.—For observations on living tissue, we now make use of the cold-blooded animals almost exclusively; and, on account of the convenience, use the tails of amphibian larvæ, and small fishes and frogs. For holding these small animals, while under observation, the larva holder of Schulzer (Fig. 2659) will be found very convenient. The head of the animal is placed under the edge, *a*, the tail is spread out on the bevelled plate, *b*, and covered with a cover-glass. The cell holds sufficient water to cover the animal. To keep the animal quiet, we wrap it loosely in a piece of cloth, leaving the gills free, or add a few drops of ether to the water. If the observations are to be continued for any length of time, provision must be made for the renewal of the water. This can be accomplished by any of the usual methods of irrigation.

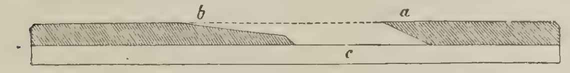

FIG. 2659.—Schulzer's Larva Holder.

For observations on the frog, it is necessary to paralyze the animal with curare. A slight nick is made in the skin over the posterior part of the head, and two or three drops of a one-twentieth-per-cent. solution of curare* is injected into the dorsal lymph sac by means of a long, slender pipette introduced through the above nick. The exact amount of curare to be used will depend upon its quality and the size of the animal, and can be determined only by experiment. In the course of a few hours the animal will become completely paralyzed, while the vegetative functions continue, the necessary amount of oxygen being supplied by cutaneous respiration.

We utilize for these observations:

1. *The Web.*—The advantage of this part of the animal is that we do not inflict any injury, consequently we are not likely to meet with any disturbances of the vital processes; but, on account of it not being very transparent, it is inferior to other parts. A frog poor in pigment should be selected, and after being wrapped in a moist cloth it is laid on an oblong sheet of cork, in one end of which a hole, at least 15 mm. in diameter, is made; at the edges of this hole four or five pins are stuck, to which bits of soft string attached to the toes are tied, spreading the web out over the hole. The cork is now placed on the stage of the microscope, and the web is moistened at intervals to prevent its drying.

2. *The Tongue.*—For observations on this and other organs of the animal, Professor Thoma has invented a series of frog plates, which are shown in Fig. 2660. The one in the centre of the figure is for the tongue; that on the left for the mesentery; that on the right for the lung and bladder. These plates consist of a bed plate, *a*, of brass, covered by a thin sheet of hard rubber. At *B* is an opening, which varies in the different plates, covered with a thick glass plate on which the organ to be examined is placed. At some distance from this glass plate runs the brass rim, *c*, *c*, *c*, 7 mm. high, which by a proper inclination conveys the irrigating fluid, as it flows off the organ, to the tubes, *d*, *d*, to which are attached rubber tubes leading to a vessel for receiving the waste fluid. The supports, *t*, are for holding the irrigating cannula, *g*. They are pivoted to the plate, and move on a perpendicular axis; to the upper end is attached a short split tube, which is tightened by a small screw; this is connected with the support by a hinged joint, allowing it to be moved on a horizontal axis. In this tube is placed the glass irrigation cannula, *g*. It will be noticed that in the tongue and mesentery plates two supports are provided. This is to allow of the use of two cannulæ, one for irrigating the upper, and the other the under, surface of the organ. At *e* is a perpendicular rod for supporting the ring holding the cover-glass. At each side of the plates (in the tongue plate it is at the end) is a notched support, *k*, for holding the rubber tube attached to the cannulæ introduced into the different organs for inflation, etc. Between the rim, *c*, *c*, *c*, and the plate, *B*, bits of cork are wedged for pinning out the organs.

For examining the tongue, the animal is placed on the plate belly down, and the nose is brought close to the edge of the glass plate; the tongue is drawn out over the plate, and fastened to the bits of cork by pins which are cut off short.

3. *The Mesentery.*—Male frogs are to be used, so that the examiner may not be embarrassed with the ovaries. An incision is made through the skin, on the side, from the pelvis nearly to the axilla. After all hemorrhage has ceased, the abdominal cavity is opened by an incision of 10 to 20 mm. in length; a coil of intestine is drawn out carefully over the glass plate so that it will fall upon the bits of cork, to which it is pinned, leaving the mesentery spread out in a thin layer on the glass plate.

4. *The Bladder.*—A glass cannula (*B*, Fig. 2661) is filled with a three-fourths-per-cent. salt solution, and the rubber tube closed with a bit of glass rod. The cannula is now inserted into the cloaca, and directed forward into the bladder; it is held in place by a thread passed through the skin over the sacrum and tied around the cannula. An incision, similar to the one for the mesentery, is made in the side of the animal. The glass rod is removed from the rubber tube, and the latter is raised slightly so

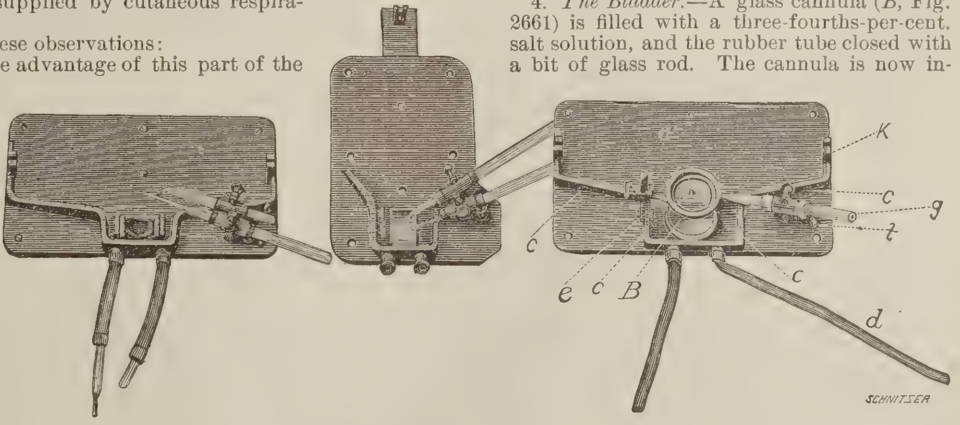

FIG. 2660.—Thoma's Frog Plates.

---

* S. H. Gage recommends the following solution: Curare, 0.2 gm.; ninety-five-per-cent. alcohol, 20 c.c.; water, 20 c.c. Grind up the curare in a mortar with the water and alcohol. Do not filter.

as to cause the fluid to flow into the bladder, distending it. The animal is now placed on the frog plate, and by gentle manipulation with the handle of a scalpel the distended organ is brought upon the glass plate and further distended if necessary; the glass rod is now replaced in the rubber tube, and the latter fixed in the support (*k*, Fig. 2660). The animal is covered with a bit of moistened filter paper, and the frog plate is placed on the microscope.

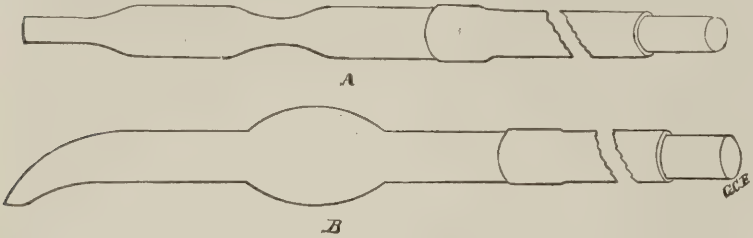

FIG. 2661.—Inflation Cannulæ.

5. *The Lung.*—The cannula (*A*, Fig. 2661) is introduced through the epiglottis, and held in place by a thread passed through the nose and tied around the constriction of the cannula. An incision, carried well into the axilla, is made through the skin on the side of the animal, and when all hemorrhage has ceased the thoracic cavity is opened. The operator should now remove the bit of glass rod from the end of the rubber tube attached to the cannula, and gently blow into the same, when the distended lung will be forced through the incision. The animal is placed on the frog plate, and the distended lung brought upon the plate *B*. In Fig. 2662 is shown the arrangement of the frog plate on the microscope, and the irrigating bottle. The stage of the microscope is to be inclined so as to cause the irrigating fluid to flow away. The bottle attached to the ring stand, filled with a three-fourths-per-cent. salt solution, is closed tightly with a rubber cork, through which pass two glass tubes. To one is attached a rubber tube, which is connected with the glass cannula (*g*, Fig. 2660) and conveys the irrigating fluid. The other is for regulating the pressure, which can be varied by raising or lowering the tube. The flow from the end of the irrigating cannula should be by drops, at short intervals, and is regulated by the pressure in the bottle, the size of the opening in the point of the cannula, and, if necessary, by a spring clip placed on the rubber supply-tube.

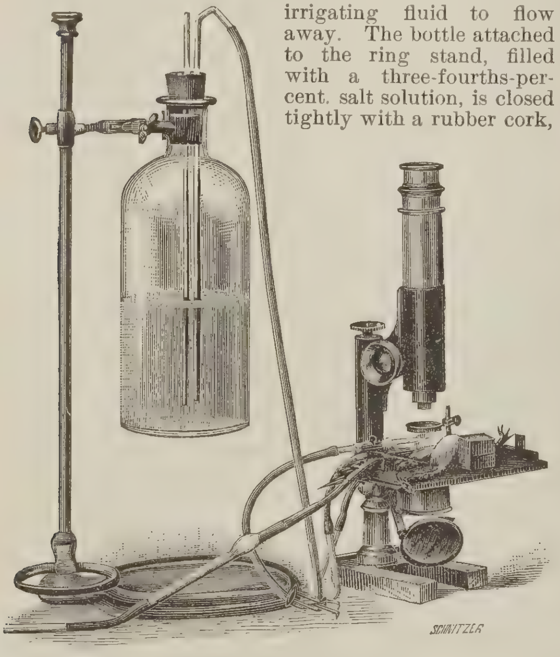

FIG. 2662.—Frog Plate and Irrigating Apparatus.

Fresh tissues are to be examined in the fluid that bathes them during life, or in a fluid that will change them but little if at all. Such fluids are known as indifferent fluids, and resemble in composition the natural fluids of the body. They are as follows:

Aqueous Humor of the Eye.—Obtained by puncturing the cornea of a recently killed animal, and allowing the aqueous humor to escape.

Blood Serum.—The blood of a recently killed animal is poured into a tall glass cylinder and allowed to coagulate. After coagulation has taken place, the upper margin of the clot is separated from the sides of the vessel, to permit it to sink; the vessel is allowed to stand for twenty-four hours, and the clear serum is then drawn off with a siphon, care being taken not to disturb the clot.

Iodized Serum.—Prepared by adding to every 1,000 c.c. of blood serum, obtained as above, 10 c.c. of tincture of iodine. This fluid alters the tissues slightly and stains them yellow. Instead of blood serum, amniotic or pericardial fluid may be used, but it must be absolutely fresh.

Artificial Serum.—This is to be used only when the natural serous fluids cannot be obtained. It is prepared by dissolving 2 gm. of sodium chloride and 28 gm. of egg albumen in 250 c.c. of distilled water, and adding 2.3 c.c. of tincture of iodine; the solution is then filtered.

Salt Solution (three-fourths per cent.).—Made by dissolving 7.5 gm. of perfectly dry, chemically pure sodium chloride in 1,000 c.c. of distilled water. This solution alters fresh tissues but slightly.

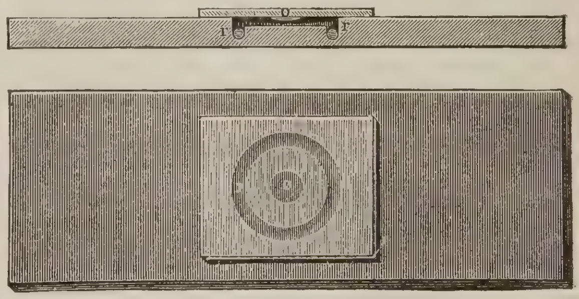

FIG. 2663.—Moist Chamber.

Fresh, thin membranes can be examined in one of the above solutions without any previous preparation. Bits of organs, fibres, etc., are to be teased on a slide, in a drop of one of the indifferent solutions, or sections can be made by the freezing microtome.

In observations on fresh tissue it is necessary to prevent evaporation, and in most cases pressure. The first can be prevented by painting a ring around the cover with oil or vaseline; the latter by placing a hair between the cover and slide; or we may use the moist chamber.

In Fig. 2663 is shown a moist chamber. In the centre of a thick glass slide is cut a cavity, around the circumference of which is a groove (*rr*). The latter is filled with water; the specimen is placed on the cover-glass (*o*), or in the middle of the cavity.

METHODS OF APPLYING REAGENTS.—*Application of Fluids, Irrigation.*—A drop of the reagent is placed on the slide in contact with the edge of the cover-glass, and on the opposite side of the cover a bit of filter paper. The latter sucks out the fluid, which is replaced by the reagent flowing in on the other side. This process of irrigation can be continued for any length of time, if the reagent be renewed as it becomes exhausted, and the filter paper as it becomes saturated.

Application of Vapors and Gases.—A simple way of applying a volatile reagent to a specimen is to put a drop of such reagent in a cell on a slide, and invert a cover-glass, on which the specimen has been placed, over it. For gases it is necessary to use a gas chamber. Such a piece of apparatus is shown in Fig. 2664.

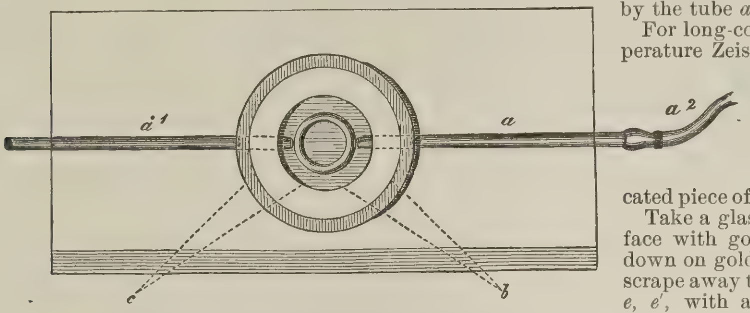

FIG. 2664.—Stricker's Gas Chamber.

It consists of a thick glass slide, in the upper surface of which is ground out a circular cavity. Two glass tubes are cemented into the two half-canals. The tube a is connected by an india-rubber tube, a^2, with the gas generator, and conducts the gas to the chamber; the other, a^1, serves for its exit.

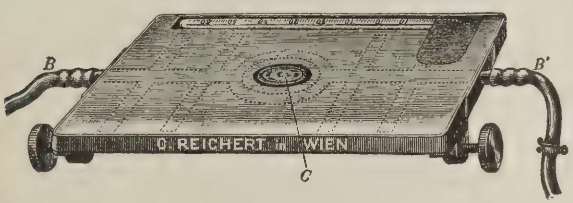

FIG. 2665.—Warm Stage.

Application of Heat.—Fig. 2665 shows the latest form of warm, stage in which hot water, used for heating, or which, by the use of ice water, may also be converted into a refrigerating slide. The central opening C (Fig. 2665) permits the passage of light. At each end of the slide a small tube, B, B', is inserted, by means of which it is connected with a vessel of water.

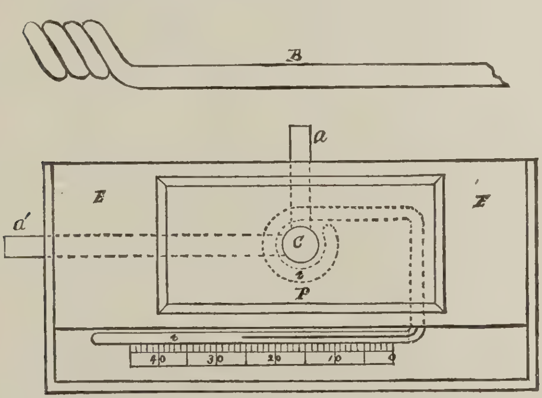

FIG. 2266.—Stricker's Warm Stage and Gas Chamber.

In Fig. 2666 is shown a combined warm stage and gas chamber. It consists of a rectangular piece of ebonite, E, E, fixed to a brass plate that rests on the stage of the microscope. On the upper surface of the ebonite is a brass plate, P, with an opening in the centre, C, leading into a brass tube, closed below by a piece of glass. For heating, the copper wire is placed on the tube a, the temperature of the plate being indicated by the thermometer t. The gas is conducted into the chamber by the tube a', while a serves as an exit.

For long-continued observations at an elevated temperature Zeiss' warm chamber (Fig. 2667) for enclosing the microscope should be employed.

Application of Electricity.—For the application of the electric current to specimens, the slide shown in Fig. 2668 will answer as well as a more complicated piece of apparatus. This can be made as follows:

Take a glass slide 27 × 127 mm., and cover the surface with gold size; press the moist surface firmly down on gold-leaf or tinfoil; allow it to dry, and then scrape away the metal so as to leave the two triangles e, e', with an interval, a, between their apices, of about 5 mm. for the object. The specimen is placed at a, and covered with a cover-glass. For transmitting the current the ends of the slide are clamped by the clips c, c', to which the wires leading from the battery are attached.

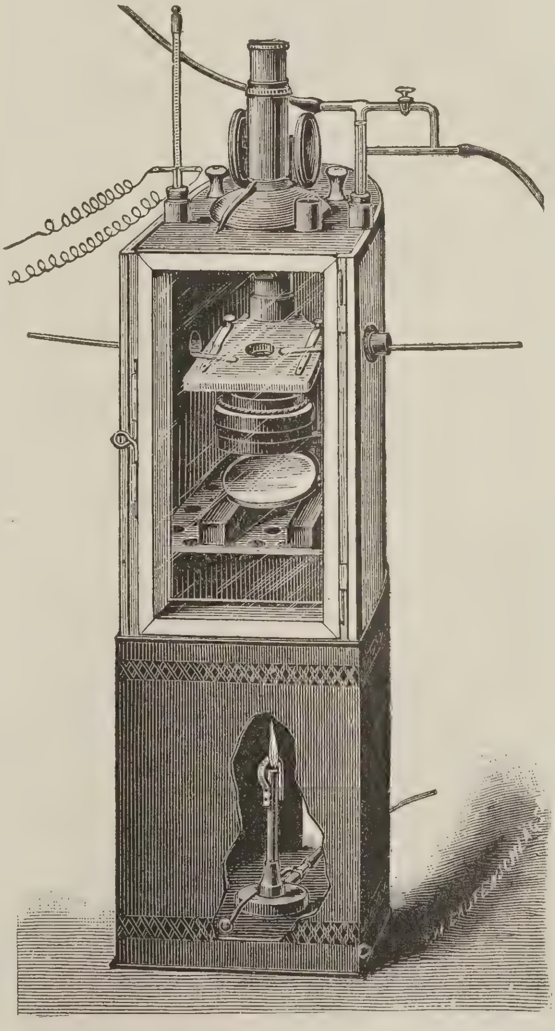

FIG. 2667.—Zeiss' Warm Chamber.

In Fig. 2669 is represented a combined moist chamber and electric slide. The slide, *s*, is covered with tinfoil, *f*, on its upper and lower surfaces, the foil on the upper surface being carried to the upper edge of the glass cell, *c*, which is cemented to the slide. The slide is placed on the copper supports, *k*, *k*, that are attached to the stage, *p*, if it be a glass one; if not, they must be insulated by strips of hard rubber. Two small strips of foil are cemented to the cover-glass, leaving a space of 5 mm. between the ends. The bottom of the cell is filled with a few drops of water; the specimen is placed on the cover-glass, in contact with the tinfoil, and the cover is inverted and placed on the cell, *c*, so that the foil comes in contact with that covering the cell. The electric current is conducted to the specimen through the metal supports by wires placed in the holes in their ends.

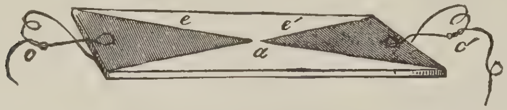

FIG. 2668.—Gold-leaf Electrodes.

METHODS OF FIXING, HARDENING, AND PRESERVING.—By the term "fixing" is meant the rapid killing of the tissue elements, so that they are preserved in nearly the same condition, as regards form and structure, that they had during life. The process of fixing also partially hardens the tissue, so that it is not injured by the subsequent manipulations.

The process of fixing produces optical differentiation in the tissues causing alterations in their indices of refraction. The index is raised in varying degrees, some elements being more affected than others, thus producing optical differences that were not present in the living tissue.

The fixation causes a coagulation of certain tissue elements rendering them insoluble, the fixing agent entering into chemical combination with them. At times these chemical compounds are soluble and are removed in the process of washing. Some of the insoluble compounds form mordants to certain stains, giving differential stainings. Some of the chemicals used for fixing prevent the subsequent staining of the tissue unless they are removed by special treatment. This is especially so when osmic or chromic acid is used.

A perfect fixing reagent should meet the following requirements: It should penetrate rapidly; it should kill quickly, without having an injurious action on the tissue; it should not dehydrate, as the withdrawal of water causes shrinkage; it should not interfere with the subsequent staining.

Of the numerous reagents used for this purpose, there is not one that meets all of the above requirements. Some cause shrinking, others more or less swelling, while others fix nuclear structures well but not cytoplasm, or *vice versa*. By combinations of several fixing agents, the faults of one may be counterbalanced by those of another.

The following rules should be observed in the use of fixing solutions: The size of the specimen should be *small*, averaging about 0.5 c.c. in bulk, and the quantity of fluids should be *large*, as much as a hundred times the bulk of the specimen.

The specimen should be removed from the fixing fluid as soon as it has been thoroughly penetrated by the latter. This depends upon the fixing agent used, and on the size and density of the specimen. Usually from twelve to twenty-four hours is a sufficient time for proper fixation.

In some instances it is desirable to fix an entire organ. In such cases the fixing fluid is injected through the artery and allowed to flow from the vein for from one to two hours, after which the entire organ is immersed in a large quantity of the fixing fluid.

After the specimen has been fixed it is to be washed in running water until all of its fixing agent has been removed. The specimen is then further hardened in graded alcohols.

Hardening.—After the fixative has been thoroughly removed from the specimens they are then hardened by passing them through graded alcohols, beginning with sixty per cent. and increasing the strength by about ten per cent. at the end of each twelve hours until strong alcohol, ninety-five per cent., is reached.

Absolute alcohol as found in commerce varies from 98 to 99.5 per cent.; it is very expensive, and it is almost impossible to keep it up to the proper strength after it has been exposed to the air. An alcohol that will meet all the requirements of absolute alcohol may be prepared after the plan of Ranvier: Cupric sulphate is pulverized and heated at a temperature of 100° C. until all the water of crystallization is driven off, and a white powder is the result. A glass-stoppered bottle is filled about one-third full with this powder, anhydrous cupric sulphate, and ordinary alcohol is added. After standing for twenty-four hours, the surface of the copper will have become decidedly blue, from the absorption of the water from the alcohol. A test made at this time will show the alcohol to be over ninety-nine per cent. Fresh alcohol is added, from time to time, until all of the copper has become blue in color, when it is no longer of any use for dehydration. The supernatant alcohol is now poured off, and the bottle placed in a hot-air sterilizer at a temperature of 100° C. until the cupric sulphate is again rendered anhydrous.

Commercial alcohol usually tests about ninety-five per cent. and is known as strong alcohol. The graded alcohols used in hardening are prepared by diluting this strong alcohol with water. The amount of water to be added to each one hundred volumes of ninety-five-per-cent. alcohol is as follows: For making 60-per-cent., add 41.5 volumes of water; 70-per-cent., 21 volumes of water; 80-per-cent., 6.5 volumes of water; 90-per-cent., 5.5 volumes of water.

All fixing agents if allowed to act long enough will harden the tissues, but as a general rule their prolonged action renders the tissues brittle.

Preservation.—For preserving the tissues after hardening, eighty-per-cent. alcohol is to be used, as prolonged immersion in strong alcohol interferes with the subsequent staining of the specimens.

Osmic Acid is a very volatile substance, its vapor being extremely irritating to the conjunctiva and nostrils. It is found in commerce in glass tubes, each containing 1 gm. or 0.5 gm. of the crystals. It is used in aqueous solutions of the strength of 0.1 to 2.0 per cent., or in combination with other acids in the proportion of 1 to 10,000.

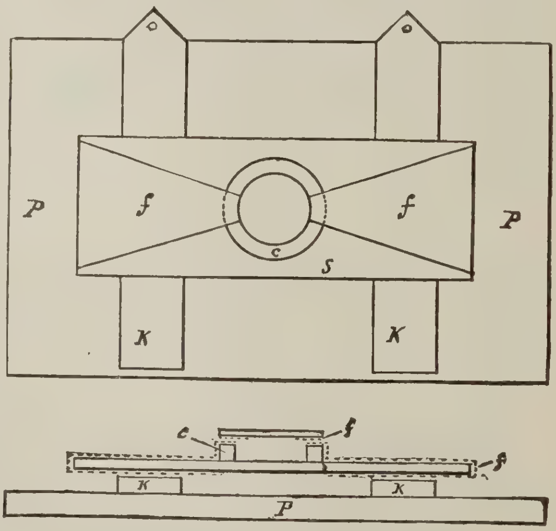

FIG. 2669.—Electric Slide and Moist Chamber.

For making a solution, a bottle is thoroughly washed with sulphuric acid, then with distilled water, that all traces of organic matter may be removed; then the label is removed from the tube, and the tube is washed in sulphuric acid and distilled water; the tube, its two extremities being broken off, is now put into the bottle, and the proper amount of distilled water is added to make a solution of the required percentage. The solution is to be kept in a well-stoppered bottle protected from the light. According to Cori this solution will keep perfectly, if enough potassium permanganate be added to give the fluid a slight rosy tint. As the fluid becomes colorless small quantities of the permanganate should be added to restore the tint.

Solutions that have deteriorated by the reduction of the osmic acid may be restored by the addition of a few drops of hydrogen peroxide.

Osmic acid is more valuable as a fixing than as a hardening agent. It fixes cytoplasm perfectly, nuclei badly. Its penetrating power is but slight, so that exceedingly small pieces of tissue must be used, and even then its action will be confined chiefly to the superficial parts. The vapor of osmic acid has a much greater penetrating power.

Tissues to be submitted to the action of the vapor are pinned out on a cork, fitted to a wide-mouthed bottle, in which there are a few cubic centimetres of a one-per-cent. solution of the acid, and allowed to remain until they become of a brownish color. After fixing, the excess of the osmic acid must be thoroughly removed by washing in running water. Any acid remaining will cause an over-blackening and it will also interfere with the subsequent staining.

Any over-blackening is best removed by immersing the tissue in a mixture of one part of hydrogen peroxide and twenty-five parts of seventy-per-cent. alcohol (Overton).

Osmic acid stains fatty matter black and is used as a stain for fat.

For increasing the penetrating power of osmic acid, Kolossow uses a one-half-per-cent. solution in a two- or three-per-cent. aqueous solution of uranium nitrate. Lately he has recommended the following mixture: Absolute alcohol, 50 c.c.; distilled water, 50 c.c.; hydric nitrate, 2 c.c.; osmic acid 1 to 2 gm. This mixture, he states, keeps well.

Chromic Acid.—Chromic acid is an exceedingly deliquescent salt, and in the presence of organic matter is readily reduced to the sesquioxide. It should be kept in ten-per-cent. aqueous solution, which may be readily diluted to the required strength for use.

It is used in aqueous solutions of one-tenth to one per cent. as a fixing agent, and allowed to act for a few hours only. For fixing nerve tissue, solutions of one-fiftieth to one-eighth per cent. are used. The pieces of tissue should be small, and after removal from the fluid should be well washed in water and preserved in eighty-per-cent. alcohol.

Mayer rinses the fixed material in water and then places it in seventy-per-cent. alcohol in the dark; the alcohol is changed daily until it ceases to become colored by the chromic acid; then the tissue is hardened in strong alcohol. Any chrome compound that may be present in the sections is removed by soaking the sections in 100 c.c. of seventy-per-cent. alcohol, to which is added four to six drops of hydric chloride. After being in this mixture for a short time the sections become perfectly white and stain well with the usual stains.

As a hardening agent, chromic acid is used in aqueous solutions of one-sixth to one-half per cent. It is very slow in its action, taking weeks, and even months if the specimen is large. As a rule, the pieces of tissue must be small, 2 to 3 cm. on a side, and the quantity of fluid large, 200 c.c. for each cubic centimetre of tissue. The fluid must be renewed at the end of the first, third, and fifth days. After the hardening is completed the specimen is placed in water for a day or two, to remove all traces of the acid, and then preserved in alcohol. After partial hardening in chromic acid, the action can be completed in alcohol, care being taken thoroughly to wash out the former before placing the specimen in the latter. Two or three weeks' immersion in the acid will be sufficient if the hardening is to be completed in alcohol.

The action of chromic acid seems to be analogous to that of tanning. The acid enters into combination with the tissues, rendering them tough like leather. A prolonged action of the acid will render them brittle.

Chromic acid has the property of softening bone, and is often used as a decalcifying agent. The acid is an excellent hardening agent for the central nervous system, nerve tissue, glandular tissue, and epithelium.

Chromic Acid and Alcohol.—Klein used a mixture of two parts of a one-sixth-per-cent. solution of chromic acid and one part of alcohol for his investigations on cells, and claims that it gave better results than the ordinary reagents, even osmic acid.

Urban Pritchard uses the following mixture: Chromic acid 1 gm., water 20 c.c., alcohol 180 c.c. The chromic acid is dissolved in the water and added to the alcohol. This was used for hardening the cochlea.

Chromic and Picric Acids.—A mixture of ten parts of a saturated solution of picric acid, twenty-five parts of a one-per-cent. solution of chromic acid, and sixty-five parts of water makes an excellent hardening fluid. Its action is slow.

Chromic Acid and Platinic Chloride (*Merkel's Fluid*).—This is recommended by its originator as an excellent fixing agent, especially for the retina. The formula is: Platinic chloride, 1 gm.; chromic acid, 1 gm.; water, 800 c.c. The specimen is to be kept in this fluid for from two to three hours, then preserved in alcohol. Eisig allows specimens to remain three or four hours in this fluid, and then preserves them in seventy-per-cent. alcohol. Specimens so treated stain well with almost any stain.

Chromic and Osmic Acids.—Flesch recommends the following mixture: One-per-cent. solution of osmic acid 10 parts; one-per-cent. solution of chromic acid, 25 parts; water, 65 parts. Specimens remain in this mixture for from twenty-four to thirty-six hours. The hardening is completed in alcohol and the specimen is preserved in the same.

Chromic and Acetic Acids.—One-per-cent. solution of chromic acid, 20 to 25 c.c.; one-per-cent. solution of hydric acetate, 10 c.c.; water, 70 c.c. This solution is recommended by Flemming when the after-staining of the specimen is to be effected with hæmatoxylin. These preparations do not stain well with aniline dyes.

Chromic and Formic Acids.—Ralb adds from four to five drops of formic acid to 200 c.c. of a 0.33-per-cent. solution of chromic acid. This mixture must be prepared fresh at the time of using. Small pieces of tissue are fixed for twenty-four hours and then washed in water.

Flemming's Fluid.—First Formula: Chromic acid, 0.25 gm.; osmic acid, 0.1 gm.; hydric acetate, 0.1 c.c.; water, 100 c.c. Second Formula: Chromic acid, one-per-cent. aqueous solution, 15 parts; osmic acid, two-per-cent. solution, 4 parts; hydric acetate, 1 part.

Small pieces of tissue are fixed in this fluid for from twelve to twenty-four hours, then well washed in running water and hardened in graded alcohols. These fluids were used by Flemming in his investigations on cell division. They fix the nuclear structures perfectly, but the cytoplasm not so well.

Fol's Modification.—Osmic acid, one-per-cent. solution, 2 parts; chromic acid, one per cent. solution, 25 parts; hydric acetate, two-per-cent. solution, 8 parts; distilled water, 68 parts.

Carnoy's Modification.—Osmic acid, two-per-cent. solution, 16 parts; chromic acid, two-per-cent. solution, 45 parts; hydric acetate, 3 parts.

Hermann's Modification.—Chromic acid, one-per-cent. solution, 12 to 15 c.c.; hydric acetate, 1 to 2 drops; osmic acid, 0.25-per-cent. solution, 8 to 10 drops.

Vanlair's Modifications.—I. Osmic acid, one-half-per-cent. solution, 40 parts; chromic acid, one-half-per-cent.

solution, 140 parts; hydric acetate, 10 parts. II. Osmic acid, one-half-per-cent. solution, 10 parts; potassium dichromate, one-half-per-cent. solution, 10 parts; hydric acetate, 2 parts.

Hermann's Fluid.—This is a modified Flemming's fluid in which platinic chloride is substituted for the chromic acid; its composition is as follows: Platinic chloride, one-per-cent. aqueous solution, 15 parts; osmic acid, two-per-cent. solution, 2 parts; hydric acetate, 1 part.

Potassium Dichromate.—The action of this salt is similar to that of chromic acid. It is used in aqueous solutions of one to two per cent. for fixing, and two to five per cent. for hardening. Its action is slow, and it has the advantage of never rendering the tissues brittle.

Müller's Fluid.—This fluid was first introduced by H. Müller for hardening the retina. It is an excellent hardening fluid for the majority of tissues, especially for the central nervous system. Its action is slow, but its penetrating power great. It requires a month to six weeks to complete the hardening of a spinal cord. If the temperature of the fluid is kept at 30° to 40° C., the time is reduced to from eight to ten days (Weigert).

The composition of the fluid is as follows: Potassium dichromate, 2 to 2.5 parts; sodium sulphate, 1 part; water, 100 parts. It should be used in large quantities, renewed at the end of twelve hours, then every third day until the hardening is completed. Then wash well in water and preserve in alcohol. (See Orth's fluid under Formalin Mixtures.)

Kultzschitzky recommends the following for fixing the gastro-intestinal canal: Potassium dichromate, 2 gm.; mercuric chloride, 0.25 gm.; hydric acetate, two-per-cent. solution, 50 c.c.; alcohol, 50 c.c. Some of the dichromate precipitates out, so the fluid must stand for a few days and then be filtered. The specimen is to be fixed for from three to five days; then washed in water and hardened in graded alcohols.

Dichromate-osmic-platinic Mixture (Lindsay Johnson). Potassium dichromate, 2.5 gm.; osmic acid, two-per-cent solution, 10 c.c.; platinic chloride, one-per-cent. solution, 15 c.c.; hydric acetate, 5 c.c.; water, 70 c.c. Dissolve the dichromate in the water and then add the other ingredients. This mixture is an excellent fixing fluid for the most of tissues, though used first by Johnson for the retina.

Erlicki's Fluid.—This is also an excellent hardening fluid for the central nervous system. It consists of potassium bichromate, 2.5 parts; cupric sulphate, 0.5 part; water, 100 parts. At a temperature of 30° to 40° C. it hardens the spinal cord in four days.

Tellyseniczky's Fluid.—Potassium dichromate, 3 gm.; hydric acetate, 5 c.c.; water, 100 c.c. Small pieces of tissue in this fluid are fixed for from one to two days and then washed well in water. This is an excellent fixative for cytoplasm and fair for nuclear structures.

Ammonium Dichromate.—This is used in one to two per cent. solution in water, in place of the previous salt, for hardening the central nervous system. If 1 c.c. of ammonia be added to each 100 c.c. of potassium dichromate solution, the color changes to a bright yellow, and its power of penetration is increased.

Ammonium Chromate (*Neutral Chromate*).—As a fixing agent this salt is used in five-per-cent. solution, and allowed to act for twenty-four hours. The specimen should afterward be washed well in water and preserved in alcohol.

Picric Acid.—Used in cold saturated solution in water, 1 part of picric acid to 86 parts of water at a temperature of 15° C. The bits of tissue must be small—1 to 2 cm. on a side for each 100 c.c. of fluid. The solution must always be in a state of saturation; to accomplish this a few picric-acid crystals are placed in the bottle, and the latter is shaken occasionally. After fixing, the tissues *should always be washed in alcohol and not in water.* A few drops of a saturated solution of lithium carbonate in water, added to the alcohol, will hasten the process.

This reagent acts by gradually transposing the albumin into an insoluble compound, so that tissues harden in it entirely without shrinking. As the tissues become less solid than with other reagents, it is necessary to complete the hardening in alcohol. The majority of tissues are stained yellow, but the color is withdrawn by alcohol, water, glycerin, etc.

Picro-acetic Acid.—Bolles Lee recommends a saturated solution of picric acid in a one-per-cent. solution of hydric acetate.

Boveri dilutes a saturated aqueous solution of picric acid with two volumes of water and adds one per cent. of hydric acetate.

These solutions are recommended for fixing cellular elements.

Picro-chromic Acid (Fol).—Saturated aqueous solution of picric acid, 10 parts; chromic acid, one-per-cent. aqueous solution, 25 parts; water, 65 parts. At the time of using add 0.005 gm. of osmic acid.

Picro-hydrochloric Acid (Mayer).—Water, 100 parts; hydric chloride, 8 parts; picric acid to saturation.

Picro-nitric Acid (Mayer).—Water, 100 parts; hydric nitrate, 5 parts; picric acid to saturation.

Picro-sulphuric Acid (Kleinenberg).—Distilled water, 100 parts; hydric sulphate, 2 parts; picric acid to saturation.

Picro-mercuric Chloride (Mann).—Picric acid, 4 gm.; mercuric chloride, 15 gm.; tannic acid, 6 to 8 gm.; alcohol, 100 c.c. Recommended for all animal tissues. Fix for twenty-four hours at the body temperature of the animal, then wash in iodine alcohol.

Picro-platinic-Osmic Acid (von Rath).—Saturated aqueous solution of picric acid, 200 c.c.; platinic chloride, 1 gm. dissolved in 10 c.c. of water; hydric acetate, 2 c.c.; osmic acid, two-per-cent. solution, 25 c.c.

Picric Alcohol (Altman).—Picric acid, 2.5 gm.; alcohol, ninety-five per cent., 35 c.c.; water, 70 c.c.

Picric Alcohol (Gage).—Picric acid, 2 gm.; alcohol, ninety-five per cent., 500 c.c.; water, 500 c.c.

Fix in the above solutions for from one to two days. Wash out in graded alcohols.

Picro-formalin (Graf).—Graf recommends the following solutions for cytological work:

1. Sat. aq. sol. picric acid, 1 vol., Formalin, 5 per cent., 1 vol.
2. " " " " " 1 " " 10 " " 1 "
3. " " " " " 1 " " 15 " " 1 "
4. " " " " " 95 vols., " full strength 5 vols.
5. " " " " " 90 " " " " 10 "

Small pieces of tissue are fixed for thirty minutes; then washed for one hour in a large quantity of thirty-per-cent. alcohol; then in fifty-per-cent. alcohol; seventy-per-cent. alcohol; eighty-per-cent. alcohol; and finally preserved in ninety-five-per-cent. alcohol.

Picro-Formalin—Platinic Chloride (Bouin).—Platinic chloride, one-per-cent. aqueous solution, 20 parts; picric acid, saturated aqueous solution, 20 parts; formalin, 10 parts; formic acid, 5 parts.

Palladium Chloride.—Employed by Waldeyer in one-thousandth-per-cent. aqueous solution, with the addition of a few drops of hydric chloride to aid in the solution, for softening the cochlea. The specimen is placed in this solution for twenty-four hours, and then in absolute alcohol for the same length of time.

F. E. Schulze uses this salt in 0.01 to 0.2 per cent. solutions. As the penetrating power is slight, small pieces of tissue are to be used—a piece the size of a bean to 30 c.c. of the solution. The hardening is completed at the end of thirty-six to forty-eight hours, but the specimen may remain in the fluid for months without harm. This solution stains protoplasm dark yellow, striated muscle brownish yellow, smooth muscle straw yellow, medullated nerves black. Hyaline membranes and elastic fibres stain slight yellow and remain transparent. Interstitial substance of connective tissue remains colorless, and will stain deeply with carmine and other stains, while the tissue colored by the palladium remains unstained. Sections are to be well washed in water and mounted in glycerin.

Fraenkel recommends the following as a fixative for connective tissue: Palladium chloride, one-per-cent. aqueous solution, 15 parts; two-per-cent. solution of osmic acid, 5 parts; and a few drops of acetic acid.

Mercuric Chloride is an excellent fixing agent. It kills rapidly and does not interfere with the subsequent staining of the tissues. It is slow in penetrating so that small pieces of tissue must be used. As a fixative it is used in saturated aqueous solution (about seven per cent.); or in saturated solution in three-quarters-per-cent. solution of sodium chloride. The simple aqueous solution does not keep well, depositing after a time a fine white precipitate. This precipitation can be prevented by the addition of a slight amount of hydric nitrate (Bolles Lee).

A better fixation is obtained if a small quantity of hydric acetate, about one per cent., be added to the aqueous solution. Bolles Lee speaks highly of a saturated solution of mercuric chloride in five-per-cent. hydric acetate. Van Beneden uses a saturated solution in twenty-five-per-cent. hydric acetate.

The specimens should be left in the fixing fluid as short a time as possible. A prolonged immersion renders them brittle.

After fixation, the tissues are washed in seventy-per-cent. alcohol, to which tincture of iodine is added until the alcohol becomes of a mahogany color. If the alcohol becomes decolorized more iodine is added, and this is repeated until the alcohol ceases to lose color. Finally the specimens are washed in eighty-per-cent. alcohol to remove the iodine. This procedure must be followed with all specimens that have been fixed in a fluid containing mercuric chloride. They are then preserved in ninety-per-cent. alcohol, in which after prolonged immersion they become very brittle.

Alcoholic Solutions of Mercuric Chloride.—Mercuric chloride is more soluble in alcohol than in water, so that by the use of this menstruum a stronger solution may be obtained.

Gilson's Fluid.—Absolute alcohol, 1 part; hydric acetate, glacial, 1 part; chloroform, 1 part; mercuric chloride, to saturation. Small specimens are fixed for from twenty-five to thirty seconds, then washed in alcohol (see above).

Ohlmacher's Fluid.—Absolute alcohol, 80 parts; chloroform, 15 parts; hydric acetate, glacial, 5 parts; mercuric chloride, to saturation (about twenty per cent.). Small pieces of tissue are fixed for from fifteen to thirty minutes, and then washed out in iodine-alcohol.

Lang's Fluid.—First Formula: Mercuric chloride, 3 to 12 gm.; sodium chloride, 6 to 10 gm.; hydric acetate, 6 to 8 c.c.; distilled water, 100 c.c. Second Formula: Saturated solution of mercuric chloride in picro-sulphuric acid, to which is added five per cent. of hydric acetate.

Carnoy's Modification of Lang's Fluid.—Mercuric chloride, 5 gm.; sodium chloride, 5 gm., hydric acetate, 5 c.c.; water, 100 c.c.

Pacini's Fluid.—Mercuric chloride, 1 gm.; hydric acetate, 2 c.c.; water, 300 c.c.

Zenker's Fluid.—Mercuric chloride, 5 gm.; potassium dichromate, 2.5 gm.; sodium sulphate, 1 gm.; hydric acetate, 5 c.c.

The hydric acetate is added just before using. The specimen is fixed for from two to forty-eight hours; washed well in water, then in graded alcohols, and finally in ninety-per-cent. alcohol to which is added from one-half to three-quarters per cent. of tincture of iodine. This is an excellent fixing fluid, especially for muscular tissues. Tellyseniczky states that it is equal to Flemming's fluid for cellular structures.

Apathy's Fluid.—Alcohol, fifty per cent., 100 c.c.; sodium chloride, 0.5 gm.; mercuric chloride, 3 to 4 gm.

Rath's Fluid.—Alcohol, 200 c.c.; mercuric chloride, 1 gm.; hydric acetate, glacial, 2 c.c. Fix for from four to five hours.

Alcohol is used for the purpose of fixing tissues either in the form of one-third alcohol, "alcohol au tiers" of Ranvier, or absolute alcohol. The one-third alcohol consists of 1 part of ninety-per-cent. alcohol and 2 parts of water. Tissues are placed in this fluid for twenty-four hours; then stained in an alcoholic staining fluid. They should never be treated with an aqueous medium, except picrocarmine, alum carmine, or methyl green.

Absolute alcohol penetrates quickly and fixes fairly well, but there is apt to be some distortion on account of shrinkage. It hardens at the same time. Except in a few special cases alcohol should be discarded as a fixative and its use restricted to hardening and preserving.

ALCOHOLIC MIXTURES.

Carnoy's Fluids.—I.* Hydric acetate, glacial, 1 part; absolute alcohol, 3 parts. II. Hydric acetate, glacial, 1 part; absolute alcohol, 6 parts; chloroform, 3 parts.

The chloroform in the second formula makes its action more rapid.

Zacharias' Fluid.—Hydric acetate, glacial, 1 part; absolute alcohol, 4 parts; one-per-cent. solution of osmic acid, 2 to 3 drops to each 10 c.c. of the above.

Fix for from one to three hours in the above mixtures and then wash out in alcohol. These fluids give good fixation of mitotic figures and of the central nervous system.

Alcohol and Osmic Acid (Vignal).—Alcohol and one-per-cent. osmic acid, equal parts. After fixing wash in eighty-per-cent. alcohol.

Formalin.—Formalin is a forty-per-cent. solution in water of the gas formaldehyde (HCOH), an oxidation product of methyl alcohol. It is also known in commerce as "formol" and "formalose." The commercial product rarely tests over thirty-eight per cent. When exposed to the air a partial decomposition takes place with the formation of a white deposit, paraformaldehyde. The vapor of formalin is irritating to the mucous membranes. It also has an irritating effect on the skin, hardening it and causing the formation of annoying cracks which do not heal unless the hands are kept from coming in contact with the formalin.

Formalin penetrates rapidly and kills quickly, but unfortunately in most instances does not fix the tissue elements sufficiently to enable them to withstand the subsequent manipulations without change. On account of this fault pure formalin has been almost entirely abandoned as a fixative, but the agent is quite extensively employed in mixtures.

As a fixative it is used in the strength of from one to five per cent. In five-per-cent. solutions I have found it to be a good fixative for cystic tumors of the ovary, also for the mucous membrane of the uterus.

Bolles Lee has called attention to what he considers an inaccurate manner of stating the percentages used. He claims that the proper way of stating the strength of the solutions is to say "formalin diluted with so many volumes of water." It is now understood that when a percentage is given it means the stated percentage of commercial formalin and not of the gas formaldehyde.

The following is a table for formalin solutions:

100%	formalin	= 40%	formaldehyde		
50%	"	= 20%	"	= 1 vol. formalin	+ 1 vol. water.
25%	"	= 10%	"	= 1 " "	+ 3 " "
12½%	"	= 5%	"	= 1 " "	+ 7 " "
10%	"	= 4%	"	= 1 " "	+ 9 " "
5%	"	= 2%	"	= 1 " "	+ 19 " "
2½%	"	= 1%	"	= 1 " "	+ 39 " "
1%	"	= 0.4%	"	= 1 " "	+ 99 " "

As a preservative agent for gross specimens, formalin is used in the strength of from two to ten per cent., a five-per-cent. solution usually giving the best results. The weaker solutions cause more or less swelling of the tissues.

The quantity of the fluid should be large—one hundred times the volume of the specimen—and the fluid should be renewed at the end of twenty-four hours. In cases of large specimens it is well to renew the fluid a second or even a third time.

When used in this manner, formalin preserves the form and to a certain extent the natural color of the specimens. In some cases the blood color appears to be bleached out, but if the specimen is placed in strong alcohol, this is nearly if not entirely restored.

---

* This is also known as Van Gehuchten's fluid.

For preserving the blood color of specimens, Johres makes use of the following procedure and fluid: Sodium chloride, 1 part; magnesium sulphate, 2 parts; sodium sulphate, 2 parts; water, 100 parts. To this mixture are added from five to ten parts of a forty-per-cent. solution of formalin. After the specimen has become sufficiently hardened, the formalin solution is poured off, the specimen is washed in ninety-five-per-cent. alcohol, then kept in ninety-five-per-cent. alcohol until the blood color becomes restored, and finally is preserved in a mixture of equal parts of glycerin and water.

A ten-per-cent. solution of formalin is the best hardening reagent for eyes. The cornea remains translucent and the vitreous humor retains its natural transparency perfectly.

For hardening the central nervous system it is used in the strength of from four to ten per cent. Sections stain well with Weigert's hæmatoxylin method.

Formalin Mixtures.—For fixing purposes formalin is now used almost entirely in combinations with acids and chemical salts.

Lovdowsky's Fluids.—I. Distilled water, 20 c.c.; alcohol, ninety-five per cent., 10 c.c.; formalin, 3 c.c.; hydric acetate, 0.5 c.c. II. Distilled water, 30 c.c.; alcohol, ninety-five per cent., 15 c.c.; formalin, 5 c.c.; hydric acetate, 1 c.c.

These fluids are recommended by Lovdowsky for fixing the mitotic figures of cells.

Cox's Fluid.—Mercuric chloride, saturated aqueous solution, 30 parts; formalin, 10 parts; hydric acetate, 5 parts. Used by the author for fixing the nerve cells of the spinal ganglia.

Orth's Fluid (Formalin Müller's Fluid).—Potassium dichromate, 2.5 gm.; sodium sulphate, 1 gm.; water, 100 c.c.; formalin, 10 c.c. This fluid must be freshly prepared each time as it soon decomposes. When it is used in large quantities the salts may be made up into solution and the formalin added at the time of using; or a solution of the salts may be made of double strength and diluted with an equal volume of twenty-per-cent. formalin at the time of using.

Small pieces of tissue are fixed in this fluid for from twelve to twenty-four hours; then washed in running water for from six to twelve hours; and finally placed in eighty-per-cent. alcohol.

This fluid is the best general fixing fluid we have.

Methods of Decalcification.—Specimens to be decalcified should be reduced to pieces about 2 mm. in thickness. This can be done with a fine saw. They are then thoroughly hardened and placed in the decalcifying fluid. When they are decalcified, which may be tested by passing a needle into the tissue, they are thoroughly washed in running water until all the acid is removed; they are then hardened in alcohol.

Hydric Chloride.—One part of strong hydric chloride is mixed with ten parts of water, and ten per cent. of sodium chloride is added. Without the addition of the latter the acid will cause some tissues to swell. The specimen of bone is placed in a large quantity of this fluid, and a little fresh acid added day by day until the bone has become soft. Then it is washed in water until all traces of acid are removed, and preserved in alcohol.

Hydric Chloride and Palladium Chloride.—Waldeyer employs a one-thousandth-per-cent. solution of palladium chloride with one-tenth of its volume of hydric chloride for softening the cochlea. Small pieces of bone are placed in this fluid for twenty-four hours. If they are not softened at the end of this time the fluid is renewed, and they are allowed to remain another twenty-four hours, when, as a rule, they will be found completely softened. The specimens are then washed in alcohol, which is renewed at the end of twenty-four hours. This fluid does not cause the tissues to swell, nor does it interfere with the staining.

V. Ebner recommends a two-per-cent. solution of hydric chloride in a half saturated solution of sodium chloride. This fluid is slow in its action and should be changed daily until the specimens are thoroughly decalcified. The specimens are then washed in a half saturated solution of sodium chloride, to which a few drops of ammonium hydrate are added, until the reaction of the bone becomes neutral.

Hydric Chloride and Alcohol.—Hydric chloride, 2.5 c.c.; alcohol, 500 c.c.; water, 100 c.c.; sodium chloride, 2.5 gm.

Or hydric chloride, 1 to 5 c.c.; alcohol, 70 c.c.; water, 30 c.c.; sodium chloride, 0.5 gm.

Hydric Nitrate.—This acid is highly recommended by Busch. He employs a ten-per-cent. solution for adult bones and a one-per-cent. solution for fœtal bones. Fresh bones are placed for three days in ninety-five-per-cent. alcohol; then placed in the nitric-acid solution, which is changed daily until decalcification is complete. This requires from eight to ten days. The bones are then washed in runing water for two hours, and finally placed in ninety-five-per-cent. alcohol, which is renewed at the end of three days.

Fœtal bones are first placed in a mixture of one-per-cent. potassium bichromate and one-tenth per cent. of chromic acid for one or two days; then decalcified in one-per-cent. hydric nitrate. When thoroughly decalcified they are washed in water and preserved in alcohol.

Sections of bone treated by this method stain well with eosin, but staining with hæmatoxylin is seldom successful.

Hydric Nitrate and Alcohol.—Mayer uses a five-per-cent. solution of hydric nitrate in ninety-per-cent. alcohol; Thoma 5 parts of strong alcohol and 1 part of hydric nitrate, renewing the fluid daily until the specimens are decalcified.

Phloroglucin and Hydric Nitrate (Haug).—Phloroglucin, 1 gm.; hydric nitrate, 10 c.c. The phloroglucin is placed in a porcelain dish and the hydric nitrate added drop by drop; it should be warmed carefully, as the action of the acid on the phloroglucin is very energetic. When all the acid has been added, the solution is diluted with 100 c.c. of distilled water. This should give a clear ruby-red colored fluid. Then there must be added 10 c.c. of hydric nitrate, the solution being afterward brought up to 300 c.c. by the addition of water.

The phloroglucin acts as a protector to the organic constituents and has no decalcifying action.

The action of this fluid is very rapid. Fetal and young bones become soft in half an hour; older bones, like pieces of the femur, require from four to five hours.

After decalcification the specimens are washed in running water for two or three days.

This solution may be made with hydric chloride instead of hydric nitrate, 30 c.c. of the HCl being used.

A slower acting fluid can be made as follows: Phloroglucin, 1 gm.; hydric nitrate, 5 c.c.; alcohol, 70 c.c.; water, 30 c.c.

These solutions should be made fresh as they do not keep well.

Ferri's Solution.—Dissolve 1 gm. of phloroglucin, by the aid of heat, in a mixture of 100 c.c. of water and 10 c.c. of hydric chloride; when cold add 200 c.c. of seventy-per-cent. alcohol.

Picric Acid.—This is used in saturated aqueous solution. It is slow in its action. The specimen should be small, and be suspended in a large quantity of the fluid. The latter must be kept in a saturated condition by the addition of fresh crystals of the acid and frequent agitation.

Schmol recommends the following mixtures: A. Formalin, 100 c.c.; hydric nitrate, 20 c.c. B. Müller's fluid, 100 c.c.; hydric nitrate, 3 c.c.

Trichloracetic Acid.—This acid has been recommended for decalcification. It acts slowly, and is used in five-per-cent. solutions.

Methods of Dissociation.—*Mechanical.*—*Scraping and Teasing.*—Which of these methods is to be employed will depend upon the nature of the tissue. Epithelium can be easily scraped off in large flakes by a knife, while fibrous parts must be teased apart with needles. Scraping is performed as follows: A small bit of the tissue is placed on a slide, with the epithelial surface uppermost, one end fixed with a needle, and the surface lightly scraped with the blade of a scalpel, the result of the scraping diffused in a drop of water, salt solution, or glycerin on a slide, and examined.

For teasing we employ needles mounted in handles. Various forms of the latter are supplied by instrument-makers, but a needle forced into the end of an ordinary pen holder will answer every purpose. In order to tease a specimen successfully, it is necessary to have some idea of its structure, whether its elements are arranged in parallel fibres or interlaced. In tissues arranged in parallel fibres, the needles are applied to one extremity and the specimen is torn into two parts; one of these is selected and the operation is repeated until it is impossible to separate the fibres any more. In other tissues a small bit is fixed by one needle, and with the other, commencing at one edge, the teasing is carried on in a deliberate manner until the tissue is reduced to the required degree of fineness. The operation of teasing is performed on a slide in a small drop of fluid. Unstained material is placed on a black background, stained material on a white background.

Brushing.—This operation is performed under water by gently brushing the surface with a camel's-hair brush.

Shaking.—Thin sections of tissue are shaken in a test-tube with a suitable fluid, then the contents of the tube are poured into a dish of water, the sections being floated on a slide.

Compression.—By making pressure on the cover-glass, especially after maceration of the specimen, one is often able to separate the elements. This pressure can be made with the handle of a teasing needle, but it is apt to be unequal, and there is danger of breaking the cover and thus destroying the specimen. It is better to use an instrument called a compressorium, constructed especially for this purpose. In Fig. 2670 is shown one form, invented by H. Jung, of Darmstadt.

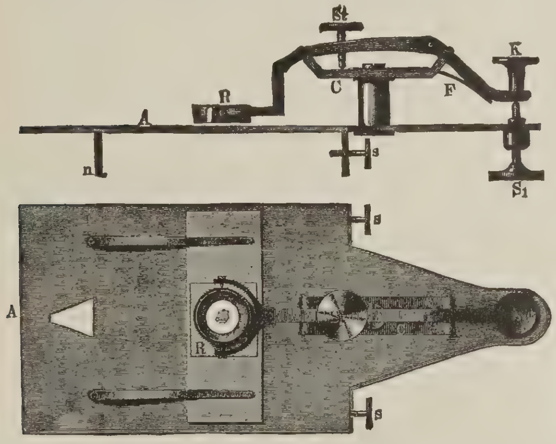

FIG. 2670.—Jung's Compressorium.

The plate *A* is attached to the stage of the microscope by the catch *n* and the two screws *s*, *s*. On this plate is a double lever, one arm of which has a movable ring, *R*, and adjusting screw, *St*, and the knob *K*. The two levers are so connected with the bent piece *C* that when *K* is pressed down the ring *R* is also pressed toward the stage plate. Conversely, an upward movement of the knob, produced by the spring *F*, raises the ring. For use as a compressor the screw S_1 is loosened, and *St* screwed down until the desired degree of pressure is obtained. This apparatus can also be employed for another useful purpose, viz., beating. The process of beating is often resorted to for the purpose of isolating cells, tissue, etc. In using the instrument for this purpose the screw *St* is so adjusted that the ring *R* lies close to a large and thick cover-glass covering the specimen, and S_1 is turned so that the lever can move but slightly. By quick and continuous movement of the lever, and the changing pressure on the cover-glass thus produced, tissues (after maceration) can be easily dissociated. When the cells are isolated they can be made, by a slower movement of the lever, to move about in all directions, so that they can be observed from all sides.

Interstitial Injection, or Artificial Œdema.—A hypodermic syringe is filled with salt solution or a warm solution of gelatin, the needle is inserted into the tissue—*e.g.*, the subcutaneous tissue of a freshly turned-up flap of skin—and the fluid is forced out. The fluid does not immediately diffuse itself, but forms a bulla covered with a thin film of tissue. A bit of this film is snipped off with scissors and examined. If gelatin be used, it soon solidifies, when thin sections are made with a razor.

Chemical Dissociation.—By submitting tissues to the action of different chemical solutions certain parts become dissolved or softened, while others remain unaltered. Consequently certain elements can be easily isolated by one of the mechanical methods.

The reagents used for this purpose are as follows:

Dilute Alcohol, "Alcohol au tiers" of Ranvier.—Alcohol of ninety-per-cent. strength is diluted with two parts of water. Bits of tissue are placed in this fluid for twenty-four hours; if at the end of this time the tissue is not sufficiently softened, the fluid is renewed and the action continued for twenty-four hours longer. Recommended highly by Ranvier for isolating epithelial cells.

Osmic Acid of the strength of one-tenth per cent. is recommended by Rindfleisch for the cerebral cortex. Small pieces of the cortex are placed in a considerable quantity of the fluid for a week or ten days, then in glycerin.

Chromic Acid is employed in the strength of two to three parts to one thousand of water. Recommended especially for nerve tissue and smooth muscle. The amount of fluid should be ten times greater than the piece of tissue. After macerating for twenty-four hours, the tissues are easily dissociated.

Potassium Dichromate is employed in the same strength as chromic acid, its action being similar. Müller's fluid, diluted with an equal volume of water, is also employed as a macerating fluid. Its action requires from twenty-four hours to a week.

Potassium Hydrate.—Used in twenty- to forty-per-cent. solutions in water. It acts very quickly on fresh tissues, and is used mostly for isolating the cells of nails, hairs, and epidermis. Sodium hydrate may be used in its place, but in more dilute solutions. Preparations made by this method cannot be permanently preserved.

For isolating histological elements S. H. Gage uses a thirty- to fifty-per-cent. solution of potassium hydrate. Perfectly fresh tissue is used. Pieces about half a cubic centimetre in size are placed in a large amount of the potassium hydrate solution until they can be easily shaken apart. The potash solution is then poured off and replaced by a sixty-per-cent. solution of potassium acetate containing one per cent. of hydric acetate. After a short time the tissue is washed in water; then stained in alum carmine for twenty-four hours; then washed in water and preserved in glycerin.

Sodium Chloride.—Used in ten-per-cent. solution in water for isolating white fibrous tissue. It requires from two to three days for its action.

Hydric Nitrate.—Used in twenty-per-cent. solution for muscle fibres. After being acted upon for twenty-four hours, the fibres are easily isolated by shaking the specimen in a test-tube with water. Schwalbe uses a twenty-per-cent. solution for isolating nerve fibres for measurement. He macerates the nerve trunk in the above solution at a temperature of 40° C. for twenty-four hours, and then washes in water. The fibres retain their normal diameter, but become very brittle.

Hydric Nitrate and Potassium Chlorate.—A piece of striated muscle is buried in crystals of potassium chlorate placed in the bottom of a vessel, and four times the volume of the crystals of hydric nitrate is poured on and allowed to act half an hour; the muscle is then shaken in a test-tube with water, when it will break up into isolated fibres.

Hydric Chloride is used mixed with an equal volume of alcohol for isolating the tubules of the kidney. A small bit of fresh kidney is placed in this mixture for twelve hours, then soaked in water for a few hours to remove the acid, and preserved in glycerin. The acid partially dissolves the intertubular tissue, so that by very careful teasing the tubules can be isolated. It is also employed in the strength of 1 to 250 of water for cleaving striated muscle tissue into discs.

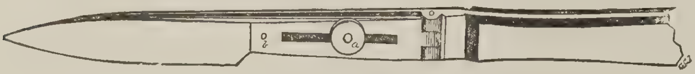

Fig. 2671.—Valentine's Knife.

Artificial Digestion.—For the purpose of artificial digestion we make use of either pepsin or trypsin.

Brücke's Pepsin Fluid. — Glycerin extract of pig's stomach, 1 part; 0.2 per cent. HCl, 3 parts; thymol, a few crystals.

Kuskow's Pepsin Fluid.—Pepsin, 1 gm. is dissolved in 200 c.c. of a three-per-cent. solution of oxalic acid. The fluid should be prepared fresh each time.

Pancreatic fluid can also be made by dissolving six to seven per cent. of trypsin in water containing one per cent. of salicylic acid.

Schiefferdecker's Pancreatin Fluid.—A saturated solution of Pancreatinum siccum (Witte) is made in cold distilled water and filtered.

Pieces of tissue may be first digested in these fluids and then sections cut, or the sections may be first cut and then submitted to the action of the fluids. The digestive process is to be carried on at a temperature of from 37° to 38° C., either in an incubator or on a warm stage on the microscope.

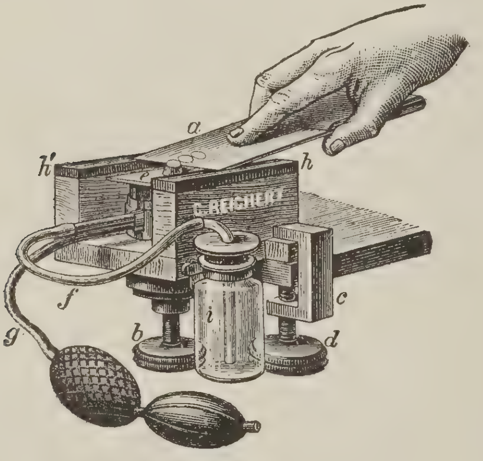

Fig. 2672.—Ether-Freezing Microtome.

Pepsin quickly dissolves connective tissue, muscle, most cellular elements, etc., but not elastic tissue or nerve fibres. Trypsin, on the other hand, dissolves elastic fibres and neuroglia, while connective tissue is not acted upon.

Methods of Making Sections.—*Sections of Hard Tissues.*—Sections of undecalcified bone, teeth, etc., are made by cutting thin plates by means of a fine saw or an iron disc, on a lathe fed with flour of emery and water. These plates are then ground on a metal plate charged with flour of emery and water until transparent; they are then polished on a Turkey hone, washed in water, and dried in the air.

Sections of Fresh Tissue.—For making sections of fresh tissue Valentine's double knife (Fig. 2671) may be used, though the sections are generally too thick. This knife consists of two parallel blades attached to each other at their lower end by a hinge. At *a* is a screw sliding in a slot, by means of which the blades are approximated. For use, the knife is forced into the organ; cutting a thin slice which remains enclosed between the blades. The knife is then withdrawn and the blades are opened by sliding back the screw *a;* the slice of tissue adhering to one of the blades is floated off in salt solution.

At the present time one of the numerous forms of freezing microtomes is used for making frozen sections of fresh tissues. For freezing the tissue ether, rhigolene, or compressed carbon dioxide is used. Compressed carbon dioxide can now be obtained in steel cylinders, and is used to a considerable extent in place of ether. One of the usual forms of ether-freezing microtomes is shown in Fig. 2672. The specimen to be frozen is placed on the metal plate *e*, and is frozen by a spray of ether delivered on the under side of the plate by the spray tubes passing through its side. The ether is placed in the bottle *i*. The air is compressed by the double bulbs and conveyed to the spray tubes through the tube *g;* the ether through the tube *f*. The knife *a* is broad and has a chisel edge; it slides on the glass ways *h'h*. The surface of specimen plate is raised by the micrometer screw *b*.

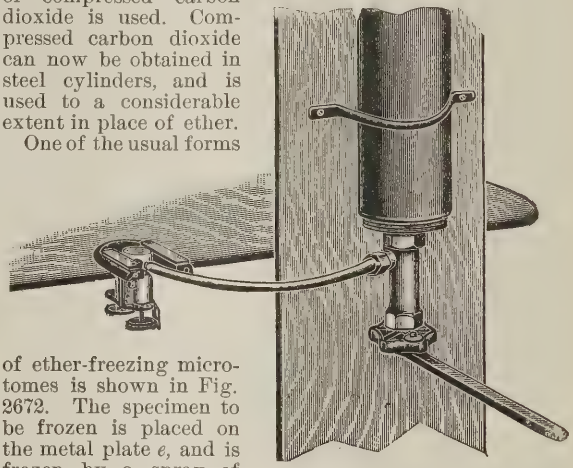

Fig. 2673.—Carbon-dioxide Cylinder Connected with Freezing Microtome.

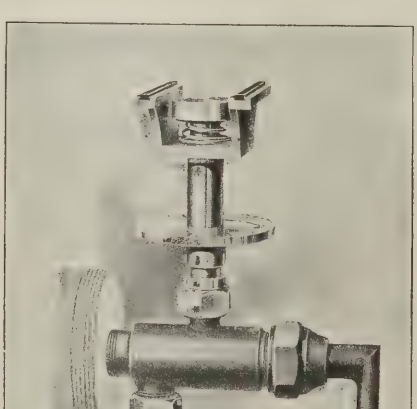

Fig. 2674.—Bardeen's Microtome.

In Fig. 2673 is shown one of the arrangements for using carbon dioxide for freezing. The steel cylinder is fastened to an upright plank so that its valve end comes on or about the level of the table. A thick rubber tube for conveying the gas passes to the microtome. The valve is opened by a long lever allowing the flow of gas to be easily controlled.

Professor Bardeen's freezing microtome is shown in Fig. 2674. This microtome is very simple in construction and is attached directly to the outlet tube of the steel cylinder The improvements introduced by Professor Bardeen, in both the microtome and the valvular arrangements of the cylinder, have resulted in a great saving of the carbon dioxide.

Specimens from which frozen sections are to be made should not be over 4 mm. thick. The freezing should be done slowly, and they should not be allowed to become too hard.

Several methods are now in use whereby sections of fresh tissue may be cut, stained, and mounted in a very short time. One of the earlier methods, that of Cullen (*Johns Hopkins Hospital Bulletin*, April, 1895, and May, 1897), has been modified and improved. Two of the principal modifications are as follows:

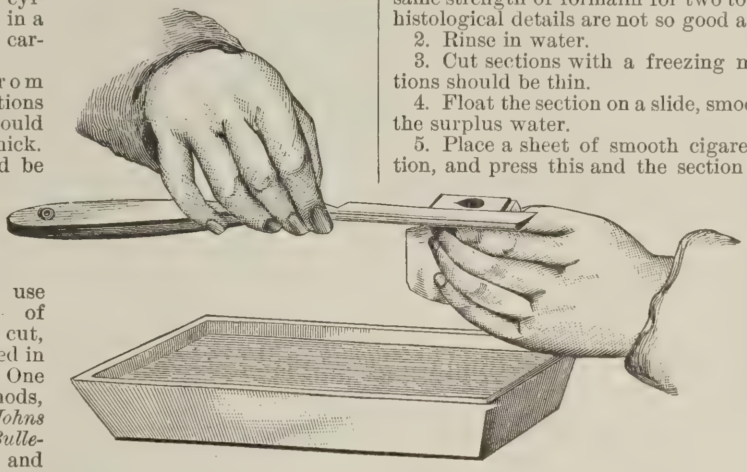

FIG. 2675.—Section-cutting.

Hodenpyl's Modification.—Any form of freezing microtome may be used. The technique is as follows:

1. Sections may be cut from perfectly fresh material, or from material which has been previously hardened one or two hours or longer in ten-per-cent. formalin. (It is convenient to drop bits of tissue into ten-per-cent. formalin at the time of the operation or during the post-mortem examination. By the time they reach the laboratory they are usually sufficiently impregnated to be cut and stained.)

2. Tissues already hardened in formalin should be soaked in water for a minute or two to remove the formalin before cutting.

3. Sections as they are cut may be dropped directly into the albumin solution, where they remain until needed. A solution of albumin which has been found to answer the purpose is prepared by adding to 50 c.c. by volume of egg albumen 150 c.c. of distilled water and sufficient of a solution (usually about 50 c.c.) of salicylic acid (saturated), which has been rendered slightly alkaline with lithium carbonate, completely to dissolve the albumen. The solution may be kept unchanged several weeks by adding a little gum camphor.

4. Unhardened sections should be placed in five-per-cent. formalin for from three to five minutes, after which they are soaked in the albumin solution for two or three minutes.

5. The sections are floated on cover-glasses, the excess of fluid being removed with filter paper when necessary. The sections are then blotted evenly, care being taken not to use pressure enough to cause them to bear the imprint of the cloth. (The best blotting material seems to be washed cheesecloth used in several layers. The use of filter paper, towels, muslin handkerchiefs, etc., for this purpose has not been satisfactory.)

6. The section must then be transferred immediately to alcohol, alcohol and ether (equal parts), osmic acid, or mercuric chloride, etc., in order to coagulate the albumin and to fix the section and complete the hardening.

7. Sections may be stained on the cover slip in various ways. For ordinary diagnostic work staining with hæmatoxylin and eosin answers well. The following is the method of procedure. (*a*) Stain for from two to five minutes in hæmatoxylin. (*b*) Decolorize by passing rapidly through acid alcohol—hydric chloride, 1 part; eighty-per-cent. alcohol, 99 parts. (*c*) Wash thoroughly in water. (*d*) Dehydrate and stain in eosin alcohol. (*e*) Clear in oil of origanum, oil of cloves, xylol, etc. (*f*) Mount in balsam.

Wright's Modification.—1. Place the fresh specimen in ten-per-cent. solution of formalin for about two hours. If time does not allow of this, boil the specimen in the same strength of formalin for two to three minutes. The histological details are not so good after boiling.

2. Rinse in water.

3. Cut sections with a freezing microtome. The sections should be thin.

4. Float the section on a slide, smoothe out, and remove the surplus water.

5. Place a sheet of smooth cigarette-paper on the section, and press this and the section down with a pad of soft, smooth filter paper, the face of which has been moistened with a few drops of ninety-five-per-cent. alcohol. Remove the filter paper and carefully strip off the cigarette paper, leaving the section adhering to the slide.

6. Flood the section, adhering to the slide, with absolute alcohol; after about thirty seconds drain off the alcohol.

7. Flow over the section and the adjacent surface of the slide a *thin* solution of celloidin; drain off immediately.

8. Flood the slide with ninety-five-per-cent. alcohol, and immediately place the slide for ten seconds in water. This hardens the celloidin film and prevents the section from curling.

9. Stain with hæmatoxylin or any combination of stains.

10. Dehydrate in ninety-seven-per-cent. alcohol.

11. Clear in oil of origanum, and mount in balsam.

Sections of Hardened Tissue.—Sections of hardened tissue may be made by free-hand cutting, or by the microtome. For free-hand cutting, the first requisite is a good razor or knife. An ordinary hollow-ground razor, with the lower side ground flat, will answer; but if one practises free-hand cutting to any extent, it is better to be provided with a larger and heavier one.

The section cutting is performed as follows: A shallow dish is partially filled with alcohol, with which the specimen and razor blade are to be constantly flooded, the blade being dipped into the alcohol. The specimen is held firmly between the fingers and thumb of the left hand (Fig. 2675), and the razor lightly with the right, the handle resting on the fingers, the thumb being used for changing the direction of the edge of the razor. The section is cut by drawing the razor blade diagonally

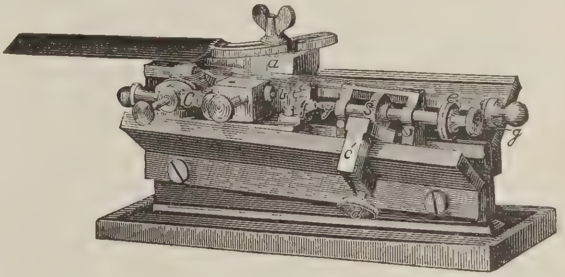

FIG. 2676.—Thoma's Sliding Microtome.

through the specimen, from heel to point, and then floated off into a dish of alcohol. After cutting every third or fourth section the razor should be stropped, so as to keep the edge in the best possible condition.

Microtomes.—Thoma's sliding microtome (Fig. 2676) consists of a stand of cast iron, on which slide two carriers. The section knife is attached to one of these, *a*, which slides horizontally. The other, *b*, holds the specimen to be cut, and moves on an inclined plane.

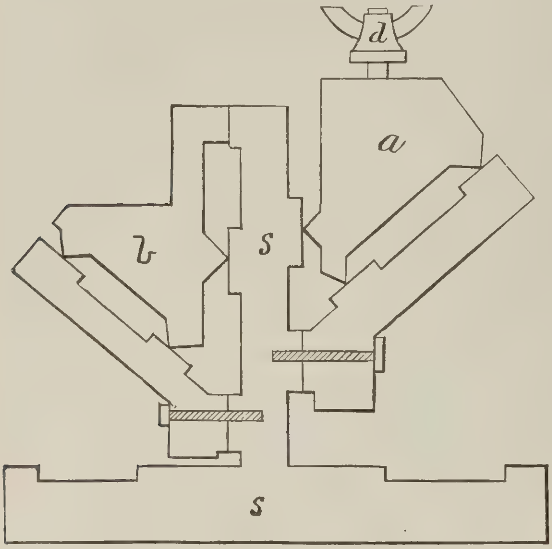

FIG. 2677.—Vertical Section, Thoma's Microtome.

Professor Thoma found that a carrier moving on five points between two plane surfaces, will slide without difficulty between these planes, even if they are not absolutely geometrical planes, or if the angle included is not everywhere the same. Such a carrier will always take the same course, and consequently the knife will cut a series of perfectly parallel sections through an object which is successively raised to a higher plane after each cut.

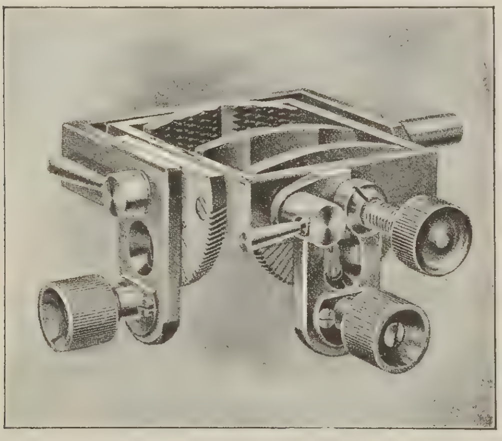

FIG. 2678.—Naple's Universal Clamp.

A cross-section of the instrument is shown in Fig. 2677. On the lower surface of the carrier *a* are shown three points, which give the geometrical projection of the five points of the carrier.

The inclination of the plane upon which the carrier *b* (Figs. 2676, 2677) slides is one in twenty; consequently, if the carrier *b* is moved 1 mm. on this plane it will raise the surface of the specimen .05 mm. A scale of millimetres, *e*, with a vernier *e'* (Fig. 2676), allows the operations to be easily regulated, and will be found sufficient for sections of 0.015 mm. in thickness. When sections of greater delicacy are required the micrometer screw *g*, *g* (Fig. 2676) is to be used, as it allows of the greatest exactitude in the management of the carrier *b*. The carrier *c'* slides on the same plane as the carrier *b*. In all positions of the latter it is possible to bring the point of the micrometer screw *g*, *g* in contact with the polished plate of agate, *f*, fixed on *b*. When in this position, *c'* should be firmly fixed to the stand of the microtome by the screw *d*. Every revolution of the micrometer screw *g*, *g* will then push the carrier *b* 0.3 mm., giving a thickness of section equal to 0.015 mm. The periphery of the drum, *s*, attached to the screw *g*, *g* is divided into fifteen equal parts; consequently, each division corresponds to a thickness of section equivalent to 0.001 mm. The first sections cut by this instrument have been 0.002 mm. in thickness.

When the microtome is used, it is placed on a table before the operator, the slides are freely oiled, and the surface of the knife is flooded with alcohol. The specimen fixed to a block is fastened in the clamp.

The Naple clamp (Fig. 2678) is the one now generally used and can be adapted to most of the microtomes. It is movable on two axes, one parallel to the long axis of the microtome, the other at right angles to it. This allows of the adjustment of the surface of the specimen to the plane through which the knife passes in cutting. The clamp is then fixed in a position as near the knife carrier *a* as possible.

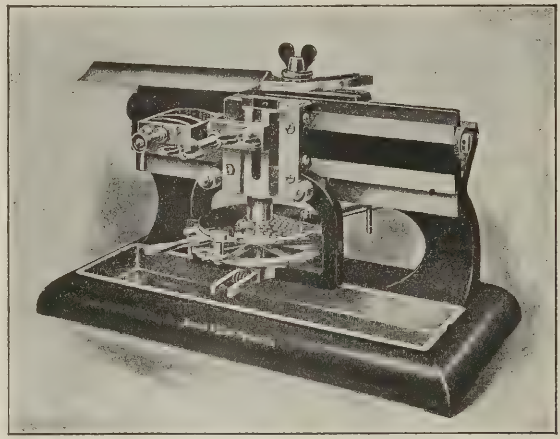

FIG. 2679.—New Form of Sliding Microtome with Automatic Feed Attachment.

The knife is so adjusted that it will be drawn obliquely through the specimen from heel to point. The sections, after being cut, are removed from the knife with a camel's-hair brush, and placed in a dish of alcohol.

In cutting sections of hard substances, such as the aorta and cartilage, it often happens that the sections, instead of being even, are thicker at one point than at another; or that the sections are striped, their thickness varying at different points. Professor Thoma has found that this is due to the fact that hard substances bend the edge of the ordinary knife. For preventing this he has introduced knives with stronger edges and shorter blades.

In Fig. 2679 is shown one of the newer forms of sliding microtomes with automatic feed attachment. It is adapted either for celloidin or paraffin cutting. The object clamp remains fixed during the cutting. The knife is clamped to the knife carrier, a triangular block, which slides on horizontal runways.

The automatic feed attached to the micrometer screw is operated by the motion of the knife carrier and is so adjusted that sections from 2 to 60 μ in thickness may be cut.

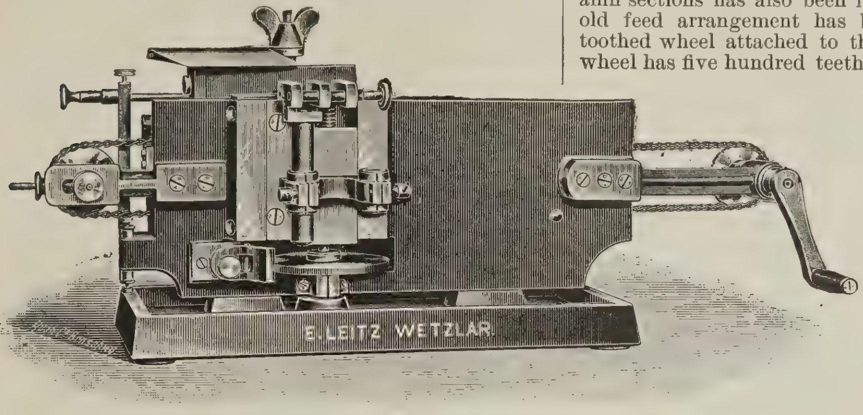

FIG. 2680.—Large Sliding Automatic Microtome.

A larger form of automatic sliding microtome is shown in Fig. 2680. The knife carrier runs on a horizontal track and is moved by a chain attached to either end of it. This chain passes around two wheels, one of which is turned by a crank attached to it, causing a uniform sliding motion.

The specimen clamp is raised vertically by a micrometer screw to which is attached a large, toothed, circular disc, each tooth of which equals an elevation of 0.0025 mm.

The automatic feed is so arranged that each time the knife carrier reaches the left-hand end of the tract it strikes a lever which causes the circular disc attached to the micrometer screw to revolve. The lever being adjustable, it can be made to cause the disc to move any number of teeth from one to ten with each movement of the knife carrier, thus giving a thickness of section from 0.0025 mm. to 0.025 mm. in thickness.

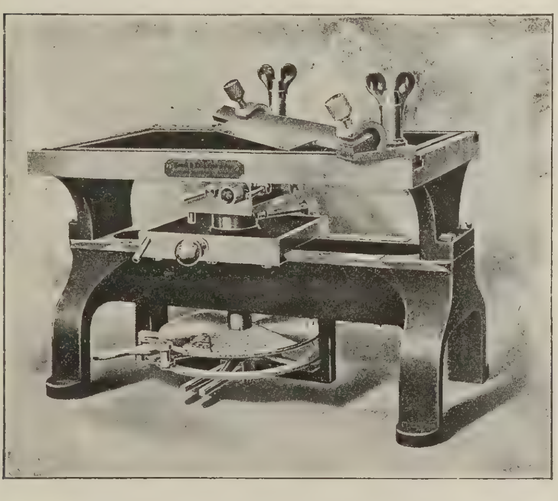

FIG. 2681.—Minot Automatic Precision Microtome.

The "Precision" microtome of Minot (Fig. 2681) is a departure from the usual form of sliding microtome in that the knife is fixed and the object clamp is on a sliding carrier.

The knife is clamped to the frame of the microtome, and the object clamp carrier runs on slides under the knife. There is an automatic feed attachment that may be regulated so that sections from 1 to 60 μ in thickness may be cut. This microtome may be used for celloidin or paraffin preparations.

The older form of Minot's rotary microtome for paraffin sections has also been improved (Fig. 2682). The old feed arrangement has been replaced by a large-toothed wheel attached to the micrometer screw. This wheel has five hundred teeth, and the micrometer screw has a pitch of 0.5 mm., so that each tooth of the wheel equals a feed of 1 μ. The feed of the micrometer screw is controlled by an adjustable cam, so that the thickness of section may be made to vary from 1 to 25 μ.

An adjustable carrier (Fig. 2683) for serial ribbons may be attached.

Microtome Knives.—The usual form of microtome knife is shown in Fig. 2684. Its upper surface is concave, its under one flat. Its cutting edge is of a double chisel form, and must be perfectly straight. The knife should be heavy and its length adapted to the size of the microtome used.

A knife for cutting paraffin should be heavier than one used for celloidin.

In order to obtain good sections the cutting edge of he knife must be kept in the best possible condition. This is accomplished by stropping the knife frequently and honing it occasionally.

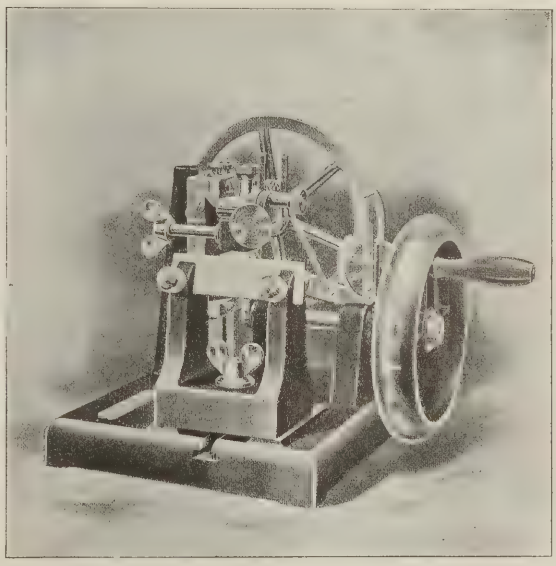

FIG. 2682.—Improved Rotary Microtome of Minot.

For honing, a yellow Belgian hone of large size is to be used. Its surface is thoroughly covered with a lather made with a pure soap and water. This lather is better than oil as it keeps the pores open and gives a better grinding surface. In honing, one of the backs (Fig. 2684) is fastened to the knife. This is for the purpose of keeping the angle of the edge of the knife constant. The knife is first sharpened on its concave side, then turned and sharpened on the flat side. The pressure on the knife should be light; it should be drawn across the hone from heel to toe, the edge being drawn against the surface of the hone. The movements are illustrated in Fig. 2685.

For stropping the best form of strop is that known as the bow strop (Fig. 2686). The movements of the knife are the reverse of those of honing, and are shown in Fig. 2686. After use the knife should be carefully dried with a soft cloth.

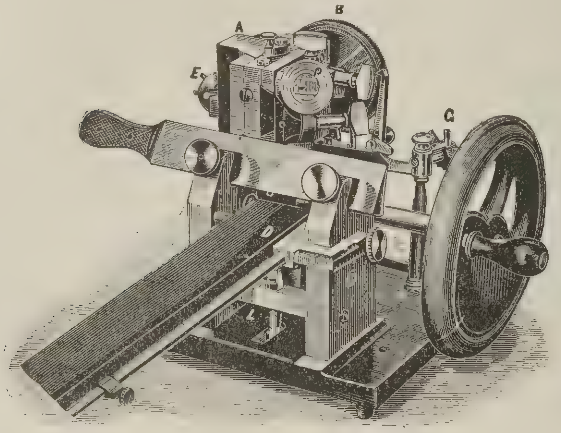

FIG. 2683.—Showing Carrier for Ribbon Sections Attached to Minot's Rotary Microtome (Old Form).

After the sections are cut they are removed from the microtome knife with a camel's-hair brush and placed in a dish of fluid. For sections of fresh tissue and frozen sections, salt solution should be used, the sections being submerged in it; for sections of alcoholic specimens, alcohol or water may be used.

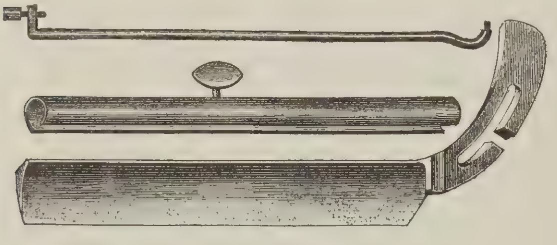

FIG. 2684.—Microtome Knife with Two Forms of Backs used in Honing and Stropping.

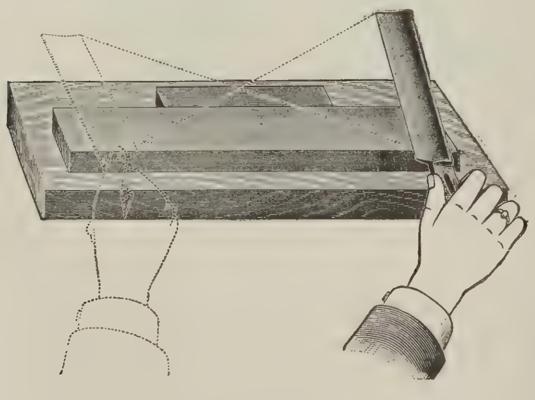

FIG. 2685.—Showing the Movements of the Knife in the Process of Honing.

In the further manipulation of the sections great care must be taken or they will be destroyed. For transferring them from the different reagents, stains, etc., a needle, camel's-hair brush, or nickel-plated steel spatula (Fig. 2687) must be used. In the majority of cases the latter instrument will be found most convenient. It is placed cautiously under the section floating in the fluid, gently raises it, and transfers it to a second vessel of fluid or to a slide.

When sections are transferred from alcohol to water, they spin about in a lively manner and finally spread out into thin laminæ. This is caused by the rapid diffusion of the alcohol.

Sections can be preserved indefinitely in eighty- to eighty-five-per-cent. alcohol.

Serial Section Cutting.—The preparations to be cut are to be embedded in paraffin. The melting point of this must have a certain relation to the laboratory temperature. A laboratory temperature of 17° C. requires a paraffin melting at 45° C. At a temperature of 15° C. this paraffin would be too hard. At 22° C. a paraffin melting at 48° C. will be required.

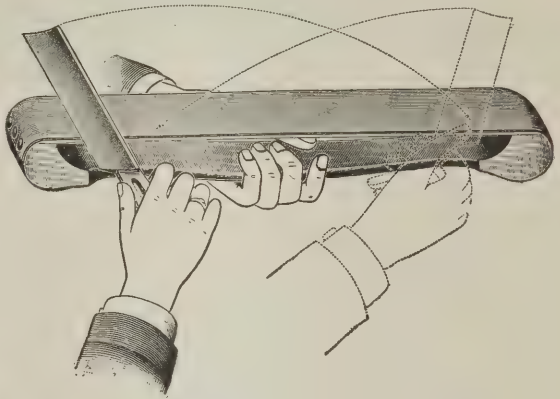

FIG. 2686.—The Bow Strop, and the Mode of Stropping.

After impregnation the specimens are embedded by one of the methods described under paraffin embedding.

The block of paraffin should be pared down close to the specimen, and should be cut so as to present a straight edge parallel to the edge of the knife, and the opposite edge parallel to this. If this precaution is not taken the sections will not adhere, and will not pass off in a straight line.

The sections can be cut on any sliding microtome, provided the knife be set square. Several special microtomes have been constructed for this kind of section cutting, viz., Caldwell's automatic microtome, Cambridge rocking microtome, and Minot's automatic wheel microtome.

The sections are fixed upon a slide by one of the following methods:

Water Method: The ribbons of sections are cut to proper lengths and floated on warm water, warm enough to soften the paraffin, but not to melt it, when the sections will flatten out. They are then floated on a slide and arranged in position. The slide is then drained and allowed to become perfectly dry. To hasten the drying the slides may be placed in a water-oven at a temperature of 40° C. The paraffin must not be allowed to melt until the sections are perfectly dry. When perfectly dry the sections adhere to the slide, when the paraffin is melted and washed off with xylol.

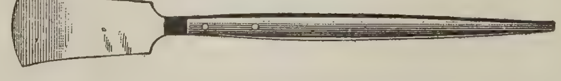

FIG. 2687.—Spatula.

Mayer's Method: Paint a mixture of equal parts of filtered white of egg and glycerin (and a few drops of carbolic acid as a preservative) on a slide with a camel's-hair brush, and arrange the sections with this; then warm the slide on a water bath for a few moments until the paraffin is melted. As the paraffin in the sections melts it carries the albumen away from them. The paraffin is next to be dissolved out with turpentine or xylol, the latter removed with alcohol, and the sections stained.

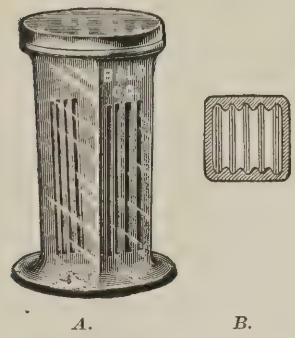

FIG. 2688.—Staining Jar for Serial Sections Mounted on Slides.

Schällibaum's Method: Mix one part of collodion with three or four parts of oil of cloves and shake well. Spread this solution in a thin layer, with a brush, on a slide; arrange the sections and evaporate them by gentle heat on a water bath. Then dissolve out the paraffin with xylol. The sections thus fixed may be stained in the usual way and mounted in balsam or glycerin.

Serial Sections of Celloidin-Embedded Specimens. — 1. Prepare a series of glass plates; coat these with a thin layer of celloidin, as a photographer makes a moist plate, and allow them to dry.

2. Make sections and arrange ribbon-wise on strips of transparent porous paper, which should be double the width of the sections. Keep the strips, with the sections on them, moist by placing them on blotting paper in a dish with alcohol.

3. Transfer the sections to the celloidin-coated plate. Lay the strips, section side down, upon the glass plates, press them softly, and peel off the paper; remove all superfluous fluid with filter paper, taking care not to dry the sections.

4. Cover the sections with a thin layer of celloidin. When dry, the celloidin may be marked with a brush dipped in methyl blue, so that the series may be recognized.

5. Immerse the plates in water, and the celloidin will peel off from them, and we shall have the sections enclosed between two layers of celloidin, allowing them to be handled like a rag.

6. The celloidin plate may be cut up into as many pieces as there are sections, or it may be stained uncut and mounted in the usual way.

Staining.—The tissues may be stained *in toto* before being embedded in paraffin or after they are fixed to the slide. The latter is the method generally adopted, as a greater variety of stains may be employed.

In Fig. 2788, *A*, is shown a staining jar for holding ten slides. In *B* is shown a transverse section of the jar. The sides of the jar are grooved, the width of the groove being such that two slides, back to back, may be placed in it. These jars may also be used for dissolving out the paraffin, dehydrating, clearing, etc.

Born's Method of Reconstructing Objects from Microscopical Sections.—By the aid of a camera the outlines of the sections are transferred to wax plates, which are then cut out so as to correspond in outlines as well as in dimensions to the sections equally magnified in all three directions.

He makes three rectangular boxes of tin, 270 mm. × 230 mm. × 2.5 mm. The sections should be 0.04 mm. thick (never thinner than 0.02).

If we wish to construct a model of a specimen from sections $\frac{1}{30}$ mm. thick and magnified sixty diameters, the wax plates must be 2 mm. thick. Such a plate made in a box of the above dimensions contains 62.1 mm.; and its volume will be 124.2 mm. The specific gravity of beeswax is 0.96 to 0.97. It is melted with a small quantity of turpentine, which reduces its specific gravity to about 0.95; and the weight required to make one plate of the above size is, in round numbers, 118 gm. This quantity of wax is weighed out and melted. The tin box is filled 1.5 cm. deep with boiling water and the melted wax poured upon it. As soon as the plate has begun to stiffen, and while it is still soft, it should be cut away from the edges of the box, and, when the water has become tepid, removed to a flat support to stiffen.

For drawing the outlines of the section a piece of blue paper is placed, colored side down, upon the wax plate, and over this an ordinary sheet of drawing paper. The outlines are drawn on the latter, by the aid of a camera, and at the same time blue lines are traced on the wax. Then, with a small knife, the wax is cut out, the outlines being followed, the plates are placed together in the proper order, and fastened by passing the warm spatula along the edges.

METHODS OF EMBEDDING.—This process is divided into two classes: simple embedding, when the specimen, being small, cannot be held conveniently in the hand or clamped in the microtome, and is simply surrounded with an embedding mass to give it bulk; interstitial embedding, or impregnation, when the specimen is permeated with the embedding mass. The latter process is used when we have a specimen that lacks the necessary consistence for cutting (lung, etc.); or when the specimen contains cavities, the contents of which we wish to retain in their normal condition and position; or when the specimen is so brittle that it would be destroyed in the process of cutting.

Melted Masses.—Simple embedding in a melted mass (paraffin) is performed as follows: A small box is placed on a cork, and the specimen is placed in it and fixed in position by means of pins. The box is now filled with the melted mass and allowed to cool—when the pins and papers are removed, leaving the specimen enclosed in a solid block of the embedding material. Or a block of the embedding mass is taken, and a hole, a little larger than the specimen, is scooped out of one face; the specimen is washed in a melted mass of the same material and placed in the cavity, which is then filled.

The embedding boxes are made of paper. A plan which I have found very convenient is to have a series of wooden blocks, the faces of which correspond to the sizes of the boxes to be made. One of these blocks is taken, and the paper is folded over the face corresponding to the size of box wished for.

In Fig. 2689 is shown an adjustable metal embedding box for paraffin. It consists of two pieces, having the form of a carpenter's square—the long arm being 7 cm. the short 3 cm. in length, by 7 mm. high. On the outer side of the short arm is a block of metal, on the top of which is a spring (*a*, Fig. 2689), which curves over and presses against the long arm, thus holding the two pieces firmly together. The area of the box will vary with the position of the pieces. The area of the box having been fixed, it is placed on a glass plate, moistened with glycerin, and a thin layer of the melted mass poured in. When it has cooled, the specimen, which has been washed in the same material, is fixed in position and the box is filled up. When the embedding mass has cooled the box is removed, and the specimen will be found embedded in a solid block of the material.

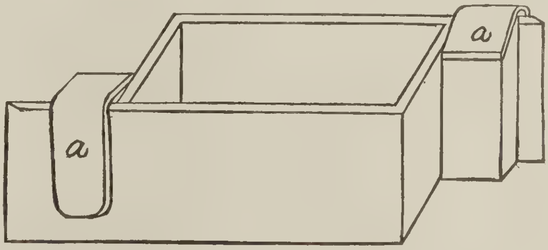

FIG. 2689.—Adjustable Embedding Box.

In manipulating with melted embedding masses, it is necessary to have a constant and comparatively low temperature, as in many cases the specimen has to be soaked in the melted mass for a considerable length of time (impregnation method). Two forms of water baths for this purpose are shown in Fig. 2690.

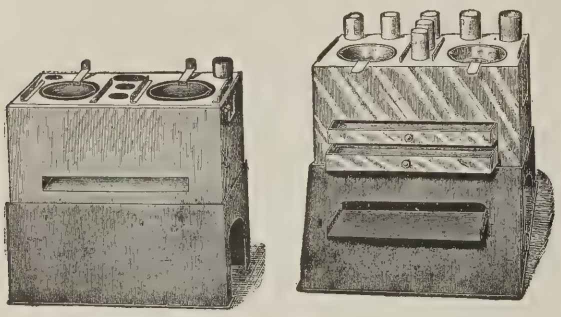

FIG. 2690.—Paraffin Water Baths.

Impregnation Embedding.—In this process the specimen is soaked in the embedding mass until it is thoroughly permeated with it. The proceeding is then like simple embedding in a melted mass.

Embedding Masses: Celloidin.—This is a pure pyroxylin, manufactured by Schering & Company, Berlin; it is free from all foreign constituents, and makes a clear solution without sediment. It is soluble in a mixture of equal volumes of alcohol and ether, and the degree of concentration can be varied to suit any particular case.

For use, a five-per-cent. solution of celloidin is made in alcohol and ether, and a portion of this is diluted with a mixture of equal parts of alcohol and ether, so as to obtain a very dilute solution. The specimen is soaked in alcohol for twelve hours; then in alcohol and ether for the same length of time; then in the dilute celloidin for at least twelve hours; then in a five-per-cent. solution for one to eight days, according to the size and density of the specimen. When the specimen has become thoroughly permeated it is to be embedded in one of the following ways:

(*a*) Cover the smooth surface of a vulcanite block with a thick layer of celloidin solution and allow it to dry. Then place the specimen, which has been soaked in celloidin, on this and cover it, layer by layer, with a solution of celloidin, allowing each layer to dry partially before applying another. When the specimen is completely covered allow it to stand in the air for half an hour, and then immerse in eighty-per-cent. alcohol for twelve hours, when it will be ready for cutting.

(*b*) Embed in a paper box in the usual way, and allow the mass to stand until a pellicle forms on the surface; then immerse in eighty-per-cent. alcohol for twenty-four hours.

Viallanes uses chloroform for hardening the celloidin. He has found that this reagent coagulates the celloidin into a mass of the consistence of wax, but very elastic and perfectly transparent. He places specimens, previously soaked in ether, in a test-tube and covers them with a solution of celloidin. As soon as a film has formed on the celloidin, the tube is filled up with anhydrous chloroform and left for two to three days, when the mass will be hardened and somewhat shrunken, so that it can be shaken out of the tube. It is then placed in fresh chloroform for six days, when it will be ready for cutting. A. B. Lee found that a few hours' immersion in the chloroform gave the required consistence, and in no case was a longer time than three days required. The celloidin frequently becomes opaque on being put into the chloroform, but becomes transparent after a time.

Oil of Cloves Celloidin (Stepknow).—Celloidin (granular form), 1.5 gm.; oil of cloves, 5 c.c.; ether, 20 c.c.: absolute alcohol, 1 c.c.

The specimen, after being dehydrated in ninety-five-per-cent. alcohol, is placed in oil of cloves for from three to six hours; then in the above solution of celloidin for six hours. Then it is embedded, preferably, in a paper box, and allowed to stand in a warm place until the celloidin thickens; then placed in eighty-per-cent. alcohol or chloroform for from one to two hours.

In case the tissues can be cut into rectangular-shaped blocks they are mounted on blocks of vulcanite and then placed in chloroform.

Sections are cut with a knife wet with alcohol, and may be stained with the usual staining agents. Some of the aniline dyes stain the celloidin intensely, and are not removed by alcohol. If sections are to be mounted in Canada balsam, they are dehydrated in ninety-five-per-cent. alcohol — absolute alcohol dissolves celloidin — cleared in oil of bergamot, sandalwood, or origanum, as oil of cedar or cloves dissolves celloidin.

Paraffin.—For embedding, paraffins of a melting point of from 45° to 55° C. are used. By mixing these in various proportions, masses may be obtained whose melting point will range between these two. Paraffin should be chosen of a melting point suitable to the temperature of the laboratory. As a rule, a laboratory temperature of 18° C. requires a paraffin whose melting point is 48° C.

The specimen to be embedded is placed, from alcohol, in chloroform until the alcohol is replaced by the latter; this takes place quickly. The specimen is then removed to a dish containing fresh chloroform and shavings of paraffin are added, so that after the evaporation of the chloroform the specimen will remain covered by the paraffin. The vessel is now placed in a water bath (see Fig. 2690), at the temperature of the melting point of the paraffin, for from one-half to one hour. The paraffin melts very quickly, and the specimen, from the evaporation of the chloroform, is bathed in a concentrated solution of paraffin in chloroform, which soon penetrates the specimen, filling up all cavities. It is essential that all the chloroform should be driven off. When this has taken place, the specimen is embedded in a box in the usual manner and allowed to cool. After cooling, the block should be trimmed and clamped in the microtome, or mounted on a cork with a little melted paraffin.

A. B. Lee recommends that the specimens be soaked in oil of cedar. This clears them rapidly, and the paraffin penetrates quickly and thoroughly.

Sections are to be cut dry. If they have a tendency to roll, they can be held down by a camel's-hair brush, or by attaching a section-smoother to the knife. After cutting, the embedding mass is to be dissolved out before staining. For this purpose, of the many solvents recommended, turpentine, naphtha, and xylol are the best.

METHODS OF STAINING.—As a rule, the sections to be stained are placed in the staining fluid from water, and allowed to remain in the former for various lengths of time—from a few seconds to twenty-four or forty-eight hours. The time depends on the nature of the stain and the result to be accomplished, and will be noted under

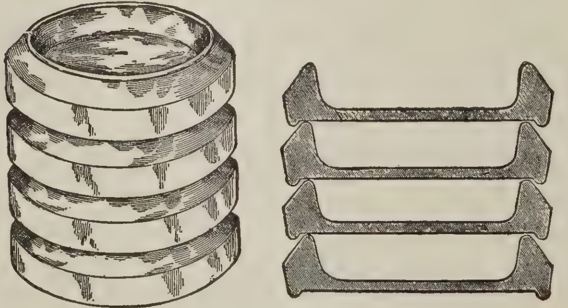

FIG. 2691.—Improved Syracuse Solid Watch Glass.

the various stains. After the staining is complete, the sections are to be washed in water, to remove all the excess of the staining fluid, mounted directly in glycerin, or, after dehydrating and clearing, in balsam.

For holding the stains and for the operations of washing, dehydrating, etc., we use small dishes of porcelain or glass, watch glasses, etc. The improved form of the Syracuse solid watch glass (Fig. 2691) will be found very convenient. For transferring the sections, the spatula or lifter (Fig. 2687), needles, camel's-hair brushes, glass rods, etc., are used.

Innumerable substances are used for the purpose of staining, and each year adds a host to the list, many of which are of doubtful value. Only the most important stains will be treated of here.

Carmine.—This dye, when first introduced, was used in the form of an ammoniacal solution, and is still, but rarely, employed in this form. Ammonia solutions are not stable; they undergo various chemical changes upon standing, so that the solution cannot be depended upon. Unless all free ammonia is driven off, the staining is apt to be diffuse. Various other solvents are now used with better results.

Tissues that are to be stained with carmine must be free from acid. Preparations hardened in chromic acid or solutions of chrome salts, must be well washed in water, and then they stain very slowly, requiring days. Obersteiner hastens the process of staining by heating the fluid to 50° C., and keeping it at that temperature for an hour, when the staining will be completed. Henle and Merkle soak sections in a 1 to 500 aqueous solution of palladium chloride for ten minutes; then in the carmine fluid for a few moments, when they become stained of a deep-red color. If the stain is diffuse it can be removed by placing the sections in a mixture of one part of formic acid and two parts of alcohol for from five to ten hours. This removes the stain, in sections of the central nervous system, from everything except the axis cylinders (Ranvier).

Before mounting, sections stained in carmine should be washed in a one-per-cent. solution of acetic or formic acid to fix the stain.

Carmine stains deeply nuclei, protoplasm, smooth and striated muscle, the basement substance of bone tissue and decalcified bone, the axis cylinders of nerves, etc.

Ammonia Carmine Solutions.—Ranvier's: Carmine, 1 gm.; ammonia, 1 c.c.; water, 100 c.c. Rub up the carmine in a mortar with a little water and add the ammonia. When the carmine is all dissolved add the rest of the water. If there is an excess of ammonia heat the solution until the carmine begins to precipitate.

Heidenhain's: Carmine, 1 gm.; ammonia, 3 c.c.; glycerin, 96 c.c.; water, 96 c.c. Dissolve the carmine in the ammonia and add the glycerin and water. Heat on a water bath until the excess of ammonia is driven off, or neutralize with acetic acid. The sections are placed in a watch glass of this fluid, and this, with a second watch glass containing water with a trace of ammonia, is placed under a bell glass for twenty-four hours. The sections at the end of this time are washed in water and exposed, as above, to the vapor of acetic acid, and mounted in glycerin.

Borax Carmine.—Grenacher's: The author gives two formulæ. In the first he dissolves 2 to 3 gm. of carmine in a solution of 4 gm. of sodium biborate in 100 c.c. of distilled water and then adds 100 c.c. of alcohol; filters, and after allowing the filtrate to stand a week, filters again. This solution is used chiefly for staining *in toto.* Pieces of tissue, according to their size, are placed in the solution for from one hour to three or four days; then in acidulated alcohol (three to four drops of HCl to 100 c.c. of seventy-five-per-cent. alcohol) for from one hour to three or four days. His second formula, known as neutral borax carmine, is as follows: 0.5 to 0.75 gm. of carmine is boiled in a solution of 2 gm. of sodium biborate in 100 c.c. of water. The solution is filtered, and acetic acid added to the filtrate until the purple tint changes to that of ordinary carmine; it is then filtered again. Sections stain in this fluid, in from one to three minutes, an intense and diffuse red color; they are then washed in a mixture of one drop of HCl to a watch glass of seventy-per-cent. alcohol, when the color is withdrawn from everything except the nuclei.

Lithium Carmine.—Oth's: Carmine, 2.5 gm.; saturated solution of lithium carbonate, 100 c.c.

After staining, the sections are washed in a mixture of 1 c.c. of HCl, and 100 c.c. of seventy-per-cent. alcohol, when the color is withdrawn from all except the nuclei.

Picro-carmine.—Ranvier's: Add ammonia carmine to a saturated aqueous solution of picric acid, until a cloudy precipitate begins to appear. Evaporate to one-fifth of its original volume, allow to cool, and filter. Evaporate the filtrate to dryness, when a reddish powder is obtained. This powder is used in one-per-cent. solutions in water.

Gage's: Take equal parts, by weight, of carmine and picric acid. Dissolve the picric acid in one hundred times its weight of distilled water, and the carmine in fifty times its weight of strong ammonia, mix the two solutions, and evaporate three-fourths at a temperature of 40° to 50° C. Allow the fluid to cool, and filter through two thicknesses of paper. Evaporate the filtrate to dryness at a temperature of 40° C., and dissolve the residue in one hundred times its weight of water. Make 50 c.c. of such a solution and filter through absorbent cotton packed in the neck of a funnel; repeat the filtering four or five times, when a clear solution should be obtained. If this is not the case, dissolve the remainder of the powder in the proportion given above, allow the solution to stand for a few days in a tall glass cylinder, and then decant the clear fluid. When a clear solution is obtained, add to every 100 c.c. of the picro-carmine 25 c.c. of strong glycerin and 10 c.c. of alcohol. This solution can be kept clear by filtering once in six months.

Weigert's: Soak 2 gm. of carmine in 4 c.c. of strong ammonia for twenty-four hours in a closed vessel; then add 200 c.c. of a saturated solution of picric acid in water, and allow it to stand for twenty-four hours. Filter, and add acetic acid to the filtrate, drop by drop, until a slight precipitate appears even after stirring. Allow this mixture to stand for twenty-four hours, when a precipitate will form which cannot be wholly removed by filtering; add ammonia, drop by drop, at intervals of twenty-four hours, until a clear fluid is obtained. If the solution stains too yellow, add a few drops of acetic acid; if too red, a few drops of ammonia.

Hoyer's: Dissolve 1 gm. of carmine powder (see Hoyer's Carmine) in 5 to 7 c.c. of ammonia and 1 to 5 gm. of picric acid in 50 c.c. of water. Mix the two solutions, and add enough water to make the mixture measure 100 c.c., and add 1 gm. of chloral hydrate for preserving. If any free ammonia is present, warm on a water bath until it is driven off.

Oth's: Mix one part of Oth's lithium carmine with two to three parts of a cold-saturated solution of picric acid in water.

Sections stained in picro-carmine should not be washed long in water, or the picric acid stain will be washed out. They may be mounted in balsam or glycerin; if the latter, the glycerin should be acidulated with a few drops of acetic or formic acid.

Alum Carmine Solutions.—Grenacher's: Boil one-half to one per cent. of carmine in a concentrated solution of ammonia or potash alum for from ten to twenty minutes, filter, and add a few drops of carbolic acid to the filtrate. Balbiani adds a few drops of acetic acid to a watch glass of this stain with good results. Tizzoni adds a little sodium sulphate, thereby increasing its staining power. This fluid stains quickly, and nuclei stronger than other parts.

Cochineal Fluids.—Mayer's: Soak 1 gm. of powdered cochineal in 10 c.c. of seventy-per-cent. alcohol, for at least three days. Filter, and use the deep-red filtrate for staining. Sections are placed in this fluid from seventy-per-cent. alcohol, and they stain in a few moments, or it may require several days, the time depending on the size and nature of the sections. When stained, wash in seventy-per-cent. alcohol until no more color comes away; then mount in the usual media. The results obtained by the use of this fluid vary with the nature of the tissue, and the presence or absence of certain salts—also upon the strength of the alcohol employed for solution. Overstaining may be removed by washing in one-tenth-per-cent. HCl, or one-per-cent. acetic acid.

Czoker's Alum Cochineal.—Boil 7 gm. of pulverized cochineal and 7 gm. of alum in 700 c. c. of distilled water, until the quantity of fluid is reduced to 400 c.c.; cool, add a few drops of carbolic acid, and filter. After allowing it to stand for a few days, filter again, when the fluid will be ready for use. Martinotti recommends the use of chrome alum in place of ordinary alum, and does not allow the temperature to go above 80° C. This fluid stains nuclei a hæmatoxylin color, other elements different shades of red. Alcoholic specimens stain quickly, in from three to five minutes; chromic-acid preparations require from three to five hours. After staining, specimens are washed in water and mounted in the usual media.

Carminic Acid.—The use of carminic acid in place of carmine was first suggested by Dimmock, but he used only aqueous or alcoholic solutions which gave but feeble stains. Mayer showed that in order to obtain suitable staining solutions of carminic-acid it must be combined with aluminum or calcium. I have found that the substitution of carminic acid for carmine in most of the formulæ given above makes a much better and sharper staining fluid.

Carmalum (Mayer).—Carminic acid, 1 gm.; alum, 10 gm.; distilled water, 200 c.c. Dissolve the carminic acid in the water and filter. Add a few crystals of thymol to prevent the formation of mould. After staining, wash out in distilled water, and if the plasma remains stained, wash in alum solution. This is a good fluid for staining tissues in bulk.

Hæmatoxylin.—This is one of the coloring substances contained in ordinary logwood. It is found in commerce in the form of reddish-brown crystals. Hæmatoxylin is not to be confounded with the ordinary crude extract which is sometimes sold under this name.

This dye is one of the best nuclei stains that we have, staining both alcoholic and chromic-acid specimens deeply and sharply. In chromic-acid preparations the color is likely to fade after a time, unless all the acid has been removed and the sections have been thoroughly dehydrated before mounting.

The clearest stainings are obtained with dilute solutions. After staining, the sections are washed well in water and mounted as usual.

Delafield's Solution: Saturated solution of ammonia alum, with an excess of crystals, 100 c.c.; to this is added 1 gm. of hæmatoxylin crystals dissolved in 6 c.c. of alcohol. This solution is allowed to stand in an unstoppered bottle in the light for four or five days, and then filtered. Then glycerin, 25 c.c., and wood naphtha, 25 c.c. are added; this is allowed to stand, as above, for from one to two days, and then filtered; the filtering is to be repeated at intervals, until all sediment ceases to form. It is to be diluted at least one-half with water for use.

Ehrlich's Acid Hæmatoxylin: Hæmatoxylin crystals, 1 gm.; strong alcohol, 60 c.c.; glycerin, 60 c.c.; water, 60 c.c., to which ammonia alum is added to saturation; hydric acetate, glacial, 3 c.c. This fluid is exposed to the light until it becomes of a deep-red color.

Gage's Hæmatoxylin: Distilled water, 200 c.c.; ammonia or potash alum, 7.5 gm.; this is boiled for five to fifteen minutes to destroy any germs in the water or alum; after cooling add 0.1 gm. of hæmatoxylin crystals dissolved in 10 c.c. of ninety-five-per-cent. alcohol and 4 gm. of chloral hydrate to prevent the development of germs.

For staining, this solution may be used full strength or diluted with alum water.

Up to a few years ago all formulæ for the preparation of hæmatoxylin solutions, especially those containing alum, ended with the following directions: "allow to stand in the light from eight to ten days before using." This was for the purpose of allowing the staining fluid to "ripen," as it is well known that freshly prepared solutions are of no use for staining.

This "ripening process" was found to be due to the oxidation of the contained hæmatoxylin and the formation of *hæmatein,* through the absorption of oxygen from the air. Paul Mayer and Unna found that this oxidation could be brought about immediately by the addition of a small quantity of hydrogen peroxide; Hansen, by the addition of potassium permanganate. I have hastened the process by passing air through the solution, using air compressed by the usual spray apparatus.

All hæmatoxylin solutions deteriorate in the course of time, the oxidation process continuing until precipitates form and the solution becomes colorless. Unna found that this over "ripening" could be delayed by the addition of a small quantity of sulphur. Paul Mayer used glycerin, and Gage, believing this to be due to the action of bacteria, sterilized his alum solution and then added chloral hydrate as a preservative. Owing to the investigations of Paul Mayer we are now in a position whereby *hæmatein* staining solutions can be quickly made, without the long "ripening" process.

Hæmatein, which Mayer uses in place of hæmatoxylin, comes in the form of dark greenish crystals or powder, and is freely soluble in alcohol and water. The commercial form is not always pure, and owing to this *hæmateate of ammonia* has been recommended in the place of hæmatein. This salt is also found in commerce, but of doubtful purity. It can be readily made in the laboratory as follows: One gram of hæmatoxylin crystals is dissolved, by the aid of heat, in 20 c.c. of distilled water and filtered. To this solution 1 c.c. of ammonium hydrate (sp. gr. 0.875) is added, and the dark purple fluid placed in a shallow porcelain dish, of such a size that the layer of fluid shall not exceed one-half a centimetre in depth. The dish is covered with filter paper, to exclude dust, and the solution is allowed to evaporate at the room temperature. The hæmateate of ammonia about equals in weight the hæmatoxylin used. In the preparation of this salt no metal instruments should be used until the powder is absolutely dry.

Mayer gives formulæ for three different solutions of hæmatein as follows:

Hæmalum.—Dissolve 1 gm. of *hæmatein* or *hæmateate of ammonia* in 50 c.c. of ninety-per-cent. alcohol, and add this to 1,000 c.c. of a five-per-cent. aqueous solution of *potash alum,* filter, and add a crystal of thymol to prevent the formation of mould. This fluid has a color resembling that of borax carmine. It may be used for staining in full strength, or it may be diluted with weak alum solution. In full strength it stains sections in about two minutes.

Acid Hæmalum.—This is prepared by adding two per cent. of hydric acetate to the above hæmalum solution. After staining, wash well in water to bring out the bluish tint of the nuclei. This solution is decidedly less diffuse in staining, and keeps better than the hæmalum.

Glycerin Hæmalum.—The above solutions of hæmatein do not keep well. To correct this, Mayer adds glycerin as a preservative. The solution is made as follows: Rub up 0.4 gm. of hæmatein in a mortar with a small quantity of glycerin; dissolve 5 gm. of potash alum in 70 c.c. of distilled water, and add 30 c.c. of glycerin. This mixture is gradually added to the hæmatein solution. This stain keeps well, but is somewhat slow in its action.

During the last year I have been using *hæmatein* in place of hæmatoxylin with the most satisfactory results. The staining fluid I have used is one made after a combination of Mayer's and Gage's methods. The solution is made as follows: A five-per-cent. solution of potash alum is made in distilled water and boiled, or what is better, placed in a steam sterilizer from one to one and a half hours. While this solution is warm, 0.001 per cent. of *hæmatein,* dissolved in a small quantity of alcohol, is added (it is my practice to keep a one-per-cent. alcoholic solution of hæmatein as a stock solution). After the fluid has cooled, 2 gm. of chloral hydrate should be added for each 100 c.c. of the staining fluid. This stain keeps well, and in full strength stains sections in from two to three minutes. It may be used diluted with distilled water, when the staining requires a longer time.

Heidenhain's Iron Hæmatoxylin.—Sections are placed in a 1.5 to 4 per cent. aqueous solution of ammonio-ferric sulphate, $(NH_4)_2,Fe_2,(SO_4)_4$, for from one-half to four hours; then they are washed in water; and then stained in a 0.5-per-cent. solution of hæmatoxylin in water for half an hour. They are then removed from the stain and washed in water. The sections which are now deep black are decolorized in the ammonio-ferric sulphate solution. This acts slowly and its progress should be watched under the microscope. This is done by removing the specimens, from time to time, from the decolorizer and examining them in water. As soon as a proper differentiation has been obtained the sections are washed in water for at least an hour, the water being changed several times. All chromatin elements of the nucleus stain black and are sharply differentiated.

ANILINE DYES.—*Fuchsin, Rosaniline Hydrochloride.*—Soluble in alcohol and water. Used for staining fresh tissue, blood cells, and connective-tissue cells. Chiefly used for staining bacteria. Merkle has used it for staining the structureless membrane of the retina.

Acid Fuchsin, Rosanilin Sulphonate.—(Fuchsin S, No. 130 of the Baden aniline factory.) First used by Weigert for staining the central nervous system, and now used chiefly in combination stains.

Safranin.—An oxidation product of pure toluol, of which there are numerous preparations on the market. The form usually used is safranin O, which is soluble in alcohol and water. This is a nuclei stain best suited for chromic-acid preparations.

Flemming dissolves one-tenth to five-tenths per cent. in a mixture of equal parts of alcohol and water. He stains sections for twenty-four hours; washes in weak alcohol, which frees them from part of the color, then in absolute alcohol until no more color comes away; then in oil of cloves only long enough for them to become penetrated, as it extracts the colors; mounts in balsam.

Babes recommends the following methods:

1. Sections of alcoholic or chromic-acid preparations are stained for half an hour in a warm, concentrated aqueous solution of safranin, or in a mixture of equal parts of concentrated aqueous and concentrated alcoholic solutions. They are then washed in absolute alcohol quickly, as it withdraws the stain, cleared in turpentine, and mounted in balsam.

2. For demonstrating the details of cell structure. A supersaturated solution of safranin in water is warmed to 60° C. and filtered. After cooling the solution becomes muddy. A small quantity of this fluid is placed in a watch glass with the sections, and warmed slightly over an alcohol lamp for a minute, when the fluid will become clear. The sections are then washed in water, cleared in turpentine, and mounted in balsam.

Safranin is also a good reagent for amyloid substance, staining it orange-yellow, other tissue rose-red. It is also used for staining elastic fibres.

Eosin (Erythrosin, Primrose).—This dye is found in commerce in two forms, one soluble in alcohol (tetrabromofluorescin), the other in water (a potash salt of the first).

Fischer, who first introduced the dye, precipitates the coloring matter from an aqueous solution with an acid; filters, washes the precipitate with water, and then dissolves the precipitate in alcohol. He prefers the alcoholic solution for chromic-acid preparations.

Eloui dissolves the eosin in glycerin, and after staining, fixes the dye with a saturated solution of alum in glycerin.

For general use a 1 to 1,500 solution in alcohol of the precipitated eosin will be found most convenient. Sections are stained for a few moments and mounted in glycerin tinged with eosin, as pure glycerin withdraws the color. For mounting in balsam the sections are dehydrated in the alcohol eosin and cleared in oil.

This dye, in combination with hæmatoxylin, is the best for general work, the hæmatoxylin staining the nuclei of the cells purple, while the cell bodies and intercellular substance are stained rose-red.

Methylene Blue.—An oxidation product of pure aniline, soluble in both alcohol and water. It is used chiefly for staining bacteria: in combination with eosin as a nuclear stain; in a chemically pure state in Ehrlich's method for nerve fibres; and in Nissl's stain for nerve cells.

Unna's Alkaline Methylene blue.—Methylene blue, 1 gm.; potassium carbonate, 1 gm.; water, 100 c.c. This solution is diluted in the proportion of 1 to 10 with water for use. It is a good nuclear stain in combination with eosin.

Methyl Green.—The double zinc salt of the base pentamethyltri-p-amidotriphenylcarbinolmethylate. Used in one-per-cent. aqueous solutions, and is chiefly a nuclei stain.

Carnoy employs it in a concentrated aqueous solution, to which is added one per cent. of acetic acid and one-tenth per cent. of osmic acid for staining fresh tissue. Nuclei stain sharply. The excess of color is washed out with water.

Curshmann recommends this dye as a reagent for amyloid, which it stains violet. It is also used in several of the multiple stains.

Iodine Violet, Hoffman's Violet (*a*, Dahlia, bluish tint; *b*, Primula, reddish tint). The pentamethyltriamidotoluyldiphenylcarbinol.

Ehrlich employs a saturated solution in a mixture of 500 c.c. of alcohol, 100 c.c. of water, and 12.5 c.c. of acetic acid. He stains sections for twenty-four hours; then washes in water acidulated with acetic acid, and mounts as usual. Protoplasm and connective tissue are partially stained; nuclei stain blue-violet. Sometimes the fat of fat cells and goblet cells stain.

Jürgens employs an aqueous solution as a reagent for amyloid, which stains bright red, while the rest of the tissue stains blue-violet.

Flemming employs the dye in the same manner as safranin.

Gentian Violet.—Employed chiefly for staining bacteria.

Methyl Violet.—The pentamethyltriamidotriphenylcarbinol.

Cornil found that aqueous solutions stained the cells of hyaline cartilage violet, the basement substance reddish, connective tissue, fibrillated and elastic fascia violet.

This dye is also used as a reagent for amyloid, which it stains red. According to Capparelli this reaction is an optical instead of a chemical one. He examined unstained sections by light transmitted through a thin layer of this dye and found that the amyloid substance appeared as if had been stained. He then examined unstained sections on glass stained with the colors of the spectrum, and found that in the section on the violet the amyloid substance appeared red, while the normal tissue appeared blue. His conclusion was that the amyloid substance permits the red rays to pass, but stops the violet.

This dye is also used in staining bacteria.

DOUBLE STAINING.—*Hæmatoxylin and Eosin.*—Sections are first stained in a solution of hæmatoxylin until they are of a distinct purple color, then washed well in water, and then stained in a dilute alcoholic solution of eosin. They can be mounted in either glycerin or balsam. If in glycerin, it is to be slightly tinged with eosin, or the color will be extracted from the specimen. If in balsam, the specimens are placed in alcoholic eosin, in which they become stained and dehydrated at the same time; then cleared in oil of origanum cretici, and then mounted in balsam or dammar. Nuclei stain purple, cell bodies and intercellular substance rose-red. This method is extremely useful for general work.

Eosin and Methylene Blue (Mallory).—Fix the specimens in mercuric chloride or Zenker's fluid.

Stain sections in a five to ten per cent. aqueous solution of eosin for from five to twenty minutes. Stain in Unna's alkaline methylene blue solution, diluted with from one to ten parts of water, for from one-half to one hour. Wash in water. Differentiate and dehydrate in ninety-five-per-cent. alcohol until the pink color returns in the sections. Clear in xylol and mount in xylol balsam or xylol dammar.

Nuclei stain blue, intercellular substance and cytoplasm red.

SPECIAL STAINS.—*Biondi-Heidenhain Triple Stain.*—Saturated aqueous solution of orange G, 100 c.c.; saturated aqueous solution of acid fuchsin, 20 c.c.; saturated aqueous solution of methyl green, 50 c.c.

Prepare the above solutions and let them stand for several days with an excess of the dyes. Then mix the solutions and dilute with water in the proportion of 60 c.c. of the staining solution to 100 c.c. of water. This dilute solution should redden upon the addition of hydric acetate; a drop of the mixture placed on filter paper should show a bluish-green centre and an orange periphery. If the orange zone is surrounded by a red zone, the mixture contains too much fuchsin.

Sections should be stained for from six to twenty-four hours. Those of tissues fixed in mercuric chloride give the best results. After staining wash in water; dehydrate in alcohol; clear in xylol; mount in xylol balsam or dammar.

Picro-Acid Fuchsin (Van Gieson).—Van Gieson introduced this stain for staining the peripheral nerves and sections of the central nervous system. His solution was not made up with any definite proportion of the acid fuchsin.

As the results of my experiments I have succeeded in establishing the following formulæ for the staining fluid: For connective tissue the proportions giving the best results are 5 c.c. of a one-per-cent. aqueous solution of acid fuchsin to 100 c.c. of a saturated aqueous solution of picric acid. For sections of the central nervous system the proportion of the acid fuchsin has to be increased and that of the picric acid diminished. The elements in this tissue stain more slowly, consequently the prolonged action of the picric acid removes the hæmatoxylin from the nuclei. The proportions of the staining agents that have given me the best results are 15 c.c. of a one-per-cent. solution of acid fuchsin to 100 c.c. of a half-saturated solution of picric acid.

Sections of tissues hardened in Müller's fluid or mercuric-chloride solutions—alcohol hardening does not give as brilliant results—are first deeply stained in hæmatoxylin (v. Kahlden recommends alum carmine) and then well washed in water. They are then placed in the picro-acid fuchsin fluid for from one to three minutes. Sections of the central nervous system require fully three minutes, those from other organs, as a rule, require only one minute. After the sections are removed from the staining fluid they are washed in two alcohols. I find that the addition of a small amount of picric acid to the second alcohol increases the brilliancy of the yellow stain. The sections are cleared in oil of origanum cretici and mounted in balsam.

This staining fluid, when used as above described, stains connective-tissue fibres a bright red; protoplasm, muscular tissue, and red blood cells, yellow. The hæmatoxylin stain in the nuclei is usually changed in color; sometimes it shows purplish-red, at other times black. Axis cylinders, nerve cells, and neuroglia fibres stain red.

Kantorwicz uses 150 c.c. of a saturated aqueous solution of picric acid and 3 c.c. of a saturated aqueous solution of acid fuchsin.

He stains sections in Delafield's hæmatoxylin for half an hour and then in the picro-acid fuchsin for from three to five minutes. He recommends the stain for cell inclusions.

Weigert's Stain for Elastic Fibres.—Boil basic fuchsin 2 gm., resorcin 4 gm., in 200 c.c. of water; while this is boiling add 25 c.c. of liquor ferri sequichlorati and continue the boiling for five minutes. Allow to cool and filter. The dark precipitate remaining on the filter is dissolved in 200 c.c. of strong alcohol by boiling the filter in it. Bring up the solution to 200 c.c. by the addition of alcohol; cool and add 4 c.c. of hydric chloride.

Stain sections for from one-half to one hour. Wash in strong alcohol until the color ceases to come away, then clear and mount in balsam.

Elastic fibres stain bluish-black.

Unna's Stain for Elastic Fibres.—Orcein (Grubler's), 1 gm.; hydric chloride, 1 c.c.; alcohol (absolute), 100 c.c. Sections are placed in the stain and warmed at a temperature of 30° C. for from ten to fifteen minutes. The stain becomes thick from the evaporation of the alcohol. Wash in seventy-per-cent. alcohol; dehydrate in strong alcohol; clear in oil of origanum, and mount in balsam. Elastic fibres stain a deep brown color. If a nuclear stain is wanted stain in Unna's polychrome methylene blue.

Weigert's Stain for Fibrin.—Stain sections of tissue fixed in alcohol or Zenker's fluid in aniline-gentian-violet solution for five minutes; place the sections on a slide and absorb the surplus stain with filter paper; then treat with iodine, 4 gm.; potassium iodide, 6 gm.; water, 100 c.c., for one minute; wash with water; decolorize in aniline, 2 parts, and xylol, 1 part, wash in several changes of xylol; mount in xylol balsam. The fibrin threads stain blue.

Jenner's Blood Stain.—Grubler's water-soluble eosin 1.2-per-cent. aqueous solution, 100 c.c.; Grubler's *pure* methylene blue, 1-per-cent. aqueous solution, 100 c.c. These solutions are mixed, allowed to stand for twenty-four hours, and then filtered. The precipitate is dried on the filter at 55° C., then washed with distilled water; dried and powdered.

For use, a 0.5-per-cent. solution of the dried powder is made in *pure methyl* alcohol. Cover-glass preparations and slide smears of blood are stained by immersing them in this solution for from three to five minutes; they are then washed in water; dried thoroughly in the air, and mounted in balsam.

METALLIC IMPREGNATIONS.—*Silver Nitrate.*—This is used chiefly for staining the cement substance between cells, especially the endothelium of serous membranes, lymphatics, and blood-vessels. It also stains the basement substance of connective tissue and cartilage. It may be used either in the solid state or in solution. The tissues to be acted upon must be fresh.

For membranes, silver nitrate is used in solutions of 1 to 300 to 1 to 500. The fresh membrane (omentum or mesentery) is carefully removed and stretched over the rim of a porcelain dish, filled with distilled water, and is allowed to sag in the centre so that both sides of the membrane will be immersed in the water; it is washed carefully by agitating the dish, so as to remove any blood or albuminous substance that may be on the surface. Now pour off the water carefully, and fill the dish with a 1 to 500 aqueous solution of silver nitrate. Agitate the dish frequently, and after from twenty to thirty minutes—when the membrane has become semi-opaque—pour off the silver solution and wash carefully with distilled water. Now transfer to a dish containing alcohol and water (1 to 2) and expose to the sunlight until it becomes of a brown color. This requires from twenty minutes to half an hour. Preserve in glycerin and protect from the light. The silver is deposited in the cement substance between the cells as an albuminate, and after being reduced by the action of the light, shows as fine black or brownish lines.

The cornea may be treated with silver in solution or in the solid state. In treating the cornea with the solid salt proceed as follows: Remove the eye and rub the anterior surface of the cornea with a piece of silver nitrate. Excise the cornea and place in distilled water; brush with a camel's-hair pencil to remove the epithelium. Then expose the cornea to the action of the light until it has become brown. Preserve in glycerin.

Silver in solution is applied as follows: Submit the cornea of a freshly killed animal to the action of a jet of steam, and scrape off the opaque epithelium, gently, with a scalpel. Allow a five-per-cent. solution of silver nitrate to flow over it, from a pipette, for two or three minutes; then wash with a one-per-cent. solution of sodium chloride; excise and expose to the light in a mixture of alcohol and water (1 to 2) until it becomes brown. Preserve in glycerin.

By these processes the basement substance becomes stained yellowish-brown, the cell spaces appearing as clear, irregular-shaped openings.

For injecting the blood-vessels, a fourth-per-cent. aqueous solution is used. The animal is bled to death, and the vascular system is washed out with distilled water;* this is followed by the silver solution, which is allowed to act for ten minutes and is then washed out with distilled water. Bits of thin membrane are removed and exposed to the light until brown, and then mounted in glycerin. In warm-blooded animals the solution should be heated to 30° C.; in cold-blooded animals the injection may be made at the ordinary temperature.

Hoyer adds to a solution of silver nitrate, of known strength, concentrated ammonia until the precipitate which forms is seen to be just barely redissolved; then dilutes this solution with distilled water until it contains from 0.5 to 0.75 per cent. of silver nitrate. This solution stains the cement substance only, leaving the ordinary tissues unstained.

Instead of reducing the silver by light I have employed an aqueous solution of hydrochinon (1 to 1,000), to which is added a few drops of a saturated solution of ammonium carbonate to render it alkaline. The tissue, after being treated with the silver, is placed in this solution until it becomes brown, which requires from five to ten minutes; then it is washed thoroughly in water and preserved in glycerin.

Auric Chloride.—Gold is reduced in the bodies of cells of cartilage, connective tissue, cornea, and epithelium, leaving the intercellular substance free; also in the axis cylinders of nerve fibres. It is very uncertain in its action, but when successful beautiful pictures are obtained. Tissues submitted to its action must be fresh.

Cohnheim's Method: Cohnheim, who introduced this salt, proceeds as follows: Bits of fresh tissue are placed in a one-per-cent. solution of auric chloride until they become yellow, and are then exposed to the light in water acidulated with acetic acid until the gold becomes reduced—until it becomes of a deep purple color; this requires from one to three days. The specimens are preserved in glycerin.

Löwit's Method: Löwit employs the following method for nerve terminations in muscle: Bits of tissue are placed in a mixture of 1 part formic acid and 2 parts water, until they become transparent; then for ten or fifteen minutes in a one-per-cent. solution of auric chloride until they become yellow; then in the formic-acid mixture for twenty-four hours in a dark place; then for twenty-four hours in pure formic acid in the dark. After this they are washed in distilled water and preserved in glycerin.

Ranvier's Method: Bits of fresh tissue are placed in fresh filtered lemon juice until they become transparent; then are washed in water and placed in a one-per-cent. solution of auric chloride for fifteen to twenty minutes; then again washed in water, and placed in dilute acetic acid (2 drops to 50 c.c. of water), and exposed to the light for two to three days, when the reduction will become complete. In the case of muscle Ranvier places the tissue from the gold solution in a twenty-per-cent. solution of formic acid in the dark for twelve hours, when the reduction is complete.

He also employs the following mixture: One-per-cent. solution of auric chloride, 4 parts; formic acid, 1 part; boil and allow to cool. Bits of fresh tissue are placed in this mixture for twenty minutes; then washed in water, and placed in formic acid 1 part, water 4 parts, in the dark for twenty-four hours.

Pritchard's Method: After the tissue has been treated with the gold solution, Pritchard reduces the gold with the following mixture: Amyl alcohol, 1 c.c.; formic acid, 1 c.c.; water, 98 c.c. The tissue is removed from the gold solution, washed in water, and placed in the above mixture for twenty-four hours in the dark, when it will probably have become of a violet color; if not, it is placed in a fresh quantity of the fluid for twenty-four hours longer. Wash in water and harden in alcohol.

Chrchtschonovitsch's Method: The fresh tissue is placed in a one-half-per-cent. solution of auric chloride for from thirty to forty-five minutes; then in distilled water for twenty-four hours; then in a saturated solution of tartaric acid, at a temperature of 50° C., until the gold is reduced; it is washed in water and hardened in alcohol.

Auric and Potassium Chloride.—This is of a more unvarying composition than the simple chloride; it is perfectly neutral in its reaction, and its solutions are more stable. It is used in solutions of the same strength as auric chloride. As a reducing agent Hoyer employs the ordinary pyrogallic acid developing solution used in photography. He adds one or two drops of this solution to 50 c.c. of water, and places the specimen in this for sixteen to twenty-four hours.

Osmic Acid.—The property possessed by osmic acid of staining fat black makes it a useful stain for the medullated nerve fibres. It also stains some other tissues various shades of black, but its action is uncertain. At present it is used chiefly for staining fat and nervous tissue.

It is best used in the form of vapor, as its penetrating power is then greater. The specimen to be submitted to the action of the vapor is pinned out on a cork fitted to a wide-mouthed bottle, in the bottom of which a few crystals, or a few cubic centimetres of a strong solution, of osmic acid are placed and left until the desired coloration is obtained.

It may also be used in solution in water or glycerin of the strength of from one-half to one per cent. Small bits of the tissue are placed in the solution for from one-half to twenty-four hours, and then washed thoroughly in water. Or a mixture of 1 part glycerin, 1 part alcohol, 1 to 3 parts water, and 1 part of a one-per-cent. solution of the acid may be used. Specimens may remain in this mixture for several days, until they are sufficiently stained.

All osmic-acid preparations should be preserved in glycerin.

Overstained specimens may be bleached by hydrogen peroxide.

Methods of Injecting.—*Self-injection of the Living Animal.*—This is accomplished by allowing a definite quantity of blood to escape from an opening in a vein of a living animal, and replacing the blood lost by some innocuous coloring matter, so that by the contractions of the heart the vessels are filled with much less injury than by an injection apparatus.

Chrzonszczewsky recommends a solution of 7.75 gm. of carmine in 3.6 c.c. of ammonia, to which is added 30 c.c. of distilled water. This fluid is to be filtered before injecting. Ten cubic centimetres of blood are removed from the jugular vein of a medium-sized rabbit, and 10 c.c. of the above fluid injected. If the larger vessels are now rapidly ligated, first the vein and then the artery, a physiological injection of the blood-vessels is obtained. Good results are obtained in the case of the kidney, spleen, etc. The injection may also be accomplished by placing the above fluid in the stomach, rectum, and abdominal cavity; and in amphibia by placing it in the lymph cavities. After the injection is accomplished the organs are placed in acidulated alcohol, to cause the fixation of the carmine.

This solution, as well as the sulphindilate of sodium, when injected in large quantities, is rapidly excreted by the kidneys, and the latter substance is precipitated in the biliary passages. If the ureter is ligated immediately after injecting a rabbit and the animal is killed at the end of an hour, the urinary tube will be found filled with carmine. In injecting the biliary passages it is not necessary to ligate. The blood-vessels of the organ are to be washed out and the original coloring matter that remains in them is to be replaced with another. The organs injected with the sulphindilate of sodium, after the blood-vessels have been washed out, are placed in a concentrated solution of calcium chloride, then in alcohol, when the coloring matter will become fixed.

---

* Reich (Sitzber. d. Wien. Akad., 1873) uses a one-eighth to one-fourth per cent. solution of potassium nitrate in water for washing out the vessels.

Heidenhain found that the commercial indigo-carmine was composed of a mixture of substances, generally three in number: (1) indigo blue-sulphate; (2) indigo blue-hyposulphate; (3) phœnizine-sulphate of sodium. He found for the purpose of injection that 1 and 3 were the only ones useful. He injects 25 to 50 c.c. of a cold-saturated solution of one of the above salts into the vein of a medium-sized rabbit, and 50 to 75 c.c. into that of a medium-sized dog. After the animals have passed blue urine for some time they are killed by bleeding, and the coloring matter is fixed by injecting the kidney through the renal vessels with absolute alcohol.

For injecting the biliary passages of the frog, he places a piece of indigo-carmine, the size of a pea, in the lymph sac of the thigh, and closes the wound in the skin firmly. After twenty-four hours the biliary passages will be found beautifully injected.

Injection after Death.—For filling the vessels of an animal after death, or the vessels of a removed organ or tumor, we employ two kinds of injecting masses: one fluid, the other solid at ordinary temperature—cold- and warm-flowing masses.

Cold-flowing Masses.—If a solution of gelatin in water, to which is added a little ammonia, be boiled for several hours on a water bath, the gelatin is converted into metagelatin, and no longer congeals upon cooling. To this fluid, as a vehicle, may be added various coloring substances, when a good cold-flowing mass will be obtained. After injecting, the object is placed in formalin, which coagulates the metagelatin. The addition of glycerin and chloral hydrate, after Hoyer's method, will preserve the mass for some time.

Beale's Cold-flowing Fluid: Blue—Dissolve 0.777 gm. of potassium ferrocyanide in 30 c.c. of glycerin; mix 3.6 c.c. of tinct. ferri mur. with 30 c.c. of glycerin; add the iron mixture, drop by drop, to the potassium ferrocyanide solution. Then add to this mixture 5.5 c.c. of methylic alcohol, 30 c.c. of alcohol, and 88 c.c. of water, shaking strongly.

Carmine—Mix 1 gm. of pulverized carmine with a little water and sufficient ammonia to dissolve the carmine; add 50 c.c. of glycerin and shake well. Then add gradually, with constant shaking, 100 c.c. of glycerin, acidulated with 25 to 30 drops of HCl or acetic acid. Test the fluid with litmus paper, and if it is not decidedly acid add a few drops of acid. Then add 25 c.c. of alcohol and 75 c.c. of water.

Robin's Cold-flowing Fluids: Robin uses as a vehicle 2 parts of glycerin, 1 part of alcohol, and 1 part of water, combined with a third or a quarter of its volume of the following coloring masses:

Carmine—Rub up 3 gm. of carmine in a mortar with a little water and enough ammonia to dissolve the carmine; add 50 c.c. of glycerin, and filter. Add a ten-per-cent. solution of acetic acid in glycerin, drop by drop, until a slightly acid reaction is obtained.

Prussian Blue—(*a*) Potassium ferrocyanide (sat. sol.), 90 c.c.; glycerin, 50 c.c. (*b*) Liquor ferri perchloridi, 80°, 3 c.c.; glycerin, 50 c.c. Mix (*a*) with (*b*) slowly.

Green—Saturated sol. potassium arsenite, 80 c.c., and glycerin, 50 c.c., are mixed with saturated solution of cupric sulphate, 40 c.c., and glycerin, 50 c.c.

Yellow—(1) Cadmium sulphate (sat. sol.), 40 c.c.; glycerin, 50 c.c. (2) Sodium sulphide (sat. sol.), 30 c.c.; glycerin, 50 c.c. Mix (1) with (2) with constant shaking.

Warm-flowing Masses.—Robin's Gelatin Vehicle: One part of gelatin is soaked in seven, eight, nine, or ten parts of water, according to the consistence of the mass wanted, and when soft is melted on a water bath. This vehicle is then combined with any of the coloring masses just mentioned in the proportion of one part color to three parts vehicle. Filter through flannel before injecting.

Thiersch's Prussian Blue Mass: (1) A solution of gelatin, one part to two parts water; (2) saturated aqueous solution of ferrous sulphate; (3) saturated solution of potassium ferrocyanide; (4) saturated solution of oxalic acid.

Mix 12 c.c. of (2) with 30 c.c. of (1), at a temperature of 50° C. Mix at the same temperature 24 c.c. of (3) with 60 c.c. of (1), and add 24 c.c. of (4), with constant stirring. Add this solution to the solution of gelatin and iron; stir constantly until all the Prussian blue is precipitated. Heat on a water bath to 100° C., and filter through flannel.

Ranvier's Prussian Blue Mass: Prepare the Prussian blue as follows: Add to a saturated solution of ferrous sulphate, in water, a saturated aqueous solution of potassium ferrocyanide. Filter through a double filter of felt and paper. Wash with distilled water for several days, until the filtrate has a deep blue color. The Prussian blue has now become soluble. The precipitate is then dissolved in distilled water, and the solution kept in bottles until wanted.

Twenty-five parts of this solution are mixed with one part of gelatin. The gelatin is soaked for half an hour in water, and melted in the water it has absorbed, on a water bath. Heat the Prussian blue fluid to the same temperature, and mix with the gelatin solution, gradually, under constant stirring. Filter through flannel.

Thiersch's Carmine Mass: Carmine, 1 part; ammonia, 1 part; water, 3 parts. Dissolve and filter. Make a solution of gelatin in water, 1 to 2. Heat to 30° C. on a water bath, and add 1 part of carmine fluid for every 3 parts of gelatin solution. Then add acetic acid, drop by drop, stirring, until the free ammonia is used up. Inject at a temperature of 30° to 35° C.

Gerlach's Carmine Mass: Dissolve 5 gm. of carmine in a mixture of 4 c.c. of water and 0.5 c.c. of ammonia. Allow it to stand several days, and mix with 8 parts of a solution of gelatin, 1 to 2. Filter and inject at a temperature of 40° C.

Ranvier's Carmine Mass: Rub up 2.5 gm. carmine with a little water, and just enough ammonia to bring the carmine in solution. Soak 5 gm. of gelatin in water, and melt on a water bath in the water it has absorbed. Add the carmine fluid slowly, with constant agitation. Neutralize the free ammonia by adding, drop by drop, a mixture of acetic acid and water, 1 to 2. Filter through flannel.

Thiersch's Yellow Mass: (1) One part of gelatin in 2 parts of water; (2) 1 part of neutral potassium chromate in 11 parts of water; (3) 1 part of plumbic nitrate in 11 parts of water. Mix 4 parts of (1) with 2 parts of (3). In another vessel mix 4 parts of (1) with 1 parts of (2). Heat both mixtures to 30° C., and then combine, with constant stirring. Heat on a water bath to 90° C., and filter through flannel.

Thiersch's Transparent Green Mass: Combine the blue injection mass in various proportions with the yellow mass.

Frey's White Mass: Precipitate 125 to 185 c.c. of a cold-saturated, aqueous solution of barium chloride by adding sulphuric acid drop by drop. Allow the precipitate to settle for twenty-four hours, and decant the clear fluid. The remaining mucilaginous mass is mixed with an equal volume of strong gelatin solution.

Hartig's White Mass: Dissolve 125 gm. of lead acetate in enough water to make the whole weigh 500 gm. Dissolve 95 gm. of sodium carbonate in enough water to make the whole weigh 500 gm. One volume of each of the above solutions is mixed with two volumes of strong gelatin solution.

Fol's Dry Masses: Carmine—An indefinite quantity of ammonia is mixed with four times its volume of water, and carmine is added; after it has been standing an hour, with occasional shaking, no deposit should remain; then filter. Soak gelatin, in shreds, for two days in a sufficient quantity of the carmine solution. Then melt on a water bath with a small quantity of the solution. When melted add acetic acid until the color becomes blood-red, taking care not to add an excess of acid. Too little acid is not a disadvantage; too much will cause a granular precipitate. Allow the mass to cool, and tie up in a piece of coarse net, and by pressing with the hands, under water acidulated with 0.1 per cent. acetic acid, force the mass out into vermicelli-like strings. These are placed in a sieve, washed well with running water, and dried on waxed paper.

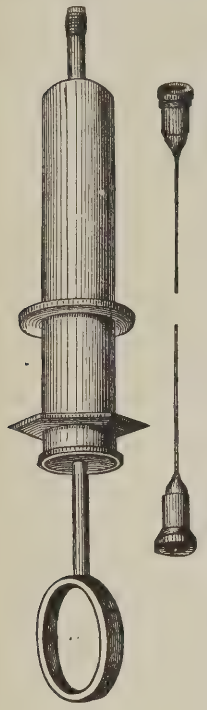

FIG. 2692.—Injecting Syringe.

Blue Mass—The mass is prepared according to Thiersch's formula. After cooling press out into vermicelli, as above, and dry on waxed paper. For use, soak the vermicelli in water; when soft, melt with enough saturated solution of oxalic acid to render the mass fluid.

Brown and Black Masses—Soak 50 gm. of gelatin in 200 c.c. of water in which is dissolved 14 gm. of sodium chloride. Melt on a water bath, and stir in briskly a solution of 30 gm. of silver nitrate, dissolved in 100 c.c. of distilled water. This produces a fine-grained, white emulsion, which is allowed to cool. When cold, press out into vermicelli, as above, wash in running water, and by clear daylight mix with the following: Cold-saturated aqueous solution of potassic oxalate, 300 c.c.; cold-saturated aqueous solution of ferrous sulphate, 100 c.c. When the mass has become black throughout, wash in running water for several hours, and dry the vermicelli on waxed paper. The color of this mass, by transmitted light, is sepia-brown. If a gray-black tint is wanted, substitute 24 gm. of potassium bromide for the sodium chloride in the first solution.

Injecting with a Syringe.—The syringe for this purpose should be made of brass or German silver, and should be of the form of that shown in Fig. 2692. Such a syringe, with half a dozen cannulæ of various sizes will answer all purposes for which a syringe can be used. It can be used only for injecting small organs.

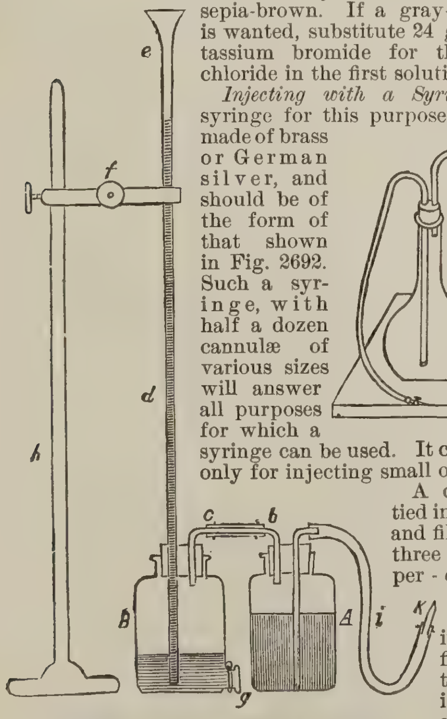

FIG. 2693.—Mercurial Injecting Apparatus.

A cannula is tied in the vessel and filled with a three-fourths-per-cent. salt solution. The syringe is then filled with the injecting mass, and to exclude all air the syringe is held vertically, nozzle up, and a few drops of the injecting mass are expelled. The nozzle of the syringe is then inserted in the cannula and the injection made slowly and steadily. On account of the difficulty of keeping up a steady pressure by the hand, the method of injecting with the syringe has been practically discarded.

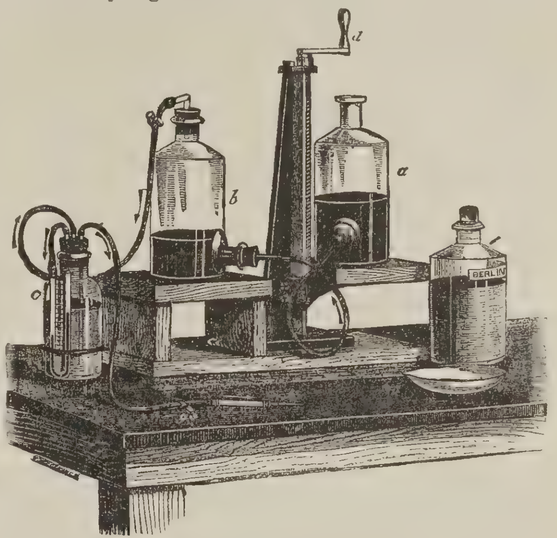

FIG. 2694.—Ludwig's Mercury-pressure Apparatus.

Injecting with Constant Pressure.—The pressure is obtained in this case by a column of mercury or water.

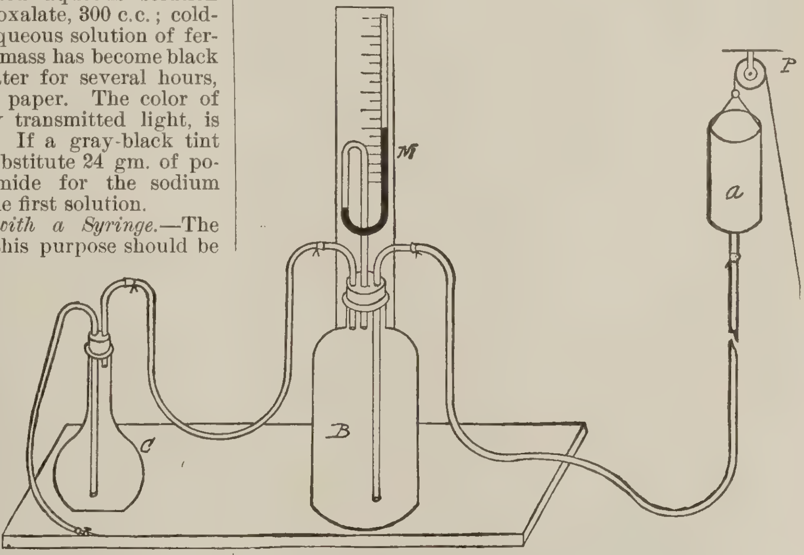

FIG. 2695.—Water-pressure Injecting Apparatus.

In Fig. 2693 is shown a simple form of a mercurial apparatus. The bottle *A* is filled two-thirds full with the injecting mass, which flows through the rubber tube *i*. The bottle *A* is connected with the bottle *B*, which is partially filled with mercury. The tube *d*, with a funnel end *e*, is fitted air-tight into the cork *B* (all joints must be air-tight). Upon pouring mercury into the tube *d*, it flows down into *B*, compressing the air, which in turn compresses the air in *A*, and forces the injecting mass out through *i*.

In Fig. 2694 is shown the more satisfactory apparatus of Ludwig. It consists of two Wolff's bottles, *a*, which contains the mercury, and *b*, into which, owing to the difference in the level of the two bottles, the mercury flows. This compresses the air in *b*, which, acting on the injecting fluid in *c*, causes the latter to flow out through the tube *g*. The pressure bottle *a* rests on a wooden support, which is raised by the screw *d*, until sufficient pressure is obtained. The mercurial manometer attached to the bottle *c* is for indicating the amount of pressure. If a gelatin mass is employed, the bottle *c* must be placed in a vessel of warm water.

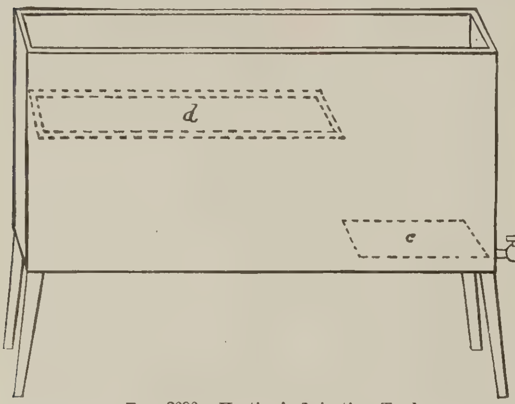

FIG. 2696.—Harting's Injecting Tank.

The water-pressure apparatus, Fig. 2695, is arranged as follows: The flask *C* is for holding the injection mass, and is connected with the pressure bottle *B* by a rubber tube. The manometer *M* is for measuring the pressure. The pulley *P* is fixed to the ceiling, and through it a rope pases which is attached to the can *a*, to the bottom of which is attached a rubber tube connected with the bottle *B*. The can *a* is filled with water which, upon raising the can, flows into *B*, compressing the air. The compressed air acting on the injecting mass, forces it through the rubber tube and cannula.

The amount of pressure can be regulated by the distance of the can *a* above the bottle *B*.

In using warm-flowing masses it is necessary that the object to be injected and the masses should be kept warm. The injecting tank of Harting, Fig. 2696, will be found very convenient for this purpose. The perforated shelf *c* is for the injecting flasks, the shelf *d* for the object to be injected. The tank is filled one-third full with water, which is heated by a Bunsen burner placed underneath.

In Fig. 2697 are shown several forms of injecting cannulæ. The two upper ones are made of brass, and should be of different sizes. The lower one is made from a piece of glass tubing. Several stopcocks, Fig. 2699, fitted to the brass cannulæ, are to be provided. Also a dozen or more serres fines (Fig. 2698), which are used for clamping leaking vessels.

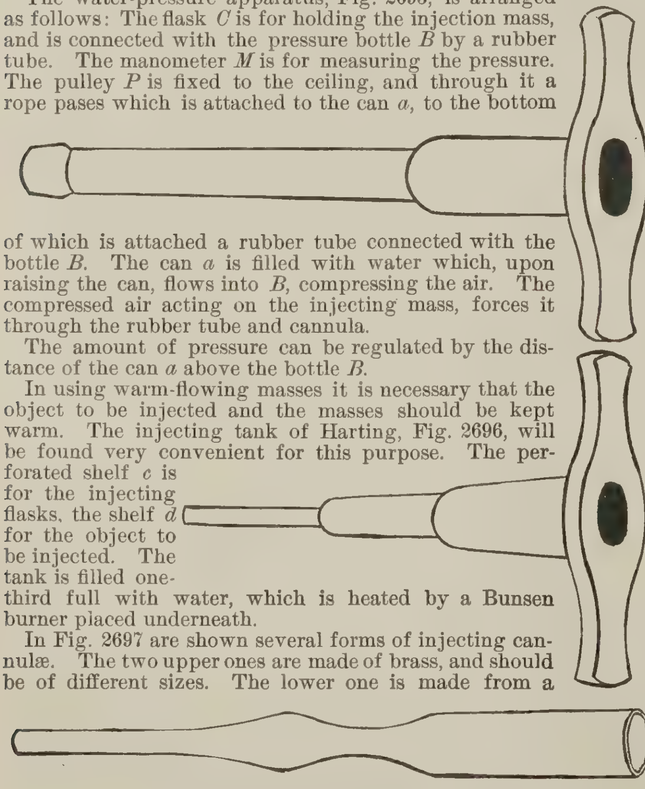

FIG. 2697.—Injecting Cannulæ.

Injecting an Entire Animal.—The animal—a rabbit or guinea-pig—is rendered insensible with chloroform. The thorax is opened by making an incision through the skin over the sternum and cutting out a small window over the base of the heart. The pericardium is opened, the heart pulled out and its apex cut off, the animal being allowed to bleed to death. The aorta is exposed, care being taken not to injure the vessels; a cannula is introduced (Fig. 2697) through the left ventricle into the aorta and fastened firmly with a ligature, the ends of the latter being tied around the arms of the cannula, or around the constriction of the glass one, if it be used. If a glass cannula be used, a piece of rubber tubing is attached to the large end and the whole filled with a three-fourths-per-cent. salt solution. The latter is retained by placing a spring clip upon the end of the rubber tube. The cannula is then introduced as above and tied.

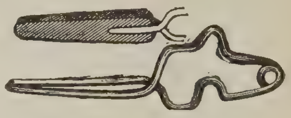

FIG. 2698.—Serres Fines.

The vessels are now washed out with a three-fourths-per-cent. salt solution. This is accomplished as follows: The animal is placed upon the shelf, *d*, of the injecting tank, Fig. 2696, the water in which has been heated by a Bunsen burner placed underneath. A flask, filled two-thirds with salt solution, is placed on the shelf *c*, and connected with the pressure bottle *B*, Fig. 2695. A piece of rubber tubing attached to a stopcock is connected with the delivery tube of the flask. The pressure is now applied by raising the can *a*, Fig. 2695, until the manometer registers about 50 mm. Now the stopcock is opened and all the air allowed to escape; then the stopcock is connected with the cannula introduced into the aorta. The salt solution is allowed to run through the vessels until it escapes perfectly clear from the right side of the heart.

The stopcock is now closed and disconnected from the cannula, and a flask containing the injecting mass is substituted for the one containing the salt solution. The stopcock is opened, and as soon as the injecting mass flows free from air bubbles the stopcock is connected with the cannula as above. The injection is continued until the mass flows from the right side of the heart, and is allowed to run for from twenty minutes to half an hour. A ligature is then tied around the vessels connected with the right side of the heart, and the injection is continued, the pressure being gradually increased to not over 100 mm., until the vascular system is filled, which can be judged from the color of the ears, lips, etc. When the injection is completed the vessels at the base of the heart are ligated, the stopcock is disconnected, and the animal put in a cold place until the gelatin has set. The organs and parts wanted are then removed and hardened in alcohol.

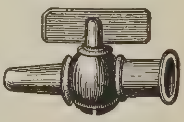

FIG. 2699.—Stopcock.

For injecting a single organ—the kidney—the animal is killed by bleeding, the abdominal cavity is opened, and the intestines are pushed aside. The renal artery is separated from its surroundings with forceps; then the renal vein in the same way. The artery is opened by a valvular opening, a cannula is inserted and firmly tied. An opening is then made in the vein. The organ is washed out with salt solution, which is followed by the injecting mass. The constant-pressure apparatus is to be used. After the injection is completed a ligature is passed around both vessels close to the organ, which is removed and hardened in alcohol.

For injecting pathological new formations, cold-flowing masses are to be preferred. The pressure employed must be moderate on account of the thinness of the walls of the blood-vessels. The serres fines will be in great demand for checking the leakage from the numerous lateral branches of the blood-vessels.

Double Injections.—Double injections are best made by injecting the artery and vein at the same time, with different colored masses—carmine for the artery, blue for the vein.

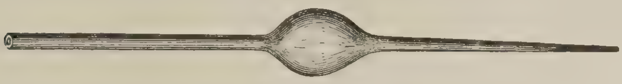

FIG. 2700.—Pipette.

A T-tube is attached to the outlet tube of the pressure bottle *B*, Fig. 2695, and from each arm a rubber tube is carried to flasks containing the injecting masses. These are then connected with the cannulæ fastened in the artery and vein. By this means both sets of vessels are filled at the same time and under the same pressure. The pressure at first must be low, so that the arteries and veins shall be completely filled before either mass passes into the capillaries. The pressure is finally increased, and each set of capillaries will be filled with its proper mass.

Injection of Lymphatics.—For injecting lymphatics the puncture method is the one chiefly employed. The puncture can be made from the cavity of a blood-vessel into the surrounding tissue, with the idea that a lymph vessel may be opened and that thus both sets of vessels may be injected. Or it may be made into the tissue and the injection made from this. The puncture must not be made at random, but in the direction in which small lymphatics are supposed to exist. The injection is made with a syringe fitted to the small cannula used for puncturing, and cold-flowing masses are to be used. If the extravasation is small and remains so, the injection is likely to succeed; but if the extravasation grows rapidly, the procedure is a failure and a new attempt is to be made.

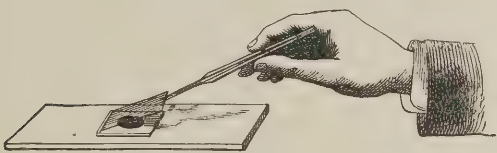

FIG. 2701.—Placing the Cover Glass in Position.

METHODS OF MOUNTING.—Specimens, after being duly prepared, are mounted on glass slides for study and preservation. The usual form of slide is known as the English. It is made of plate glass, measuring one by three inches, with the edges ground smooth. For covering the specimen thin pieces of glass, either circular or square in form, and of a size suitable to the specimen, are used. These are known as cover glasses.

The slides and covers, as received from the dealers, are generally covered with an oily material, making it difficult to clean them. This material may be removed in the following manner: Soak the slides and covers for twenty-four hours in a mixture of potassium bichromate, 960 gm.; sulphuric acid, 88 c.c.; water, 738 c.c.; then wash well in water. Wipe the slides dry with a clean linen cloth; place the cover glasses in alcohol until needed. Slides and covers that have been used are treated as follows: Put them into a mixture of equal parts of alcohol and hydrochloric acid, and, after a few days into the bichromate solution and treat them as new ones. Scrape the slides free of all balsam and put them in the bichromate solution.

In some cases, when we have an exceedingly delicate specimen, it is necessary to protect it from the pressure of the cover-glass. This can be accomplished by placing a hair under the cover, or we may make a shallow cell by painting a ring of some cement on the slide (see Fig. 2703). Again, we may have a thick specimen, or we may wish to use an aqueous mounting medium. In these cases thin glass cells are to be cemented to the slide, the specimen placed in them, and the mounting media added until the cell is filled; the cover-glass is then applied.

Mounting in Glycerin.—The specimens are either soaked in a small dish of glycerin until transparent, and then transferred to the slide; or they are placed on the slide from water, the excess of the latter being absorbed with filter paper or sucked up with a pipette (Fig. 2700), and a drop or two of glycerin is placed on the specimen, and the whole covered with a cover glass. In covering a specimen, care must be taken not to include air bubbles. If the cover glass is placed in position in the manner shown in Fig. 2701, any that may be present will be forced out with the excess of glycerin. The cover being in position, the superfluous glycerin is to be removed and the cover cemented down. All traces of glycerin must be removed, or the cement will not adhere to the glass. This is accomplished by washing out a camel's-hair brush in alcohol, absorbing the greater part of the alcohol by wiping the brush on filter paper until it is only moist, and then going over the slide in a systematic manner with the brush until all the glycerin is removed. A brush simply moistened with alcohol will not suck up the traces of glycerin; it must be well washed in the alcohol and dried very frequently.

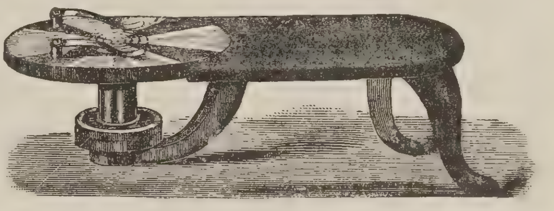

FIG. 2702.—Turn-table.

If the cover is a square one, it is cemented by passing a camel's-hair brush along the edge of the cover, whereby the latter as well as the slide receives a stripe of cement. Circular covers are easily cemented by aid of the turn-table (Fig. 2702). Concentric circles engraved on the surface of the table, according to the size of the covers, show where the brush is to be applied. The brush is to be held perpendicularly, and is filled with a cement of such a consistence that it will flow—it is not to be painted—on the cover and slide while the table is rotated. The manner of holding the brush and rotating the table is shown in Fig. 2703.

The glycerin penetrates the specimen, rendering it transparent, but on account of its high index of refraction, in some cases it renders the specimen too transparent, thereby concealing some of the minute structure. This objection can be overcome by mixing the glycerin with various proportions of water. As a rule, pure glycerin is to be used for mounting.

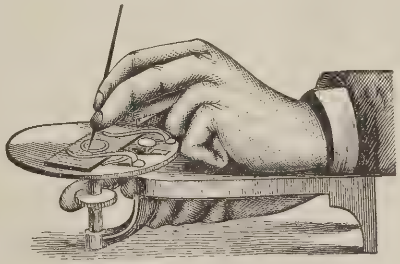

FIG. 2703.—Cementing Covers.

For cementing covers there are innumerable cements. Those that have stood the test of time are the following:

Asphalt Varnish. This can be procured from any painter's supply store, and is to be diluted with turpentine to the required consistency. Kitton recommends asphalt dissolved in benzol; to this solution he adds a little gold size.

Gold Size. What is known in commerce as Japan gold size is to be used. This sets very quickly, and may be used uncolored or colored with any of the mineral pigments.

Shellac Varnish. Shellac should be dissolved in alcohol, so as to obtain a thick solution. The addition of twenty drops of castor oil to each ounce of the solution has a tendency to render it less brittle. This is an excellent cement for specimens that are to be examined with oil-immersion lenses, as it is not attacked by the immersion fluid.

Gelatin. If the covers are first painted around with a warm, strong solution of gelatin in water, allowed to dry, and then painted with a saturated solution of potassium bichromate, an insoluble cement is formed which adheres firmly to the glass, and by the absorption of a small amount of glycerin that may be on the slide, is rendered semi-elastic. This is also a good cement for specimens to be examined by homogeneous immersion lenses.

Marine Glue. This is found in commerce already prepared. It is soluble in ether, naphtha, or solution of potash. It is used chiefly for making shallow cells, and cementing glass cells to the slide.

Mounting in Canada Balsam.—This process is divided into three steps: (*a*) dehydrating; (*b*) clearing; (*c*) enclosing in balsam.

(*a*) Dehydrating. As water is not miscible with the reagents used for clearing, or with the Canada balsam, it is to be removed. This is accomplished by soaking in absolute alcohol. The specimen is first washed in ordinary alcohol to remove the surplus of water, and then placed in the absolute alcohol for from three to five minutes.

(*b*) Clearing. For this purpose we must use a reagent that is miscible with both alcohol and balsam. The specimen is to be carefully removed from the alcohol with a spatula, the adhering fluid removed by filter paper, and the section floated off into the clearing medium. If the section is perfectly anhydrous it will float on this, and in the course of a few moments become transparent and sink to the bottom.

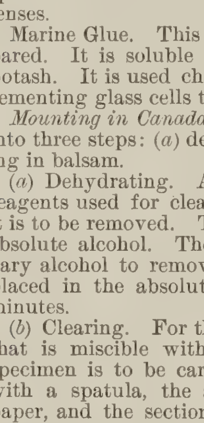

FIG. 2704.—Balsam Bottle.

For clearing we use chiefly the essential oils. Of the most commonly employed are the oils of cloves, cedar, anise, origanum cretici, bergamot, and the white oil of thyme. Carbolic acid, creosote, xylol, benzol, turpentine, and chloroform are also used. Old samples of wood creosote, xylol, benzol, chloroform, oil of origanum or thyme, are to be used for specimens embedded in celloidin, when we wish to retain the embedding material.

It is sometimes best to clear large or delicate specimens on the slide. First float the sections on the slide, and absorb the surplus alcohol with filter paper; then drop the clearing reagent on the specimen and place the slide under a bell-jar until the specimen is transparent; absorb the surplus of the clearing reagent, and add the balsam and cover.

(*c*) Enclosing in Balsam. The transparent section is removed from the clearing reagent with a spatula (Fig. 2687), and floated upon a slide, care being taken that it lies perfectly flat and that it is not wrinkled or folded upon itself. The excess of the clearing reagent is sucked up with a pipette (Fig. 2700), or soaked up with filter paper. A drop of balsam is placed upon the specimen, and the cover glass laid on as in glycerin mountings (Fig. 2701). As the balsam hardens in time, there is no need of cementing the cover. In all these manipulations great care must be taken to have the slides, covers, and all instruments perfectly dry—any moisture will cause a precipitation of the balsam, and thus cause an opacity of the specimen.

Canada balsam as found in commerce should never be used. The commercial balsam is heated on a sand bath until all volatile matter is driven off, and it becomes brittle when cold. This hard balsam is then dissolved in xylol, benzol, or oil of cedar, enough of the solvent being used to give the required consistence. These solutions, with the exception of that in oil of cedar, set quickly. The solutions of balsam are to be kept in capped bottles (Fig. 2704), or in tin tubes, such as are used for the oil colors of the artist.

Hard balsam is also used for mounting, especially sections of hard bone and teeth, in which we wish to demonstrate the lacunæ. The process is as follows: A bit of hard balsam is placed in the centre of a slide and warmed gently over the flame of a lamp, care being taken not to let it boil, or bubbles will be formed. When melted, the specimen is plunged into it and covered quickly, and the slide is placed on a cold surface, which sets the balsam immediately and prevents its entering any of the lacunæ, which, being filled with air, show as dark spaces.

Instead of Canada balsam, dammar varnish and other preparations of dammar may be used. Gum dammar dissolved in xylol or oil of cedar is now generally used in place of the above mixtures.

Glycerin Jelly.—Of the numerous published formulæ for this medium, that of Kaiser is the best. He soaks one part, by weight, of French gelatin for two hours in six parts, by weight, of distilled water; then adds seven parts of glycerin and 1 gm. of carbolic acid for every 100 gm. of the mixture; warms on a water bath, with constant stirring, until all the flakes produced by the carbolic acid disappear; filters warm through paper and preserves in a tightly stoppered bottle.

Soak the sections for a short time in this warm mixture, and then transfer to a melted drop of the same on a slide. Cover, and when the jelly has set, remove any excess and ring the cover glass.

HODGKIN'S DISEASE.—(Synonyms: Pseudo-leukæmia, lymphadenoma, anæmia lymphatica, adenia, lymphosarcoma, malignant lymphoma, lymphomatosis.)

Definition.—A disease characterized by a progressive enlargement of the lymph glands and often of the spleen, a gradually developing anæmia, and secondary growths of lymphoid tissue in the liver, spleen, kidney, alimentary tract, bone marrow, and other structures of the body.

The affection differs from leukæmia chiefly in the absence of a marked leucocytosis.

Etiology.—The disease occurs most frequently in males under forty years of age. The exact etiology of Hodgkin's disease is as obscure as that of leukæmia. The fact that the disease often follows inflammatory processes and runs a rapid febrile course suggests an infectious origin. Bacteriologic examination of the blood and lymph glands has revealed micro-organisms in over fifteen cases. The Staphylococcus pyogenes aureus, the Streptococcus pyogenes, the pneumococcus of Fraenkel, and unidentified bacilli have been cultivated. Roux and Lannois claim to have reproduced the disease by injecting animals with a coccus cultivated by them from the blood and lymph glands of a case. Delbet claims the same for a bacillus. The multiplicity of organisms found suggests that all are probably accidental.

PATHOLOGY.—The most important morbid changes in Hodgkin's disease are hyperplasia of the lymph glands, enlargement of the spleen, and the presence of lymphoid growths in the liver, bone marrow, and intestinal tract.

Lymph Glands.—As a rule, the lymph glands show the greatest change. The glands involved in order of greatest extent and frequency are the cervical, axillary, inguinal, retroperitoneal, bronchial, mediastinal, and mesenteric. In addition, the popliteal and epitrochlear glands may be enlarged. The lymphatic structures of the mouth and alimentary tract are relatively infrequently involved. Lymphoid nodules in the liver are often observed. Microscopic collections of lymphoid cells may be found in various organs that present no abnormal naked-eye appearance. The glands of the neck are usually largest. They vary in size from a hen's egg to minute nodules; unless crowded together, the glands are freely movable, and not attached to the skin. Glandular enlargement is usually symmetrical, although one side may be more extensively involved. Rarely the process is confined to one side. The natural shape of the enlarged gland is round or oval. Pressure may produce many alterations in form. A thin capsule surrounds each gland, and when not crowded together, loose connective tissue unites them in chains. The enlarged glands may be soft or hard. On section, if no secondary changes, such as hemorrhage, have occurred, the surface presents a soft mass, grayish-white in color, with a faint tinge of red or yellow. In the soft variety the cut surface bulges beyond the capsule, and a turbid fluid, made up largely of lymphoid cells, may easily be expressed. No stroma is apparent. The hard variety possesses a relatively greater reticulum than a normal gland. Little or no fluid exudes from its cut surface. Enlargement of the thoracic glands may compress the bronchi or trachea. Thrombosis of large thoracic veins may occur from pressure. The heart and lungs may be displaced by enlarged glands. Lymphoid growths may occur in the lungs; rarely the aorta, thoracic duct, and œsophagus are compressed by the posterior mediastinal glands. The recurrent laryngeal nerve may be injured. In the abdomen the retroperitoneal glands are most frequently involved; the mesenteric seldom reach a large size. Displacements of the uterus and compression of the ureters have resulted from growth of the pelvic glands.

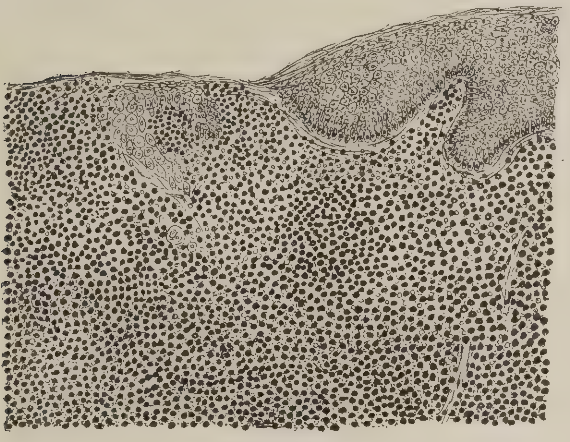

FIG. 2705.—Adenoid Growth in the Skin. (Author's case of Hodgkin's disease.)

Histology of the Lymph Glands.—The microscope shows hyperplasia of all the elements of a lymph gland. In the soft variety the increase in the lymphoid cells is relatively much more marked than that of the connective tissue. Cells presenting the appearance of ordinary lymphocytes are crowded together and held in position by an exceedingly fine network of fibrils. In the hard variety the parenchyma is likewise made up of lymph cells but the connective-tissue increase predominates. Widely varying grades of sclerosis may exist in the different cases and in the various groups of glands in the same case. The gross appearance and histologic change in the lymph glands are practically identical with those in lymphatic leukæmia.

Spleen.—Hyperplasia of the spleen exists in eighty per cent. of all cases. In the splenic variety of the disease the hyperplasia may be enormous, the organ at times filling the greater part of the left half of the abdominal cavity. In the majority of cases of the usual type of the disease, the enlargement is moderate in degree, the spleen rarely exceeding thirty ounces in weight. The organ is firm and its original shape is preserved. Local thickening of the capsule due to perisplenitis may exist. The enlargement may be a true hypertrophy. In about seventy-five per cent. of the cases in which the spleen is enlarged, however, lymphomata are found varying in size and number. The histologic structure of the spleen approaches more closely than normal the picture of a lymph gland. As a rule, the pulp is relatively more increased than the lymph sinuses and reticular tissue. Even in the hard variety of splenic enlargement the increase in the lymphocytes predominates. Sclerosis of the Malpighian bodies is now and then found. Degenerative changes in the lymphoid cells do not occur, as a rule.

Liver.—The organ is often slightly enlarged. Lymphoid growths varying in size from a minute point to a hazelnut invade the liver structure. They develop in the interlobular spaces, and may grow between the liver cells.

Bone Marrow.—A fœtal condition of bone marrow is usually present, similar to that in pernicious anæmia. Adenoid growths are found in the medulla.

Alimentary Tract.—Adenoid growths in the digestive canal seldom attain large size. They may be scattered along its entire length. The tonsils, glands at the base of the tongue, Peyer's patches, and solitary follicles may become hyperplastic. Ulceration of adenoid growths in the stomach may take place. Lymphomata may develop in the kidney, lung, testicle, thymus and thyroid glands. They are sometimes found in the dura; now and then they involve the cranial and peripheral nerves. Lymphomatous growths are practically never found in the brain and spinal cord. Adenoid growths have been found in the heart. In rare cases the skin is the seat of adenoid growths. Retrograde metamorphoses in the new-formed tissue rarely take place in true Hodgkin's disease. When marked changes are present, the condition is usually tuberculosis or mixed infection.

SYMPTOMS.—In the majority of cases Hodgkin's disease begins insidiously and progresses gradually to a fatal termination. In rare instances, however, the onset is severe; and its course rapid. The important symptoms of the disease are progressive enlargement of the lymphatic glands, a gradually developing anæmia, associated with a relative increase in the lymphocytes, enlargement of the spleen, loss in strength and weight, irregular temperature, œdema, and grave cachexia.

Lymph Glands.—As a rule, the earliest symptom noted by the patient is enlargement of the lymph glands superficially located. In most instances the cervical glands are the first involved; rarely the inguinal or the axillary glands are the first to become affected. A few cases have been described in which anæmia, loss of weight and strength, apparently preceded glandular enlargement. At times the deep thoracic or abdominal glands are diseased first, producing early pressure symptoms, such as pain in the chest, cough, dyspnœa, or pain in the abdomen or legs, with œdema. If the cervical group is primarily affected, the enlargement is usually confined to one side for a time. It may be several months before the other side is involved. The glands of the posterior triangular space and those which lie beneath the jaw are usually enlarged first. In the early stage of the disease the enlarged glands are not adherent to the skin or to each other. As the disease progresses, periadenitis may unite the glands in a firm mass. Such masses in the cervical region may project far beyond the angle of the jaw and produce great deformity of the neck. The larynx may be pushed to one side, and grave dyspnœa has resulted from narrowing of the trachea by pressure. Pressure effects upon the carotid artery, jugular vein, and pneumogastric nerve have been noted. Enlarged glands in the thorax have produced spasmodic cough, dyspnœa, paralysis of the vocal cords, œdema of the arms and lower extremities. Enlargement of the axillary glands has resulted in pain and swelling of the arms from compression of nerves and veins. The inguinal glands may compress the femoral vein; the retroperitoneal glands are sometimes palpable. Bronzing of the skin, possibly from pressure on the sympathetic plexus, has been observed in a few cases. The enlarged glands may compress the ureters, interfere with the function of the lumbar and sacral nerves, and produce œdema by occluding the iliac vein. Uterine fibroids may be simulated when enlarged glands become adherent to the uterus or broad ligament. As a rule, the glands of rapid growth are softer than those that grow slowly. Pain is not present, except when nerve trunks are compressed. Glands of very rapid growth are sometimes tender on pressure. The rapidity of growth varies in different cases, and in the different groups in the same patient. Not infrequently the glands become smaller for a short time. Under the influence of an erysipelas, a marked temporary reduction in size has been noted.

Spleen.—Moderate enlargement of the spleen is present in about eighty per cent. of the cases. No special symptoms referable to this organ are present in the common form of Hodgkin's disease. In the splenic variety, the spleen may attain enormous size. Bruits have been heard; pain from perisplenitis is often present.

Anæmia.—Anæmia is one of the characteristic features of the disease. It may not be pronounced until glandular enlargement is of considerable extent. As the anæmia develops, the patient complains of dizziness, tendency to syncope, headache, dyspnœa on exertion, and cardiac palpitation. Pallor of the mucous membranes appears. The skin assumes a hue peculiar to anæmia. The conjunctivæ become subicteric. Epistaxis may occur. The advent of cachexia is characterized by a tendency to œdema, effusion into serous cavities, marked asthenia, hemorrhages, and fever.

Circulatory System.—The heart is usually somewhat dilated. Hæmic murmurs may be heard. In the later stages the carotids pulsate visibly. The veins are often prominent. The pulse is full and frequent, and may approach the water-hammer character. Retinal hemorrhages may take place.

Blood.—In the early stages of Hodgkin's disease the blood may show no marked alteration.

Red Cells.—As the disease progresses there is usually a gradual reduction in the number of red cells, and the individual cell is moderately poor in hæmoglobin. The loss in red cells and hæmoglobin does not approach that found in a corresponding stage in leukæmia; even at the time of death the red cells may number two million or more per cubic millimetre. In a few cases they have been reduced to less than one million per cubic millimetre. As a rule, no marked change in the size and form of the red cells is present. Occasional megalocytes are found, but more frequently the corpuscles are undersized. Nucleated red cells of the normoblast type are usually scarce, even in the late stage of the disease.

Leucocytes.—The number of leucocytes may be normal or even diminished. In the majority of cases of true Hodgkin's disease, the lymphocytes are relatively increased. The polynuclear cells are correspondingly decreased.

In many cases the number of leucocytes is markedly increased, although, as a rule, no greater than fifty or sixty thousand per cubic millimetre are found. The rapidly developing cases, with febrile disturbances, are more likely to show a leucocytosis than those of chronic course. A few myelocytes may be found, as in all cachectic processes. The eosinophiles are rarely increased. The coagulability of the blood is greatly reduced. A diagnosis of Hodgkin's disease cannot be made on the blood findings alone. A relative lymphocytosis is a valuable sign, but the same condition is often found in true lymphosarcoma, and in tuberculosis of the lymph glands.

Alimentary System.—The tonsils and glands at the base of the tongue are frequently enlarged. Deafness may arise from extension of adenoid growths from the pharynx, occluding the Eustachian tube. Ulceration of lymphoid growths in the stomach may simulate gastric ulcer. Diarrhœa and hemorrhage may occur from the same condition in the intestinal tract. Constipation may result from pressure of enlarged glands; jaundice from occlusion of bile ducts. The liver is often enlarged, due at times to the growth of lymphoid tissue in its structure.

Temperature.—A moderate elevation of temperature from time to time is the rule in Hodgkin's disease.

Respiratory System.—Dyspnœa incident to anæmia or pressure on the respiratory passages by lymphatic growths is a common symptom. Crepitant râles, produced by the pressure of adenoid growths in the lung may be heard. Pleural transudates take place in the cachectic stage. The terminal event is often a pleurisy or a pneumonia.

Nervous System.—Paraplegia may result from pressure on the spinal cord, as in a case reported by Osler. Epileptiform convulsions of short duration may occur. Coma may precede death. Disturbance in function of nerves from pressure is frequent.

Genito-Urinary System.—The urine often contains a trace of albumin. A real nephritis is to be considered a complication.

Skin.—Bronzing, such as occurs in Addison's disease, has been observed. Adenoid growths in the skin presenting small raw surfaces, from which serum exudes, have been observed in a few cases. In one recently studied by the writer, the growths progressed over the surface of the skin, leaving behind a healed surface, slightly indurated (Fig. 2705).

Diagnosis.—Hodgkin's disease is clinically and anatomically closely related to several affections.

Leukæmia.—The essential difference is in the blood findings. A few cases of Hodgkin's disease have terminated in true leukæmia.

Tuberculosis of the Lymph Glands.—Musser and others believe that Hodgkin's disease is probably a lymphatic tuberculosis. Most observers, however, are of the opinion that Hodgkin's disease and tuberculosis of the lymph glands are two distinct affections. All admit the difficulty at times in differentiating the two processes, both clinically and anatomically. The following points are of some value in distinguishing the two processes:

1. Localized glandular enlargement favors tuberculosis.
2. Fever is often absent in Hodgkin's disease. A fever is usually present in tuberculosis.
3. In Hodgkin's disease, deposits of lymphoid tissue may be found outside of the glands.
4. In tuberculous disease, the glands often caseate or suppurate, and become adherent by inflammation to each other and to the skin. In Hodgkin's disease the glands do not caseate or suppurate, and are freely movable beneath the skin.
5. The tuberculin test often results in local reaction in tuberculous adenitis. The positive diagnosis of Hodgkin's disease had better be reserved in all cases until tuberculous lymphadenitis has been excluded by animal inoculation and histologic examination.

Chronic Intermittent (*Rückfalls*) *Fever.*—This condition is characterized by a chronic intermittent fever, with swelling of the lymph glands. It was brought into prominence by Pel, Ebstein, Renvers, and others. It is probably a tuberculous lymphadenitis.

Lymphosarcoma.—This condition, sharply differentiated by Kundrat, is clinically and anatomically more closely related to Hodgkin's disease than to sarcoma of the lymph glands. However, the glandular enlargements possess some of the characteristics of malignant growths. Like Hodgkin's disease, they originate in lymphatic structures, although in perhaps one-half of the cases they do not develop from typical lymph glands, but from glandular elements, such as are found in the mucous membrane of the mouth and alimentary canal. The growths remain more regional than in Hodgkin's disease. They develop along the line of the lymphatics; extremely rarely do metastases occur through the blood. Universal glandular enlargement, as in Hodgkin's disease, does not occur. Histologically, the cells often present atypical development, contain at times many nuclei, become distinctly aggressive, penetrate the capsule, and invade the surrounding tissue. The glandular structure of the growth is often effaced. In many cases the histologic picture is the same as in Hodgkin's disease. Metastases in distant organs rarely occur. Retrograde metamorphoses do not occur as a rule. In rare instances lymphosarcoma develops from Hodgkin's disease.

Splenic Anæmia.—Splenic anæmia presents the clinical and histological picture of Hodgkin's disease, with the exception that the spleen is the lymphatic structure that is chiefly involved. The organ may be enormous in size. Enlargement of the lymph glands is absent, or decidedly in the background. It is, in reality, the splenic form of Hodgkin's disease.

Syphilis.—Glandular enlargement in syphilis is in the group nearest the indurated sore. Rarely does the adenopathy become general. One gland becomes enlarged first, the others of the group soon afterward. They seldom are larger than a hazelnut. In the secondary or tertiary stage of the disease glandular enlargement may be present in the proximity of a local syphilitic lesion.

PROGNOSIS, COURSE, AND TERMINATION.—The onset of the disease varies. Acute cases have been described by Cohnheim, Eberth, and Falkenthal. In one case the duration of the disease was only eleven days; in another four and one-half months. The most rapid course has been noted in children. The majority of cases are fatal within the first two years. Few last longer than five or six years. The most favorable cases are those in which glandular enlargement remains localized. General lymphatic enlargement may occur early, or it may rapidly develop after several years of local involvement. As a rule, soon after glandular hyperplasia becomes general, anæmia and emaciation develop, and the disease progresses steadily to a fatal termination. The immediate cause of death is often some intercurrent affection, such as pneumonia or pleurisy. Cases have been reported in which death occurred from asphyxia and starvation, due to pressure of enlarged glands upon the trachea or œsophagus. In a case recently observed by the writer, general convulsions and transitory unconsciousness were repeated several times during the day preceding death. Recovery has apparently taken place under treatment. The slowly developing cases are more likely to be benefited than the acute. Even in the latter arrest or improvement may occur. The prognosis is best in the splenic form of the disease, because it is amenable to surgical treatment.

TREATMENT.—Patients affected with Hodgkin's disease should avoid physical and mental fatigue. They should receive nourishing food, easily digested. Lean meats, milk, cream, butter, and eggs are especially valuable foods.

Medicinal Treatment.—Arsenic is recognized as the best drug. It may be given internally in the form of Fowler's solution, or arsenious acid. Certain advantages accrue from its subcutaneous administration. Injection of arsenic directly into the enlarged glands is advocated. When Fowler's solution is given internally, it is well to begin with two drops, three times a day, after meals, and gradually increase the dose by from one to three drops each day. If no symptoms of arsenical intoxication appear, the dose may be increased to fifteen or twenty or thirty drops three times a day. Should symptoms of arsenical poisoning appear, such as pronounced metallic taste, salivation, nausea, severe epigastric pain, vomiting, diarrhœa, tenesmus, irritable heart action, oppressed breathing, œdema, tremor, and muscular stiffness, the dose should be reduced to the point of tolerance. If a diarrhœa of moderate grade is the only symptom of intoxication, it can often be advantageously controlled by giving from three to six drops of the simple tincture of opium, three times a day. If no diarrhœa exists, it is well to administer laxatives and diuretics to help free the system from arsenic, and its products of altered metabolism. Arsenious acid may be given in the form of the so-called Asiatic pill: one part arsenious acid to eighty parts black pepper. Black pepper seems to increase the tolerance of the stomach for arsenic. Marked improvement sometimes follows the internal administration of arsenic. In chronic cases, glandular swellings have rapidly disappeared, and in some instances recovery has followed its use. Even in the rapidly developing cases, arsenic has apparently checked the course of the disease. In many cases of Hodgkin's disease, arsenic may be given to better advantage subcutaneously. The disagreeable gastro-intestinal symptoms are delayed, and much larger doses of the drug are tolerated. Pearson's solution produces the least local irritation. It is best injected in the region of the buttocks, or in localities rich in subcutaneous areolar tissue. It should be diluted with equal parts of distilled water, the mixture sterilized, and the skin and instrument rendered thoroughly aseptic. Pain, which sometimes continues for a short time after the injection, may be controlled by adding one-tenth grain of cocaine hydrochlorate. The injections may be given once daily, and subsequently twice daily. Gradually increasing doses may be given each day, until a larger amount than advised by mouth may ultimately be given and tolerated for a longer time. The effect of the subcutaneous injection of Pearson's solution is often very gratifying. The general condition may improve, the glands may diminish in size, and the patient often gains in weight. Severe pain is rarely complained of at the site of the injection. If care is taken in the preparation of the solution and instruments, inflammation and suppuration do not occur. Good results are claimed for the injection of Pearson's solution directly into the enlarged glands. This sometimes gives rise to a slight elevation of temperature. Such injections have been made directly into the enlarged spleen. The wisdom of this procedure may be justly questioned.

The manner in which arsenic acts in Hodgkin's disease is not known. If the disease is bacterial in origin, its effect may be germicidal; possibly it acts in the same manner as mercury in syphilis. Unfortunately, only a relatively small number of cases are permanently benefited by arsenic, and in a few cases no improvement follows its use. Iron is of very little value in the treatment of the disease. Quinine and phosphorus in small doses have seemed to be of some use. Cod-liver oil is a good tonic. Extracts from various glands and tissues have been used without apparent results.

Local Treatment.—Aside from the intraparenchymatous injection of arsenic, already described, the enlarged glands have been injected with solutions of various drugs. Iodine, potassium iodide, nitrate of silver, carbolic acid, and chromic acid have been used, without satisfactory results. Galvano-puncture has proved of no permanent value. Iodine applied to the skin over the gland is ineffectual. If the disease is primarily located in the glands, and if the disease spreads from them by secondary infection, an early removal of the glands primarily diseased would be rational. The subsequent course in a number of cases in which the disease was local and the glands were early removed justifies the procedure in selected cases. If the disease is widespread and deep-seated from the beginning, extensive operative treatment is not advisable. Some think it best to remove as many glands as possible, even though the glandular enlargement is general, in the hope that medicinal treatment may better control the disease. The results obtained do not warrant the procedure. All cases, chronic in character, with a tendency to localization of the process, should be treated by removal of the growths, supplemented by the administration of arsenic. Operation is indicated when accessible growths produce serious pressure symptoms. In most cases the glands are easily removed. In some cases, however, adhesions are firm and extensive. The results obtained by splenectomy in the splenic variety of the disease are exceedingly gratifying. A removal of the spleen should be seriously considered in all cases in which the diagnosis is certain, and the progress of the disease is apparently toward a fatal termination. Recovery has followed splenectomy in such cases, even after cachexia was advanced.

Bertram W. Sippy.

HOLARRHENA.—*Conessi* or *Tellicherry Bark.* The bark of *H. antidysenterica* Wall. (fam. *Apocynaceæ*), a woody plant of India. It is one of several plants whose barks have gone under the name of "Kura" or "Kuda" in India. The active constituent is an alkaloid which has been called *Wrightine* ("conessine"), and there is some doubt about its identity with what has been regarded as the same from other sources. It is contained also in the seeds. The bark appears to be a carminative and intestinal astringent, and the alkaloid somewhat antiperiodic. It is very largely used in native practice in India as an antidysenteric, and has been considerably so used in Europe. Reports as to its efficacy are discordant, but its use has declined. An aqueous extract is used in three-grain doses. *Henry H. Rusby.*

HOLOCAIN, para-diethoxy-ethenyl-diphenyl-amidin hydrochloride $[(C_6H_4.O.C_2H_5)_2.NH.C.CH_3{:}N.HCl]$, is obtained by the union of molecular quantities of phenacetin and paraphenetidin with separation of water. It crystallizes in bitter, white needles which are freely soluble in alcohol and ether and in forty parts of water. It is not affected by a temperature of 212° F. (100° C.). With alkalies it is decomposed and precipitated, the presence of a calcium salt in the water used for solution being sufficient to produce turbidity. It attacks any free alkali in glass; so, to prevent precipitation, the glass container should previously be boiled with acid.

Holocain has a deleterious effect on protoplasm, as in 0.1-per-cent. solution it stops fermentation and putrefaction, in 0.5-per-cent. solution it arrests the development of germs, and in one per cent. it stops amœboid movements and kills most micro-organisms. Hence the solutions are sterile, though if desired they may be boiled without harm. Holocain paralyzes the sensory nerve endings, and is a local anæsthetic of great power. It is claimed by Hotz, Wurdemann, Knapp, Jackson, and others to be quite as anæsthetic in the eye as cocaine, quicker in its action, and its effect more lasting, and as it is more penetrating the iris is more anæsthetized. It does not dry the cornea, increase intraocular tension, or influence the pupil or accommodation. Neither does it constrict the vessels, and, on the contrary, it tends to produce slight hyperæmia. This comparison with cocaine can be well demonstrated by dropping cocaine solution in one eye, and holocain solution in the other eye of the same patient. The amount used for eye work is two to five drops of one-per-cent. solution, and in one-half to two minutes this produces anæsthesia lasting ten to fifteen minutes. Derby and Knapp recommend it for the removal of foreign bodies as it leaves so little effect on the eye. They also find it the most serviceable drug in corneal ulcers of microbic origin, and in purulent ophthalmitis. Holocain cannot be used like cocaine by hypodermic for local anæsthesia, as it is much more toxic, its action in overdose resembling that of strychnine (Heinz).

W. A. Bastedo.

HOLZIN, HOLZINOL. See *Formaldehyde.*

HOMATROPINE.—Atropine and hyoscyamine when decomposed break up into tropic acid and tropin. The latter when combined with mandelic acid forms homatropine; mandelic acid being the product of the action of hydrochloric acid on amygdalin. Homatropine combines with acids to form salts; the hydrobromide, hydrochloride, and salicylate are those most employed. The hydrobromide is official in the British Pharmacopœia. Pure homatropine is almost insoluble in water but is slightly soluble in oil and vaseline. A two-per-cent. solution in oil and gelatin discs are prepared for ophthalmic work. The advantage claimed for the solution in oil is that it is not so readily washed from the eyes by the tears. Homatropine is weaker in its action than atropine and when administered internally acts in much the same manner as does the more common alkaloid. It is said to differ from the latter in this respect, viz., it causes a slowing of the pulse, but this difference is not marked when large doses are administered. The dose of the hydrobromide as given by the British Pharmacopœia is from one-eightieth to one-twentieth of a grain. It has been recommended for use in all conditions in which atropine is indicated, particularly in the night sweats of phthisis. It, however, has not been much employed, as it has not proved so trustworthy as atropine.

Homatropine is almost entirely employed as a mydriatic in ophthalmic work. Its action is much less intense than that of atropine, but it dilates the pupil and paralyzes the ciliary muscle almost as rapidly, and its effects pass off in a much shorter time. The pupil begins to dilate in ten or twenty minutes and paralysis of accommodation is complete in about one hour. In from twelve to twenty-four hours its action is quite recovered from. A one- or two-per-cent. solution is used. *Beaumont Small.*

HOMBURG, GERMANY.—This popular watering-place is situated in the Rhine land, ten miles north of Frankfort-on-the Maine. It is reached from Paris, from which it is 477 miles distant, direct by rail, or viâ Cologne and the Rhine.

The town is built on a spur of the Taunus Mountains at an elevation of 643 feet above sea level. Its natural situation is not picturesque, but art has done much in the way of beautiful pleasure grounds, extensive parks, and promenades. It contains 9,278 inhabitants and is annually visited by 10,600 persons, forty per cent. of whom are said to be foreigners, including a large number of English. Homburg has been one of the favorite resorts of the late Prince of Wales, now King of England.

The mineral springs and sanatoria are in a large Kurpark which extends toward the northeast into the forests of the foothills of the Taunus.

The climate is that of Central Germany, the average yearly temperature being 47.5° F.; and for summer, May, 56.3° F.; June, 66.2° F.; July, 65.6° F.; August, 66.5° F.; September 56.3° F. The yearly rainfall is 26.6 inches. The season extends from May to the end of September.

The waters of Homburg are saline-chalybeate, and are derived from the Taunus schist and quartzite. The principal constituents are the chlorides of sodium, calcium, magnesium, and lithium; the carbonates of iron and calcium; and free carbonic acid. Unlike the waters of Ems, they are cool and have to be artificially heated when used for baths. They come under the general classification of common salt or muriated waters and are similar to those at Wiesbaden, Kissingen, Baden-Baden, Kreuznach, and Nauheim.

There are seven springs, as follows, with their temperatures: Elizabethbrunnen, 51.1° F.; Ludwigbrunnen, 53.4° F.; Louisenbrunnen, 52.1° F.; Landgrafenbrunnen, 51.8° F.; Kaiserbrunnen, 52.9° F.; Stahlbrunnen, 51.8° F.; Soolsprudel, 51.8° F.

The Louisenbrunnen and Stahlbrunnen are distinguished by their excess of carbonate of iron. All these springs are used for drinking except the Soolsprudel and Landgrafenbrunnen.

The Ludwigbrunnen, Kaiserbrunnen, Louisenbrunnen, and Soolsprudel are used for bathing, the water being warmed by hot steam chambers at the bottom of the baths, with the least possible escape of carbonic acid gas. The waters of the Ludwigbrunnen are used for inhaling. All the springs are the property of the town of Homburg, which has erected the various bath-houses: the Kaiserbrunnen with sixty bathrooms, and two piscinæ for natural carbonic-acid salt baths; mud baths and mineral and fresh-water baths: Kurhausbad with thirty-three bathrooms. In the former 26,147 baths were given in 1899, and in the latter over 7,000. In the Kaiser Wilhelm's bath are inhalations with spray produced by compressed air.

Besides the mud baths mentioned there are pine-needle, electric, medicated, and steam baths; and there are also good facilities for Swedish gymnastics and massage, as well as for the milk and whey treatment.

The chief centre for visitors is the Kurhaus, containing handsome apartments, reading-room, etc., with a terrace partly covered with glass, and corridors, affording a sheltered promenade. At the back of this Kurhaus extend the beautiful pleasure grounds, with a palm-house, orangery, and well-kept flower beds.

The town contains water-works, a sewerage plant with facilities for filtration, and a steam disinfecting apparatus.

Therapeutics.—When these waters are taken internally they gently stimulate the gastric and intestinal mucous membrane, at the same time rendering the contents of the bowels more fluid; they are therefore beneficial in catarrhal affections of the alimentary tract. Taken in small quantities they are constipating, but laxative in larger quantities. They help to increase the general nutrition, according to Weber, by their action in aiding the digestion of albuminous materials.

According to the same authority, they often increase the weight in thin persons, and for such cases are preferable to the alkaline-sulphated waters.

They are also beneficial in catarrhal affections of the respiratory tract; in gout, uric-acid diathesis, obesity, hemorrhoids, diseases of women, heart disease, and malaria. Those springs containing iron are useful in cases of anæmia and chlorosis.

Fifty-five thousand litre bottles of these waters are yearly exported. *Edward O. Otis.*

HONEY.—MEL. "A saccharine secretion deposited in the honeycomb by *Apis mellifica* L. (class, *Insecta;* order, *Hymenoptera*)" (U. S. P.). For the collection and sources of honey, the reader is referred to the article *Wax.* Freshly separated from young or "virgin" combs it is a pale yellow, or greenish-yellow, or light sherry-colored liquid, about as thick as glycerin, of peculiar odor, and of very sweet and slightly sharp taste. All these properties vary with the conditions of its collection, such as season, the prevailing flowers, climate and country, and (but not in commercial honey) the species of insect producing it. The honey of older combs is darker colored and more disagreeable. With age, after removal from the combs, it becomes darker, and granular from the formation of crystals of sugar in it. Specific gravity 1.430 to 1.440. The following tests and reactions are from the Pharmacopœia:

"When recent honey is diluted with two parts of water, the resulting liquid should be almost clear, not stringy, and should have a specific gravity not lower than 1.100 (corresponding to a specific gravity of 1.375 for the original honey).

"Honey has a faintly acid reaction toward litmus paper.

"If one part of honey be dissolved in four parts of water, a clear or nearly clear solution will result, which should not be rendered more than faintly opalescent by a few drops of silver nitrate T.S. (limit of *chlorides*), or of barium chloride T.S. (limit of *sulphates*).

"If one volume of honey be diluted with one volume of water, and a portion of this liquid gradually mixed with five volumes of absolute alcohol, it should not become more than faintly opalescent (as compared with the reserved portion of the solution), and should neither become opaque nor deposit a slimy substance on the inner walls and bottom of the test tube. And when honey is incinerated, in small portions at a time, in a platinum crucible, it should not leave more than 0.2 per cent. of ash (absence of *glucose* and *foreign inorganic substances*).

"On boiling one part of honey with five parts of water, the resulting solution, when cold, should not be rendered blue or green on the addition of iodine T.S. (absence of *starch*)."

Of this, the Pharmacopœia provides a clarified form, under the title "*Mel Despumatum*, or *Clarified Honey*," which is required to respond to the above tests and which we are directed to prepare as follows:

"Mix the honey intimately with *two* (2) *per cent.* of its weight of paper pulp, which has been previously reduced to shreds, thoroughly washed and soaked in water, and then strongly expressed and again shredded. Then apply the heat of a water-bath, and, as long as any scum rises to the surface, carefully remove this. Finally, add enough distilled water to make up the loss incurred by evaporation, strain, and mix the strained liquid with *five* (5) *per cent.* of its weight of glycerin."

COMPOSITION.—Honey is a solution of several sugars in water, together with minute quantities of several acids (lactic, acetic, etc.), coloring matter, mucilage, albuminoids, and the odorous principles. Occasional pollen cells are seen in it, and, when old, crystals of sugar. The sugar of honey is principally *levulose*, or uncrystallizable fruit-sugar, but *dextrose* and even sometimes *saccharose*, or cane-sugar, are also present; *mannit* has been observed. In old honey these crystalline sugars (which perhaps increase in it with age at the expense of the levulose) are the cause of its granulating. The result of six analyses by König were: fruit-sugar, 78.74 per cent.; cane-sugar, 2.69 per cent.; nitrogenous substances, 1.29 per cent.; water, 16.13 per cent. (Hager).

Poisonous substances are frequently found in honey, apparently collected by the bees. Their origin has sometimes been traced to *Rhododendron* and other members of the *Ericaceæ*, but no method of detecting them, except by eating, has been found. The poisoning is usually mild, but numerous fatal cases have been recorded.

USES.—The employment of honey as an article of food and luxury, as well as a medicine, is of great antiquity, and extends over nearly every temperate country on the globe. In the tropics the bees are less provident, and honey is not so regularly collected. But, in spite of this popularity, honey has no medicinal value beyond that of sugar or syrup, and can be considered only a vehicle for other medicines. Partly as a convenience on account of its taste and consistence, and in part from deference to tradition, it has been used in numerous preparations; it is still official in the Honey of Rose (*Mel Rosæ*, U. S. P.), made by mixing 12 parts of a fluid extract of red rose (vehicle, diluted alcohol) with 88 of honey. It is simply a pleasantly astringent vehicle. Confection of rose contains twelve per cent. of honey. *W. P. Bolles.*

HONTHIN is a tasteless and odorless compound of tannin, keratin, and albumin, which is said to pass through the stomach unchanged, and to be separated into its constituents in the intestine. It is an intestinal astringent, is insoluble in water, and may be given alone or with chalk mixture for diarrhœa or intestinal fermentation (Reichelt, Frieser). *W. A. Bastedo.*

HOOF-AND-MOUTH DISEASE.—Hoof-and-mouth disease, also known as foot-and-mouth disease, is spoken of technically as epizootic aphtha, and has also been called eczema epizootica, vesicular aphtha, vesicular epizootic

---

(The author acknowledges his indebtedness for many of the above facts to "Deutschlands Heilquellen und Bäder," herausgegeben vom Kaiserlichen Gesundheitsamt zu Berlin, Berlin, 1900.)

and aphthous fever; among the ignorant the term murrain is sometimes used.

In France it is officially known as *fièvre aphtheuse,* and is also spoken of as *stomatite aphtheuse* and *cocette.* The Germans call it *Maul- und Klauenseuche, Maulfaule, Apthenseuche, Bläschenkrankheit,* and *Maulweh.* In Italy it is known as *afta epizootica, febbra aftosa,* etc. In the far East it is also found, being called in Bengalee *Homsa, khoorea, khoora, khoraha,* and other names; in Thibet it is known as *khuchha,* and in Singalese as *kata ledé* and *kura ledé.*

Hoof-and-mouth disease is peculiar to the cloven-footed domestic animals, the ox, sheep, goat and swine, but may be communicated by them to the horse, dog, cat, and poultry, and also to man. It is this latter property that renders it of special interest to the practitioner of human medicine. It may also occur among wild ruminants, such as deer, buffalo, camel, llama, giraffe, and antelope.

Hoof-and-mouth disease in cattle, sheep, and swine is characterized by a vesicular eruption of the mucous membrane of the mouth and under surface and edges of the tongue, the interdigital space and around the top of the foot at the juncture of the hair and horn, followed by ulceration as the vesicles break, and accompanied by high fever.

It is highly infectious, being disseminated not only by the cohabitation of sick with healthy animals, but also by manure, litter, stable utensils, the clothes and boots of attendants and veterinary surgeons, and by cattle cars. Even driving healthy cattle over roads previously traversed by cattle suffering from the disease is sufficient to produce it in the non-infected animals.

Milch cows suffering from hoof-and-mouth disease also have a vesicular eruption upon the udder and teats, and in these cases the milk becomes a medium of infection.

Hoof-and-mouth disease has undoubtedly existed for centuries, probably for the last two thousand years; it seems to be a native of Western Asia and Eastern Europe, and has long been known in India and upon the steppes of Russia. As commerce between civilized nations increased and means of communication developed, it spread over Europe from the east to the west until now it prevails from the Caspian Sea to the Atlantic Ocean. It also exists in India, Ceylon, Burmah, and the Straits Settlements. With the development of literature its description became more accurate and accounts of its spread over Europe in the seventeenth and eighteenth centuries show it to have prevailed extensively in Italy, Germany, and France. Toward the end of the eighteenth and early in the nineteenth century it reached Western Europe, but did not gain access into England until 1839, and was not known in Denmark until 1841.

Hoof-and-mouth disease seems to be a native of localities in Eastern Europe or Western Asia, and an exotic in some other countries. For example it was imported into Canada in 1870, being introduced by two Shorthorn cows brought from Liverpool, and appeared in localities in New York State and some of the New England States; but it does not seem to have assumed a severe form and in a few months entirely disappeared, and to-day it does not exist upon the North American continent. Its behavior in thus disappearing may be in part due to its having been introduced in the autumn, and as cattle in the North are housed during the winter months there is very little communication between herds; but it may also in part be due to its exotic character. The last outbreak in the United States was in the early eighties (about 1884), when some cattle imported from England were landed at Portland, Me., and driven to the United States quarantine station a short distance away. Soon after a yoke of oxen was driven over the same road, which later developed hoof-and-mouth disease,—the imported cattle having it when landed,—and gave it to the owner's herd; but the disease was soon suppressed, and there has been no reappearance of it since.

The United States Bureau of Animal Industry, of the Department of Agriculture, spares no pains to protect the live-stock interests of the country from contagious animal diseases; hence it is unlikely that this malady will ever secure a foothold here, owing to the stringent quarantine regulations imposed by the federal Government. Cattle, sheep, swine, and other ruminants can be brought into the United States only at points designated by the Department of Agriculture, the ports of entry on the Atlantic seaboard being only at Boston, New York, and Baltimore, near which places quarantine stations have been established. All neat cattle are held at these stations for ninety days, and all sheep and swine for fifteen days after landing. The reason for holding cattle longer is to guard against contagious pleuropneumonia; the period for which the sheep and swine are held is sufficient to guard against all danger from hoof-and-mouth disease. Neat cattle also have to be found free from tuberculosis as determined by the tuberculin test before being allowed to go beyond the quarantine station limits. Separate gates and lanes are provided for entrance and exit; if, therefore, any contagious disease should make its appearance, there would be no danger of healthy animals becoming infected by being driven over roads where sick animals had previously been.

Importers of animals from England or Europe must also obtain permits from the Department of Agriculture, and furthermore must have affidavits that animals come from localities free from contagious diseases, and do not pass through infected districts in transit. The collector of the port of entry is notified when the animals arrive, and immediately turns them over to the care of the agent of the Bureau of Animal Industry having charge of the quarantine station.

In countries where hoof-and-mouth disease has prevailed as an epizootic, the losses occasioned by it have been very great to the farmer from a pecuniary standpoint; not that the mortality is very large, as only from one to three per cent. of the infected animals die, but owing to the emaciation due to the fever, and the inability to walk about and eat. This loss is especially heavy when cattle or sheep are being fed for the shambles. Animals nearly ready for the butcher in a few days lose all the flesh that it has taken them months to put on.

Neat cattle have the severest lesions in the mouth, as a rule, and have great difficulty in eating, although lameness may also be present, while among sheep the foot lesions are usually the more severe and they will not walk about in search of food, but spend most of their time lying down.

In Great Britain, after its introduction in 1839, there have been several epizootics of hoof-and-mouth disease. Professor Brown has classified them as the ten great outbreaks, but it seems to have been pretty well subdued there, as from 1886 to 1896 only 1,295 cattle, 3,673 sheep, and 107 swine have been reported as having it, and during 1897 no authentic cases were reported. These results have been brought about only by the most strenuous efforts; when an outbreak has occurred public live-stock markets were closed, infected cattle quarantined, cars and premises disinfected, litter destroyed, and every precaution taken to check the spread of the disease. The results have amply justified the means adopted. Previous to 1886 the occasional great outbreaks assumed very large proportions. For example, in 1871 there were 700,000 cases among cattle in England with 7,000 deaths (one per cent.), and an equally bad outbreak occured in France at the same time. While it seems to have been nearly eradicated in Great Britain, epizootic aphtha still prevails extensively on the Continent with occasional sudden increases, in spite of a good sanitary veterinary police system in every European country. For example, in Belgium, in 1897, there were 2,453 cases of hoof-and-mouth disease; in 1898, 15,553; in France there were 1,601 outbreaks in 1897, and in 1898, 9,458; and in Italy 3,216 cases in 1897, and 45,497 in 1898.

In Hungary, in 1896, 572,809 cattle, 178,612 sheep, and 82,931 hogs were infected, while in 1897 it was diminished to 70,491 cattle, 25,450 sheep, and 3,758 hogs.

In the pig, as in the sheep, the lesions are manifested chiefly on the feet, although there may be eruptions on the snout and free borders of the lips. Sows suckling young may have an eruption on the mammæ and teats, but in the sow and ewe this is not so frequent as in the cow. Young pigs infected through milk have the mouth and intestinal lesions, and in a severe form.

The period of development from the time of exposure is short, usually from three to eight days; but it may not appear in rare instances, it is said, for from two to three weeks.

When there are no complications, such as sloughing of the feet as seen in very severe cases, the disease in cattle, sheep, and swine runs a course of from ten to twenty days.

In other animals the symptoms are somewhat the same, viz., vesicles followed by ulcerations either on the feet or in the mouth; but other domestic animals do not seem to be very susceptible. The horse shows lesions in the mouth, but only as a result of licking infected cattle or drinking or eating from buckets or troughs which diseased creatures have used. Dogs, cats, and rabbits may have the disease, but it is said to be infrequent, and, in the dog and cat, is the result of their being kept in the stable with infected ruminants or swine, or of their drinking milk from cows with udder lesions.

It is said to be rare in poultry and birds; when it occurs there may be vesicles or sores on the feet and legs, or in the mouth and upon the comb.

Hoof-and-mouth disease may occur in the human family. Among adults, attendants of cattle, veterinary surgeons, butchers, and drovers are most exposed. It may be acquired from diseased animals, and occasionally it is possible for one person to infect another. Among infants it may be caused by drinking uncooked milk from cows having the vesicles of epizootic aphtha on the udder; it is also said that fresh butter, fresh cheese, and whey can convey the germs of the disease.

The period of incubation is quite short, especially when conveyed by milk, in which case it is only from twelve to twenty-four hours before symptoms appear.

In infants the disease is not infrequently fatal. The symptoms consist of fever, headache or dizziness, conjunctivitis, an eruption on the face or around the mouth, and vesicles in the mouth, and among milkers there may be sores on the tips of the fingers around the finger nails (there may even be sloughing of the nails), or in the spaces between the fingers. When vesicles develop in the pharynx they cause great difficulty in swallowing; there may also be vomiting and diarrhœa when the infection takes place through milk, and in the case of infants and small children the disease may then end in death. Recovery usually takes place in ten or twelve days. Among animals it is said that one attack does not always secure immunity from another. Meat from animals suffering with epizootic aphtha has never been found to be infectious.

Etiology.—Hoof-and-mouth disease is undoubtedly a germ disease—both clinical and experimental evidence indicate this,—but the specific organism which produces it remains to be discovered. There are other diseases which we believe to be due to a microscopic organism of some description—such, for example, as rabies, smallpox, and cowpox,—in which the organism is so minute or so difficult to stain or cultivate that it has hitherto not been demonstrated, and the bacterium of epizootic aphtha is unquestionably one of this character. Nosotti, Klein, Schottelius, and Kurth have studied micro-organisms found in connection with the lesions of hoof-and-mouth disease, but it does not seem that the true specific cause has yet been discovered.

The vitality of the virus is not considered to be usually very great. Walley says that as a rule the danger ceases at the end of thirty days after the recovery of the last animal, but instances are given in which troughs, hayracks, and stables have caused fresh outbreaks after the lapse of several months. Therefore, in taking steps for the eradication of the disease, thorough disinfection of stables and utensils, with destruction of all litter and manure, cannot be too strictly enforced.

The post-mortem conditions found in animals suffering from hoof-and-mouth disease—in addition to the lesions in the mouth and around the feet, and eruptions on the udder previously mentioned—consist of an inflammation of the stomach and intestines, with perhaps erosions of these organs. Especially is this the case in infants, pigs, and calves infected by the use of milk from diseased cows.

The medicinal care of hoof-and-mouth disease consists in treating the symptoms as they occur, by the use of antiseptic washes, and by the application of dusting powders to the ulcerations. The food should be soft and of an easily digested character. Large flocks of sheep, where it is impossible to attend to each individual case, are sometimes treated, when the foot lesions predominate, by driving the entire flock daily through a long wooden trough containing some antiseptic drying powder.

Hoof-and-mouth disease may be confounded with other diseases if care is not exercised in making a diagnosis, such as foot root in cattle or sheep, cowpox, and poisoning with corrosive agents.

In 1884 there was an enzootic of ergot poisoning among cattle in Kansas which was mistaken at first for an outbreak of hoof-and-mouth disease (*vide* first annual report of the United States Bureau of Animal Industry, 1884).

The horse suffers at times from a contagious stomatitis which is known as *stomatitis pustulosa contagiosa*, and which has been mistaken for epizootic aphtha. This disease is not rare in the Eastern United States, while hoof-and-mouth disease, it must be remembered, does not exist on this continent. The contagious stomatitis of the horse is readily communicated from one to another, but is not serious and soon disappears from a stable. It is characterized by the formation, inside the cheeks and lips, of numerous little vesicles which break in a few days, leaving small superficial ulcers which soon heal.

More extended information on hoof-and-mouth disease may be obtained by referring to the first edition of the Reference Handbook of the Medical Sciences, Walley's "Four Bovine Scourges," Fleming's "Veterinary Science and Police," Williams' "Theory and Practice of Veterinary Medicine," Hayes' translation of Friedberger and Fröhner's "Veterinary Pathology," and the annual reports of the United States Bureau of Animal Industry. *Austin Peters.*

HOPS.—Humulus Lupulus. The carefully dried strobiles of *Humulus Lupulus* L. (fam. *Moraceæ* [" *Urticaceæ*," U. S. P.]), bearing the whole of their natural glandular coating. The hop vine is a twining perennial, with a thick-branched root, from which several long, slender, herbaceous, but tough and rough hairy cylindrical stems arise.

Description.—Ovoid-cylindrical, about 3 cm. (a little more than an inch) long, consisting of a thin, hairy, flexuous rachis and many obliquely ovate, blunt, membranaceous, rigid, glandular scales, which are parallel-veined below, reticulately veined above and each bearing a globoidal akene near the base; color of scales yellowish-green to greenish pale-brown, free from reddish or brown spots; odor strongly and peculiarly aromatic; taste bitter, pungently aromatic, slightly astringent.

Since the glandular coating (*Lupulin*) referred to in the definition contains the most of the active constituents, it should be present in normal amount, but much of the hops of the market have been deprived of a part of it by abrasion. Such hops are apt to be much broken, and are commonly pressed into cakes to conceal this appearance.

Good hops should be not much broken, and fresh. They are then of a rich, slightly yellowish or brownish green. When distinctly brown and dull, and especially shrivelled, they are stale and their composition is not the same.

The hop is a native of the temperate parts of the Old World—Europe and Asia—and grows in many places in the United States apparently wild, but probably introduced. It has been cultivated since the middle ages in Europe, and is now grown in nearly all temperate countries. England and the United States produce it abundantly, and of excellent quality.

The medicinal consumption of hops is comparatively small, and an unimportant item of the immense demand for them, mainly for flavoring ales and beers, which consumes many millions of pounds annually.

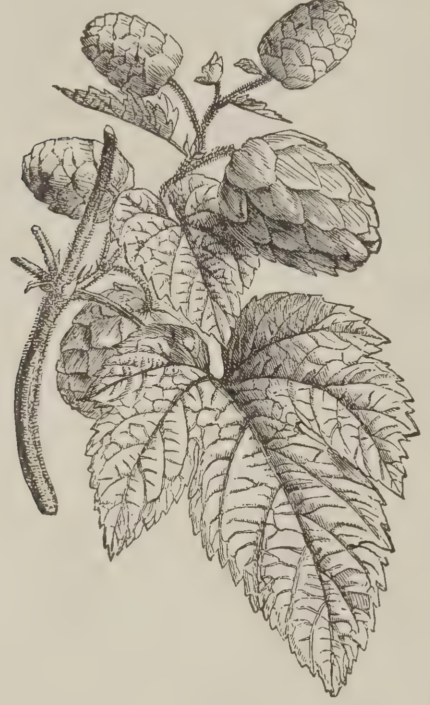

FIG. 2706.—Hop Plant in Fruit. (Baillon.)

COMPOSITION.—The entire hop, that is, inclusive of the *lupulin*, contains the following substances: Nearly one per cent. of volatile oil, of a greenish-yellow color, becoming brownish with age, and of a specific gravity of .855 to .880. It becomes at least partly converted into isovaleric acid. A very small amount of the intensely bitter *lupamaric acid* ($C_{25}H_{35}O_4$), which is soluble in alcohol or a mixture of alcohol and water. Resin, up to fifteen or eighteen per cent.; tannin two to four per cent. Small amounts of asparagin and cholin. Not more than ten per cent. of ash is allowable upon incineration. According to their staleness, more or less *phlobaphene* may be present, at the expense of the disappearing tannin.

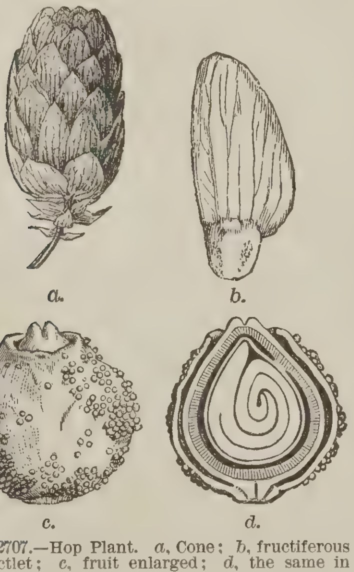

FIG. 2707.—Hop Plant. *a*, Cone; *b*, fructiferous bractlet; *c*, fruit enlarged; *d*, the same in longitudinal section.

ACTION AND USE.—Although used in many diseases with asserted benefit, but little can be said of hops more than that they are a mild bitter tonic and (especially lupulin) a feeble hypnotic and antispasmodic. In infusion they allay the pain and spasm of vesical catarrh, and improve the appetite and digestion. As an ingredient of beers they add a tonic, and perhaps diuretic, effect to that of the alcohol in those beverages. The dose is 1 to 4 gm. (gr. xv.–lx.). The Pharmacopœia provides, besides lupulin and its preparations, a twenty-per-cent. tincture, the dose of which is 4 to 8 c.c. (fl ʒ i.–ij.) and which is probably the best form of administration.

Henry H. Rusby.

HOREHOUND.—MARRUBIUM. "The dried leaves and tops of *Marrubium vulgare* L. (fam. *Labiatæ*)" (U.S. P.), but will probably be dropped from the next edition.

DESCRIPTION.—Leaves opposite, exstipulate, shortly and broadly petioled, the blades 2 to 4 cm. (1 to 1½ in.) long, roundish-ovate, truncate or subcordate at the base, obtuse, strongly rugose-veiny, more or less white-hairy, especially underneath; stems quadrangular, densely white-hairy; flowers in dense, axillary, white-wooly whorls; calyx tubular, five- to ten-nerved, with ten almost equal, erect-spreading, pungent teeth; corolla whitish, bilabiate; stamens didynamous; fruit of four ovoid, obtuse, smooth nutlets; aromatic and bitter.

A spurious marrubium is sometimes sold, having leaves of about half the size, thinner, less rugose and five of the calyx teeth much smaller or wanting.

Horehound is a European herb which has been introduced into this country, and in many places has escaped from old-fashioned country gardens to meadows and moist waste-places. Its woolly aspect and bitter odor and taste, combined with its characteristic labiate flowers and quadrangular stems, make it easily recognizable. It is also a native of Western Asia and Northern Africa.

The use of horehound dates from the ancient Romans, or even farther back. It has been a popular febrifuge and aromatic bitter tonic in many countries. The leaves and tops of the plant should be collected for use when it is in full bloom, and before the former have become old and dry; they are dried without heat, and should be preserved in dry boxes or drawers.

The most important constituent is the crystalline, neutral, bitter substance, *marrubiin*. There are, besides, a little *resin*, a little *essential oil*, *tannin*, and a considerable amount of alkaline and earthy salts.

Horehound was formerly prized as a febrifuge and antispasmodic, and used in numerous obscure diseases (hepatic, uterine, etc.), and in intermittent fever. It was also used for the only conditions for which it can be said to have any value, and for which it is still a little employed, viz., dyspepsia and debility. When a stomachic and bitter tonic is indicated, a tablespoonful or two (15 to 30 gm. = ℥ ss. ad ℥ i.) of an infusion, made in the usual way, strength one-tenth, is a tonic dose.

W. P. Bolles.

HORN'S SPRING.—Wilson County, Tennessee.

POST-OFFICE.—Lebanon. Hotel.

ACCESS.—Viâ Nashville, Chattanooga and St. Louis, or Nashville and Knoxville Railroad, to Lebanon, thirty miles northeast of Nashville; thence five miles west to springs. Conveyances meet all trains. The location of Horn's Springs is somewhat elevated and characterized during the summer months by refreshing breezes. A comfortable new hotel has recently been built, and is kept open all the year round. The springs are eight in number. According to an analysis made by Professors Safford and Summers, of Vanderbilt University, one of the springs contains the following chemical ingredients:

Calcium carbonate.
Magnesium carbonate.
Iron carbonate.
Potassium carbonate.
Sodium sulphate.
Magnesium sulphate.
Calcium sulphate.
Sodium chloride.
Phosphoric acid.
Silicic acid.
Carbonic acid.
Sulphureted hydrogen.
Organic matter (trace).

This may be taken as a type of all the springs, which, as we are informed, contain much iron and have decidedly purgative effects, resembling to some extent the water of the Crab Orchard Springs of Kentucky. The waters of Horn's Springs have an extensive reputation in Tennessee, and the contents show that they may be useful in conditions of the system requiring an alkaline regimen, a ferruginous tonic, or a mildly stimulating cathartic.

James K. Crook.

HORSERADISH.—Armoracia. The root of *Roripa Armoracia* (L.) Hitchcock (*Cochlearia Armoracia* L., *Nasturtium Armoracia* Fries., fam. *Cruciferæ*). As a drug, the fresh root is always understood, and is official in the British Pharmacopœia. The fresh leaves and herb are official in Germany and France. This well-known plant is a native of Eastern and Northern Europe, but it has been cultivated so long in other parts of the world that it occurs in a half wild state in many temperate countries. Its truly wild form is not known with certainty, and it does not readily perfect its seeds; but its roots are very tenacious of life, and make it, in localities favorable to its growth, difficult to eradicate.

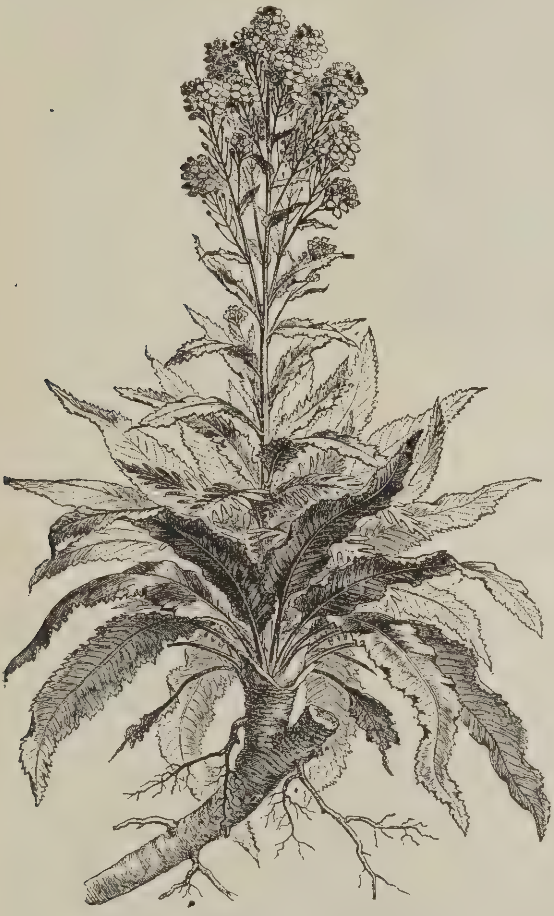

Fig. 2708.—Horseradish Plant and Root.

Horseradish root is from 1 to 3 cm. or more ($\frac{1}{2}$ to $1\frac{1}{2}$ in.) in diameter, and from 0.5 to 1 metre or more long; it is in cylindrical or slightly tapering pieces, with a large annulated and sometimes branched crown, generally broken in digging while still thick, 20 or 30 cm. from the top, but sometimes much longer and then dividing into three or four long, tapering branches, or else arising from a thick horizontal axis nearly or quite as large as the vertical one. Other pieces are of the smaller branches, or of the sucker-like horizontal portion. It is brownish-yellow outside and white within, rather too hard to be easily cut with a table-knife, but soft enough to be rapidly rasped or grated. When cut or grated, a pungent, peculiar odor is developed, which disappears upon drying or by heat; taste sharp and peppery, also disappearing with age and desiccation. Horseradish root and aconite root have more than once been stupidly confounded with each other, even with fatal result. They have no resemblance whatever excepting their pungent taste. (See *Aconite.*)

The deadly poke-root has also been fatally mistaken for horseradish.

Composition.—The root appears to contain *sinigrin* (*myronate of potassium*) and a ferment, *myrosin* (?), capable of forming with the sinigrin an oil identical with that of mustard, viz., sulphocyanide of allyl. The odor and taste of this oil are not developed until the root has been crushed or grated, or treated with water. By these means these substances, which are prevented from reacting upon each other in the whole or dry tissues, are brought together. If the root is extracted with alcohol, or if it is dried, no oil is obtained; but it can then even be produced by adding the ferment of white mustard and water. The composition is thus essentially that of black mustard. The leaves also contain a sulphureted oil said to be milder than, and not identical with, that of mustard.

Action and Use.—Essentially that of mustard, to which the reader is referred. Locally it is rubefacient, and even vesicant; internally, an aromatic and stomachic; in concentrated form, an irritant. Its long-continued use as a condiment and flavor is justified by these properties. In former times it was used in scurvy, for which it is valuable, and for gout, rheumatism, asthma, etc., for which it is useless.

Administration.—Horseradish is rarely used as a medicine in this country, but if desired as an aromatic the British compound spirit offers it in an acceptable form:

"Horseradish root, scraped	20 ounces.
Bitter orange-peel	20 ounces.
Nutmeg	$\frac{1}{2}$ ounce.
Proof spirit	1 gallon.
Water	3 pints.

"Mix and distil a gallon. Dose, 1 to 2 fluidrachms."

W. P. Bolles.

HOSPITAL SHIPS OF THE UNITED STATES ARMY.—It was appreciated very early in the spring of 1898, by the Medical Department of the Army, in anticipation of the casualties to be expected in the war with Spain, that provision must be made for moving the sick and disabled at sea.

Of the many ships chartered or purchased for the transport service of the army none was considered suitable for hospital purposes.

On April 15th, 1898, the Surgeon-General of the Army applied for a ship to be used as a hospital ship. After many vessels had been inspected, cattle ships, transports, and others, he recommended the purchase of the *John Englis* as being a suitable vessel for the purpose in view. It was his intention to fit her up as a floating hospital for the care of disabled soldiers at any point on the Cuban coast, to transport them to our own coast, and to serve as a medical supply depot for troops in the field.

By direction of the President, after considerable delay, the vessel was purchased for this purpose, and was turned over to the Quartermaster Department of the Army to be altered and fitted up for the service required. Many changes were found necessary and it was not until July 2d, 1898, that she sailed from New York for Cuba, named the *Relief.* This vessel was built by Roach Bros., in 1896, was owned by the Maine Steamship Company, and was in passenger service from New York to Portland, Me. She is built of steel to her main deck, her superstructure being of wood. She is 306 feet in length, 46 feet beam, 29 feet from keel to main deck, 17 feet draft, single screw, and of 13- to 16-knot speed depending on conditions. Her hull is divided by four water-tight bulkheads, she is well lighted throughout with electricity and heated by steam. In converting her into a hospital ship her superstructure was in the main the only portion taken for hospital purposes. All, or nearly all, of the staterooms were torn out of the upper and main decks, thus making wards in the fore and after parts of the ship extending across the whole vessel. Ward 1, upper deck, forward, was 68 feet long, 32 feet wide aft, and 24 feet wide forward, containing 76 beds. Ward 2, aft, on same deck, was 68 feet long, 32 feet wide forward, and 24 feet wide aft, and contained 62 beds. In the centre of this ward was a well or opening through the deck to the ward below. The midship space on this deck contained the engine and boiler enclosures, and the pantry and galley for the sick. On the port side were staterooms for nurses, messroom, water-closet, and wardmaster's rooms. On the starboard were the dispensary and rooms for the engineers, pantry, etc.

On the main deck, aft, was ward 3, containing 76 beds. This ward was 79 feet long, 28 feet wide aft, and 38 feet wide forward. On the starboard side of this ward was set off the operating-room, 24 by 12 feet. The midship space was given up to messrooms, galley, bakery, engine and boiler enclosures, office rooms, laboratory, dark room, and washrooms. Forward of this was a small ward of 30 beds for officers, 38 by 24 feet. A portion of this space was set aside and enclosed as the record office where all records, etc., were made and kept. Just forward of this ward were the quarters of the ship's medical officers, messroom, pantry, staterooms, bath, etc., and on this deck in the forecastle, the crew space.

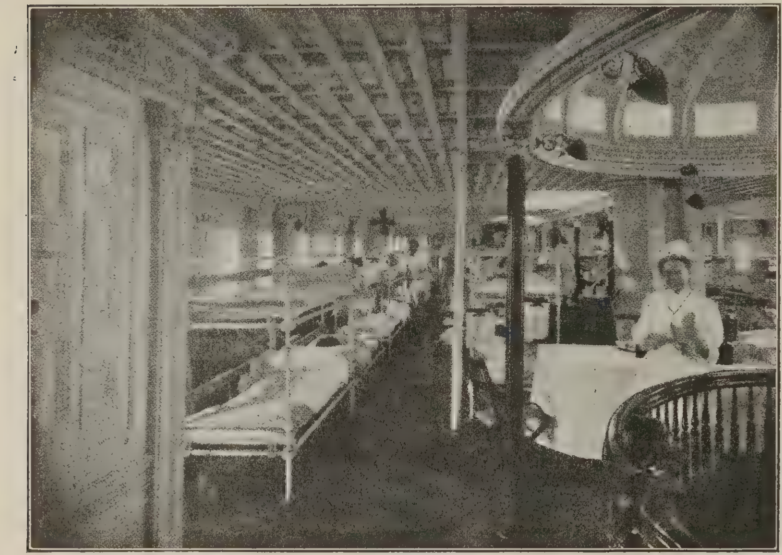

FIG. 2709.—After Ward on Upper Deck of Hospital Ship *Relief*.

On the lower deck was a ward of 46 beds aft, just forward of the "glory hole," which was given up to the ship's steward's crew. Midships were coal bunkers on either side of boiler and engine-room enclosures, store-rooms and steam laundry. Farther forward space was given up to machinery for the refrigerating plant, carbonating apparatus, disinfecting apparatus, staterooms, washrooms, and space for the crew, with elevator and steering and windlass engines.

On the orlop deck were the main store-rooms for medical, quartermaster, subsistence, and ship's stores, and bunkers for coal.

On the hurricane deck were rooms for the master and other ship's officers, eight life boats, two steam launches, and four life rafts.

The vessel was painted white with a green strake as is required by the articles of the Geneva Convention.

For her plans and general arrangements see Plate XXXII. and Figs. 2709 and 2710.

The *Missouri* was a steamship of the Atlantic Transport line, and in July, 1898, her services with her crew were offered the Government. The offer was accepted and the vessel was refitted for hospital work. She is 320 feet long, 40 feet beam, and 29 feet 6 inches in depth, and has a speed of about 11 knots. In fitting her for hospital purposes she received a steam laundry, a steam sterilizing apparatus, an ice and a carbonating plant. This outfitting may be said to have been of a temporary nature, though her equipment was excellent. After doing much good work in relieving the hospitals of Cuba and Porto Rico, and later as a floating hospital at Havana, Cuba, she was finally purchased by the Government and thoroughly overhauled for duty in the Philippines. She sailed for Manila in September, 1899, with a medical staff of four medi-

UNITED STATES ARMY HOSPITAL SHIP "RELIEF"

LIBRARY
OF THE
UNIVERSITY of ILLINOIS

cal officers, two acting assistant surgeons, two hospital stewards, seven acting hospital stewards, forty-seven privates of the hospital corps, and eleven male contract nurses. She carried large quantities of medical supplies, and officers and men as passengers for duty in the Philippines. She did good work in the islands, returned to San Francisco in the winter of 1900, and, her services being no longer needed, she was then transferred to the Quartermaster's Department for use in the transport services.

There was one other hospital ship of short life as such, during the Spanish-American War—the *Bay State,* afterward the *Aid.* She was first fitted up by the people of Massachusetts and did good work during the summer of 1898. She was purchased by the Government but was not found satisfactory for hospital-ship purposes. She was very small and unsuited for rough weather, and not long after her purchase was turned over to the Quartermaster's Department.

In the Santiago expedition the fourth divisional field hospital of the Fifth Army Corps was retained on board the steamer *Olivette,* which received patients after the battles about Santiago, and as an extemporized hospital ship did excellent and valuable work.

During the period that hospital ships were used during and following the Spanish-American War there were 8,370 admissions, distributed as follows:

Olivette: Admissions from June 14th, 1898, to August 31st, 1898, regulars and civilians, 661; volunteers, 170. Total, 831.

Missouri: Admissions from September 1st, 1898, to February 17th, 1900, regulars and civilians, 1,334; volunteers, 703. Total, 2,037.

Relief: Admissions from July 1st, 1898, to July 31st, 1901, regulars and civilians, 3,272; volunteers, 2,230. Total, 5,502.

The *Relief* sailed on her first outward voyage from New York City for Siboney, Cuba, carrying much needed supplies, arriving July 7th, 1898. She returned to New York July 23d, with 254 patients and on her second and third voyages went to Ponce, Porto Rico, returning filled with sick which she discharged at New York and Philadelphia. She then helped distribute patients from Montauk Point to hospitals in Boston and Philadelphia, and later made four more trips to Cuba and Porto Rico bringing back each time sick and convalescents to her full capacity. She was then ordered to the Philippines and after thorough repairs sailed March 3d, 1899, for Manila viâ the eastern route. She touched at Gibraltar, Port Said, Perim, Colombo, and Singapore, arriving at Manila April 12th, making the fastest time ever made between New York and Manila. She remained in Manila Bay ten weeks as a floating hospital. On June 22d she sailed for San Francisco with 250 patients, touching at Nagasaki, Yokohama, and Honolulu for coal. After arriving at San Francisco August 2d, 1899, it was decided to send her back to the Philippines for work in the islands, it having been concluded that she was not adapted to the long Pacific voyage. She continued in service as a hospital ship, taking part in the China expedition, until July 31st, 1901, when she was finally abandoned for hospital purposes and turned over to the Quartermaster's Department for use as an inter-island transport in the Philippines.

The work done by our hospital ships cannot be estimated nor appreciated by mere statistics. All cases, it may be said, did well on board. The clean, cheerful surroundings, the pure air, the good food, freedom from insects accomplished marvellous results.

The work of hospital ships properly designated as such was almost all done by the *Relief* and *Missouri.* It was the writer's fortune to serve on the former, and such knowledge as he may possess about such duty was gained by his service on that vessel. In the following discussion of the subject of Hospital Ships, he is simply giving the results of this observation and experience, and the conclusions drawn therefrom.

Paragraph 1622, Army Regulations, 1901, reads:

"Hospital transports, boats, and railway trains after being properly assigned as such, will be exclusively under the control of the Medical Department, and will not be diverted from their special purposes by orders of local or department commanders or officers of other staff corps."

It was under the provisions of this regulation that General Orders, No. 53, A. G. O., dated May 25th, 1898, was issued.

"General Orders, No. 53, Headquarters of the Army, Adjutant General's Office, Washington, May 25th, 1898. . . .

"II. By direction of the Secretary of War, the following is published for the information and guidance of all concerned:

"The steamship recently purchased for the use of the Medical Department of the Army as a hospital ship will be named the *Relief.* In accordance with the terms of the Geneva Convention the Geneva Cross flag will be carried at the fore whenever the national flag is flown, and the neutrality of the vessel will at all times be preserved.

"No guns, ammunition, or articles contraband of war, except coal or stores necessary for the movement of the vessel, shall be placed on board; nor shall the vessel be used as a transport for the carrying of despatches, officers, or men not sick or disabled, other than those belonging to the Medical Department.

"By Command of Major-General Miles:

"H. C. Corbin,
"*Adjutant General.*"

The articles of the Geneva Convention which concern the Marine are as follows:

"Art. VI. The boats which, at their own risk and peril, during and after an engagement pick up the shipwrecked or wounded, or which having picked them up, convey them on board a neutral or hospital ship, shall enjoy, until the accomplishment of their mission, the character of neutrality, as far as the circumstances of the engagement and the position of the ships engaged will permit.

"The appreciation of these circumstances is entrusted to the humanity of all the combatants. The wrecked and wounded thus picked up and saved must not serve again during the continuance of the war.

"Art. VII. The religious, medical, and hospital staff of any captured vessel are declared neutral, and, on leaving the ship, may remove the articles and surgical instruments which are their private property.

"Art. VIII. The staff designated in the preceding article must continue to fulfil their functions in the captured ship, assisting in the removal of the wounded made by the victorious party; they will then be at liberty to return to their country, in conformity with the second paragraph of the first additional article.

"The stipulations of the second additional article are applicable to the pay and allowance of the staff.

"Art. IX. The military hospital ships remain under martial law in all that concerns their stores; they become the property of the captor, but the latter must not divert them from their special appropriation during the continuance of the war.

"Art. X. Any merchant ship, to whatever nation she may belong, charged exclusively with removal of sick and wounded, is protected by neutrality; but the mere fact, noted on the ship's books, of the vessel having been visited by an enemy's cruiser, renders the sick and wounded incapable of serving during the continuance of the war. The cruiser shall even have the right of putting on board an officer to accompany the convoy, and thus verify the good faith of the operation.

"If the merchant ship also carries a cargo, her neutrality will still protect it, provided that such cargo is not of a nature to be confiscated by the belligerents.

"The belligerents retain the right to interdict neutralized vessels from all communication, and from any course which they may deem prejudicial to the secrecy of their operations. In urgent cases special conventions may be entered into between commanders-in-chief, in order to neutralize temporarily and in a special manner the vessels intended for the removal of the sick and wounded.

"Art. XI. Wounded or sick sailors and soldiers, when embarked, to whatever nation they may belong, shall be protected and taken care of by their captors.

"Their return to their own country is subject to the provisions of Article VI. of the Convention, and of the additional Article V.

"Art. XII. The distinctive flag to be used with the national flag, in order to indicate any vessel or boat which may claim the benefits of neutrality, in virtue of the principles of this Convention, is a white flag with a red cross. The belligerents may exercise in this respect any mode of verification which they may deem necessary.

"Military hospital ships shall be distinguished by being painted white outside, with green strake.

"Art. XIII. The hospital ships which are equipped at the expense of the aid societies, recognized by the governments signing this Convention, and which are furnished with a commission emanating from the sovereign, who shall have given express authority for their being fitted out and on their final departure, and that they were then appropriated solely to the purpose of their mission, shall be considered neutral, as well as the whole of their staff. They shall be recognized and protected by the belligerents.

"They shall make themselves known by hoisting, together with their national flag, the white flag with a red cross. The distinctive mark of their staff, while performing their duties, shall be an armlet of the same colors. The outer painting of these hospital ships shall be white, with red strake.

"These ships shall bear aid and assistance to the wounded and wrecked belligerents, without distinction of nationality.

"They must take care not to interfere in any way with the movements of the combatants. During and after the battle they must do their duty at their own risk and peril.

"The belligerents shall have the right of controlling and visiting them; they will be at liberty to refuse their assistance, to order them to depart, and to detain them if the exigencies of the case require such a step.

"The wounded and wrecked picked up by these ships cannot be reclaimed by either of the combatants, and they will be required not to serve during the continuance of the war.

"Art. XIV. In naval wars any strong presumption that either belligerent takes advantage of the benefits of neutrality, with any other view than the interest of the sick and wounded, gives to the other belligerent, until proof to the contrary, the right of suspending the Convention, as regards such belligerent.

"Should this presumption become a certainty, notice may be given to such belligerent that the Convention is suspended with regard to him during the whole continuance of the war.

"Art. XV. . . . (*f*) Hospital ships are required to carry the Geneva cross flag at the fore whenever the national flag is flown, and their neutrality must at all times be preserved. No guns, ammunition, or articles contraband of war, except coal or stores necessary for their movement, will be placed on board, nor should they be used as transports for carrying despatches, officers or men not sick or disabled, other than those belonging to the Medical Department."

Under existing laws and regulations the Quartermaster's Department is charged with all matters of transportation and all expenditures pertaining to the same. This department therefore makes all alterations necessary to fit the vessel for hospital purposes, and provides the necessary force to operate her at sea as a steamship. All supplies necessary for such operations, fuel, deck stores, engineers' supplies, etc., are furnished by this department. It employs a master or ship's captain and all the crew of the various departments, deck, engineer's, and steward's. These sign the ship's articles and are subject to marine laws and regulations. An officer is detailed as quartermaster on board who looks after all matters pertaining to the quartermaster's department. He submits from time to time, through the commanding officer, requisitions for supplies and repairs to maintain the efficiency of the vessel. He acts as disbursing officer and is furnished funds for the payment of the employees of his department on board and for such emergency purchases of fuel, stores, etc., as may be necessary. He also keeps on hand clothing for issue to enlisted men of the hospital corps and others who may be on duty on board, and to patients received for treatment. He should make frequent inspections of the vessel and by constant scrutiny and supervision take proper steps to keep the ship in good repair. To effect this he should consult the chiefs of the various ship's departments and require them to furnish him detailed statements of the needs of their departments which he should consolidate and carefully revise before submitting the same to the commanding officer. Except in emergencies all estimates are sent to the Superintendent of the Army Transport Service who takes proper steps to make all repairs and furnish all supplies pertaining to the Quartermaster's Department. The regulations of the Army Transport Service are followed by the quartermaster of a hospital ship in so far as they do not conflict with the regulations of the Medical Department in its management and control of the vessel as a hospital.

A hospital ship is a general hospital afloat; as such it is under the exclusive control of the Surgeon-General and is governed by such regulations as the Secretary of War may prescribe. The surgeon in charge commands and is not subject to the orders of local commanders. As commanding officer the surgeon in charge is responsible for the ship at all times. His duties as commanding officer are practically the same as those of a commanding officer of a post, and in addition he conducts and maintains the hospital department. He is responsible for the proper application and preservation of all property, for the strict enforcement of laws and regulations, and will satisfy himself that the disbursements of officers under him in charge of funds are in accordance with laws and regulations and that their accounts are correct. The commanding officer should study the regulations governing the marine and be careful to observe and conform to the laws and regulations regarding quarantine, pratique, and customs of any port the vessel may visit. For the proper navigation of the vessel he looks to the master of the ship and holds him responsible for the efficiency and discipline of the crew. He should co-operate with the quartermaster and master in all matters which tend toward the comfort, safety, and efficiency of all on board. He should require frequent fire drills and make, with the quartermaster and master, frequent inspections of all parts of the vessel.

The conducting of the various departments of the ship, deck, engineer's, and steward's departments, differs but little, if any, from the management on any steamship in passenger service.

A Commissary Department is maintained on board under the charge of an officer designated as commissary officer. The quartermaster usually acts in this capacity. There are kept on hand ample commissary supplies, not only the components of the ration, but a variety of additional stores for sale to those on board and for issue to the sick.

Early in the Spanish-American War the subsistence of those on board a hospital ship came from three different sources. First, issues of the ration to enlisted men serving on board and to the sick who did not require special diet. Second, all sick requiring special diet were subsisted by stores purchased in open market by the medical officer in charge, not to exceed sixty cents per day per man. Third, the subsistence of the ship's crew was provided by the Quartermaster's Department; an allotment was made of fifty cents per day for each man and one dollar per day for each ship's officer and placed in the quartermaster's hands for their subsistence. For convenience of administration, there was maintained on the *Relief* at this time a hospital mess only, and the ship's employees were considered as living in this mess which was maintained by the medical department. The quartermaster at the end of each month paid to the medical officer commanding the amount allotted for the subsistence of his employees, and this amount was accounted for on the hospital fund statement.

Later the subsistence of all on board was placed in the hands of the subsistence department. The employees were subsisted from supplies purchased by the commissary officer not to exceed a fixed amount; a hospital mess was maintained for enlisted men on duty and the sick, and rations were issued for all these except such of the sick as required special diet. For these an allowance of forty cents per day was made, to be expended as provided in Army Regulations, 1392, 1393, and 1395:

"Par. 1392. The medical officer in charge of a general post, or camp, hospital ship, or transport, carrying patients, is authorized to purchase, under the laws and regulations relating to purchases of subsistence stores, such articles of food, both solid and liquid, not carried in stock by the subsistence officer who issues rations to the hospital, and to call upon such subsistence officer for the issue of such quantities of articles from the stock already on hand as, in the judgment of the medical officer, are required for the diet of enlisted patients under his charge who are too sick to be subsisted on the ration as ordinarily issued; the total combined money value of the stores hereby authorized to be purchased and issued as above in any month not to exceed the rate, calculated on the month's transactions, of forty cents per man per day for those actually requiring special diet. Subsistence officers are authorized to pay all duly certified bills of purchases made by medical officers under the provisions of this paragraph, or to make the purchases themselves at the request of the medical officers, and to make issues for special diet hereunder from stores on hand at their request, provided that the rate of forty cents per man per day for those enlisted men actually requiring special diet is not exceeded in any month."

"Par. 1393. When a ration has been drawn by the hospital for an enlisted patient for a ration period and it becomes necessary during that period to put him upon special diet, due deductions will be made by the surgeon in charge on the next ration return of the hospital for the rations unused by him; and, reciprocally, when a patient on special diet has been restored in a ration period to regular diet, the necessary additions will be made on the next ration return of the hospital for the rations used by him. The object of this rule is to prevent the hospital from having the benefit of the rations of enlisted men for the period they may be put upon special diet, and to give the benefit of an issue of rations where men have been restored to regular diet when rations had not been drawn for them."

"Par. 1395. The formation of a hospital fund from articles purchased for special diet for enlisted men too sick to use the army ration, or the application of such articles to uses other than those for which intended, is prohibited. Such articles will, as far as practicable, be procured in quantities sufficient for the needs of specific patients only, and no large accumulations will be made. Nothing in this regulation will be construed to prevent the maintenance of a hospital fund from savings of the rations of the hospital corps, and the patients who do not require special diet."

The duties of quartermaster and commissary on board may satisfactorily be performed by an experienced medical officer who can otherwise materially assist the commanding officer.

The Medical Department furnishes and supplies a hospital ship the same as it would a general hospital on shore. It causes to be detailed a medical officer commanding, and medical officers to assist him in its administration. It details a suitable number of hospital stewards, privates of the hospital corps, and nurses, male or female as may be required, and employs such civilians as may be necessary as mess stewards, mess men, cabin boys, cooks, laundrymen, etc. The commanding officer has placed at his disposal funds for the payment of the employees of the department and the purchase of such medical and hospital supplies as may be necessary. For these funds he is personally accountable and must submit his accounts each month to the Treasury Department through the Surgeon-General. The ship is provided with medical supplies of every description for her own hospital needs, and stores in abundance in excess of these, for issue from time to time to shore stations, or transports, etc., where supplies may be needed.

The *Relief* was fitted up with double bunks, one above the other, with felt mattresses and woven-wire bottoms fastened to tubular bent iron frames, enamelled white. These were secured to the deck and arranged end to end lengthwise of the ward with suitable aisle spaces. Each bed was supplied with side rails of maple, about three inches wide, fastened by clips and bolts to head and foot for rolling boards. One of these was never removed; the other was used only in rough weather, being detached for convenience in handling the patient at other times. Swinging cots were not used on board, but it is believed that a certain number swung on gimbal joints would prove very satisfactory for very severe cases. Each ward had one or more bathtubs and wash basins fitted with "Gagenstrom" plumbing fixtures for both fresh and salt water, heated by steam, with shower, etc., the tubs curtained off by canvas screens suspended from the ceiling. Portable tubs on wheels were also supplied, but usually patients were carried to the ward tub when necessary. Each tub fixture was supplied with a thermometer so that the temperature of the water flowing into the tub could be accurately determined and controlled.

Directly off each ward were water-closets and urinals in sufficient number. All closets on board ship should be supplied with automatic flushing apparatus or some device to insure the security of the trap seals. In rough weather the rolling of the vessel empties out ordinary traps and permits soil-pipe odors access to the ship. Plumbing connections should be made of heavy rubber tubing in all places where the working of the ship might break the pipes. On the upper and main decks of the *Relief* were hoppers, fore and aft, with a salt-water flushing supply pipe designed to receive dejecta from bed pans, slops, refuse, etc. The outlets of these hoppers were five-inch pipes running clear of the ship outside, down to the water line. The bedding for the sick was that furnished shore hospitals, good feather and hair pillows, woollen blankets, sheets and pillow cases. An abundance of towels was supplied for all needs. The interior of the wards was painted white, touched up with gold. Each ward had many large windows by means of which fresh air and light were freely admitted. On the main deck the ward floors were kept shellacked. Floor polish was tried, but did not prove satisfactory at sea. The floors of the upper wards were the canvas-covered decks, and strips of rubber matting were used in all aisles and passageways. When the vessel first sailed her main deck was painted within and without, but paint was found to be unsatisfactory. The decks were later scraped, planed, and sand-papered; in the wards they were then treated with shellac varnish, and the outer decks were holystoned. Interlocking rubber tile floor gave excellent satisfaction in toilet, bath, and operating rooms. This comes in various designs of shapes and colors, and if well put down is easily kept clean and sanitary. On ship board when paint is used it must be frequently renewed, for chemical action is rapid both from gases of coal combustion and from the salt water. Cleansing and overhauling seem to be always necessary. Just as a satisfactory condition of cleanliness seems attained, it becomes necessary to put on coal and coal dust permeates the whole vessel. At these times windows and port holes should be kept closed to exclude all this dirt.

Each ward was supplied with a white enamelled glass and iron dressing table and a suitable outfit of instruments, dressings, and appliances for ward treatment. Each bed was numbered, had a record clip for the patient's history, charts, etc., and had a sea-can secured by its handle to the rolling board conveniently at hand for seasickness. Each ward had a small refrigerator for the keeping of such articles as required ice for preservation and to keep cool drinks and beverages for the sick. A ward table with drawers and compartments proved of great convenience as a place to keep the various articles needed in ward work.

In the ward toilet-rooms were small closets in which was kept cleaning gear, such as mops, brooms, brushes, cloths, etc., used in ward police; suitable racks were also arranged for bed pans and urinals so that they might be secure when not actually in use. Small electric diet kitchens were installed in each ward and proved valuable accessories to the central diet kitchen.

The operating room was 24 by 12 feet, on the main deck next the principal gangway. It was finished in white enamel and was fully equipped. It was supplied with an autoclave, instrument and dressing cabinets, irrigating stands, stands for bowls, bunch lights for night work, an electric transformer, formalin apparatus, etc. There was hot and cold water distilled from the condensing apparatus of the ship. Oil stoves were at first used for boiling water and preparation of instruments, but later electric stoves were supplied. The usual outfit of instruments and apparatus was furnished and modern surgical methods were strictly observed; the equipment was complete. The operating tables, two, were secured to the floor; the movements of a vessel make it necessary securely to fasten in some way all loose objects when at sea.

A wheel litter was found of service in transporting patients from wards to operating room, being more easily managed than an ordinary litter. There was installed near the operating room a fine *x*-ray apparatus. When it was placed on board it was found impracticable to put it in a dark room because of lack of space, so it was available for use only at night. It proved of great use in many cases.

Very little skiagraphy was done, but the fluoroscope was used to advantage in locating missiles or making diagnoses, and operation if indicated followed.

There was a small dark room for photographic and skiagraphic work with the necessary supplies and equipment. This room was also used for eye, ear, and throat work when necessary.

The pathological laboratory had a complete equipment and much interesting and valuable work was accomplished. While at sea it was hardly practicable to undertake more than ordinary clinical pathological work, but while serving as a floating hospital at anchor there was no limit to the investigations which might be conducted.

An ice plant, the ammonia machine of De La Vergne, was installed on board for the production of ice and for refrigeration. It produced all the ice required by all on board and kept a large chill room at proper temperature for preservation of perishable food supplies. While this machine gave excellent satisfaction, one which does not require ammonia, if equally good, would be preferred. On several occasions during overhauling and repairing the fumes of ammonia escaped to such an extent as to render that portion of the ship intolerable. A serious accident occurred on the *Bay State*, afterward the *Aid*, in which the ammonia machine exploded, killing one man and seriously injuring about a dozen others. An accident occurring to an ammonia machine while at sea, causing escape of the gas, might be followed by most disastrous results. The use of such machines is prohibited in our naval vessels, and dense air machines are used almost exclusively. It is hardly necessary to state that refrigeration will not be successfully accomplished unless great pains are taken to secure proper insulation.

Having proper refrigerating facilities, articles of food can be preserved for weeks and thus suitable diet be furnished the sick for extended periods. This is an important point and must not be overlooked in making preparation for caring for large numbers of sick at sea. The ice plant is also of value in ventilating systems for cooling when necessary air delivered to any portion of the ship. This was not done on the *Relief* which had no special ventilating system, but on our transports the ventilating system has been so arranged that air is furnished cooled by means of the refrigerating device. This system has not yet been sufficiently tried to warrant positive assertions as to its utility under the varying conditions to be met at sea. The ventilation on the *Relief* was "natural." There was no system for providing fresh nor for exhausting the vitiated air. In this respect the vessel was defective. However, her wards were all in the superstructure, extending from side to side and had numerous large windows opening on the outer deck. There were also hatches and openings in the domes of the upper wards; the lower ward, aft, opened into the ward above by a large well, an oval opening, above which were hatches on the hurricane deck which were always kept open. In bad weather when windows, doors, and hatches had to be closed the air was very poor, but fortunately it was nearly always practicable to have openings on the leeward side of the vessel. In the lower decks the air was never as good as it should have been. Small port-hole openings existed and in good weather the large cargo ports were kept open, but in bad weather the ventilation was very unsatisfactory. Much fresh air reached this portion of the ship by means of ventilating cowls on the upper deck which conducted fresh air down to the boiler and engine rooms. But this was totally inadequate. In tropical waters and in good weather when everything could be kept open there was but little fault to be found, but in stormy weather it was different. The system of ventilating adopted on our transports could very properly be installed on our hospital ships, as was done in the case of the *Missouri*. This system is worked by two sets of fans, one forward, another aft, on the spar deck, with metal air ducts leading to all berth decks. These fans are either intake or exhaust, as may be required, and deliver air at the outside temperature or warmed, cooled, or filtered, according to the needs of the situation. The rated capacity of each fan is 25,000 cubic feet of air per minute. There is an air-cleansing and cooling device attached to the fan through which when tested the air current passed at a velocity of 1,000 feet per minute with a discharge velocity at the farthermost point from the fan in the lower troop deck of 950 feet per minute. Such a system, or one similar, should be placed in all hospital ships and fresh air carried to every compartment and store-room in the vessel.

A carbonating apparatus fully equipped was installed on board the *Relief* when the vessel was fitted out and gave great satisfaction. Large quantities of carbonated water were sent ashore in Cuba and Porto Rico in ordinary bottles; that for ship's consumption was put up in siphon bottles. The distilled water made on board was charged at but trifling expense. All effervescing drinks are grateful to patients at sea, and this carbonated water with fruit juices, or without, was in great demand. The ice plant and carbonating plant were on the main deck and were operated, as were all appliances or machinery requiring steam, by the engineer's department. On this deck was installed a disinfecting and laundry plant. The former was a large Kinyoun steam sterilizing or disinfecting apparatus so arranged that formaldehyde could be used as well as steam. An apparatus of this kind seems essential and a desirable portion of the equipment. Many days or months may elapse when it is of no use, but when receiving patients from an infected district it performs an important service in assisting us to prevent access of disease to ship board through patients' effects. The laundry was equipped with a washer, a rotary dryer, mangle, and other appliances necessary in a place of this kind, and an ample drying room. Its operation on ship board was sometimes subject to interruption at sea owing to lack of fresh water, but in port at all times plenty of fresh water could be procured and no difficulty was experienced in cleaning the bed and table linen of the whole ship. The situation of the laundry on the *Relief* was an objectionable one. It was adjoining the boiler room and difficulty was experienced in excluding coal dust and smoke which soiled the clothes and made the work unsatisfactory. A location should be secured where such annoyances could be avoided. With competent laundrymen it would seem that all laundry work might be done in a laundry of this kind, but as a matter of fact only the work above mentioned was performed satisfactorily. All pieces requiring hand work could not be done satisfactorily; the reason for this was because of inadequate water and facilities for rinsing, starching, and the subsequent handling of the clothes in a place free from dust. Two civilian laundrymen were employed and three men of the hospital corps detailed for operating the laundry. A hospital steward was given general charge and kept check of the clothing passing to and from it.

The lowermost deck of the ship was given up to storerooms. Of these there were many, for all the various departments of the ship must have abundance of supplies for long voyages; the commissary department needs room for thousands of rations and special articles; the quartermaster suitable room for clothing and equipage, and the medical department much room for the great variety of supplies it must necessarily have in readiness. All these stores must be placed with due regards to space, convenience of handling, and accessibility and security. When the articles can be so arranged, their disposition should be by some system, alphabetical or supply table lists, so that account of stock may be readily taken or articles easily located when needed. A separate strong room should be used for all liquors, well secured by proper locks; this will preserve the liquor and trouble will not arise among members of the crew because of whiskey on board coming from sources unknown.

Bedding and clothing not in use should be frequently taken on deck and aired. All store-rooms should be often inspected and contents verified from time to time by a commissioned officer. All stores should be replenished when necessary by proper requisition, the responsible officer bearing in mind that he will be held accountable for any suffering which may result from his failure to ask for supplies when it is evident that they will be needed.

Fresh-water tanks should be provided so that an ample supply of fresh water may always be available. Instead of putting in quantities of iron for ballast it would have been much better on the *Relief* had she had more tanks to take additional amounts of fresh water for ballast. All water used for cooking, drinking purposes, and for the sick on board was distilled or made in the ship's condensers. This was aerated by a fresh-air intake pipe coming from the upper deck near the pilot house, and this water was also filtered before being used.

The equipment of the ship for fire in addition to life rafts, boats and life preservers, included fire plugs and fire hose and in all store-rooms hand grenades.

Deck chairs were furnished in abundance for patients and all others which when not in use were stowed in racks provided to secure them. A well-selected medical library was furnished by the Medical Department, manuals of reference by the Adjutant General's office, and a good library of about five hundred volumes of history, biography, travel and fiction was presented to the vessel by interested people of New York City. This library, a fine music box, and an Æolian, also gifts, furnished much entertainment to convalescents and added materially to the comfort and contentment of all.

A hospital ship should have dynamos of sufficient capacity to operate a lighting system, searchlights, electric fans, and electric heaters in ample quantity for all needs. Two such dynamos should be installed, each of sufficient capacity to meet all requirements, so that while one is in use the other may be receiving such repairs as may be required; with two one may be available at all times, with only one there would be times when light would be wanting. A competent electrician should be employed on board to attend to the electric appliances.

The *Relief* was well equipped in this way, though at times the dynamos proved of insufficient capacity to meet all requirements. Electric fans were placed in every portion of the vessel and were of material value in ventilation and of great comfort to all when the vessel was in tropical waters. When we consider the management of the hospital ship for hospital purposes it is found to be essentially the same as that of a shore hospital. We have our medical officers, our hospital corps detachment and nurses, and such civilian employees as may be necessary. The hospital force of the *Relief* at first consisted of a commanding officer and six other medical officers. There were three hospital stewards and twenty-nine privates of the hospital corps, ten graduate male nurses and ten graduate female nurses. Experience caused some modification in these numbers. The male nurses were dispensed with and more hospital corps men detailed and the number of women nurses reduced to eight. At times when at sea the efficiency of our working force was much reduced because of seasickness, for but few of all our staff had ever had sea duty before.

The duties of the medical officer commanding have already been partially outlined: in the hospital department he assigns his assistants to various duties and has charge of the general administration of everything concerning the welfare of the sick. One medical officer he selects as his executive officer, usually the next in rank, to aid him in his supervision. His duties are practically those of an adjutant to a commanding officer; he has charge of the office and records and sees to the details of men for special duty; the keeping of the clothing accounts of men on duty and patients under treatment rests with him and he should supervise the preparation of all regular reports, promulgate all orders, and conduct the general correspondence. He distributes patients received for treatment, and generally looks after the welfare of the patients and management of the hospital as an aid to his superior. It is not necessary that an executive should perform these duties; the commanding officer may be his own executive either in whole or part, and indicate to his assistant such duties as he desires him to perform; but the performance of the duties by an executive as outlined will relieve the commanding officer of many details and much routine work.

There should be assigned to each ward one medical officer, or if the number of patients or the character of the diseases or injuries warrant it, then more than one. All serious cases should be reported by the ward medical officer to the executive or commanding officer and consultation held as to treatment, surgical or medical. A roster should be kept, and at all times there should be a medical officer of the day. He is always on duty ready to respond to any calls in the wards at night; he should have a sick call every morning for the enlisted men and employees on board if some officer is not regularly designated to look after these, which is perhaps the better plan. When any one of these employees is excused from duty because of sickness he should be shown on the morning sick report and properly reported on the reports of sick and wounded.

Of the hospital corps detachment there is required one hospital steward in charge of records in the office; one in charge of property and returns pertaining thereto; one in charge of the general police of those portions of the ship occupied by the medical department. There should be an acting hospital steward in charge of the dispensary, one in charge of the laundry, and one in charge of each ward. The steward in charge of general police should have charge of patients' effects. With these non-commissioned officers, though more could be utilized, the work of ships of the capacity of the *Relief*, 250 patients, can be very well managed. There should be for this number about forty privates of the hospital corps; six on duty in each ward of fifty men, one as assistant in the dispensary, three in the laundry, two in the operating room, one in the office, and the others for special duty in various capacities, as clerks, diet assistants, etc. Regular instruction should be given these men for at least twenty hours per month as prescribed by Army Regulations; they should be well disciplined and every effort made to maintain the high efficiency required at the present time for men of the hospital corps. Frequent inspections should be held and each man's clothing and equipment seen to be in proper condition. Men on ship-board duty need not be furnished the ordnance equipment issued men of the corps on shore duty; they have no possible use for anything but the belt and waist belt plate. Other articles of ordnance should be kept in the general store-rooms for issue when men are detached and sent for duty ashore. The hospital corps pouch is also an unnecessary incumbrance on ship board and there is no necessity for its issue to the men; it too should be kept in the general store-rooms. Each man of the detachment should have a barrack bag to hang on his bunk and a stationary locker for storing and securing his clothing and personal effects. All boxes and trunks should be kept below in the trunk rooms. Certain days should be established as trunk days when the men may have access to their boxes and belongings for such articles as they may not be allowed to retain in locker and bag. It is impracticable for them to display their shoes under their bunks, and their other equipments upon them as is customary for inspections in shore hospitals; the movements of the ship will not permit. The duties of members of the hospital corps on sea duty differ but little, if any, from the requirements on shore. The Army Hospital Corps is discussed in another portion of THE HANDBOOK to which reference may be made for full particulars on this subject.

Women nurses did excellent service on board the *Relief*, beginning when the vessel first sailed and continuing up to the winter of 1899–1900 when their service was discontinued. At first ten nurses were on duty, but later it was found that eight were all that could be satisfactorily employed. No night duty was required except in special cases. Two nurses were assigned to each of the three larger wards, one to the officers' ward, and one in charge of the operating room and the diet room. They were employed under contract and later under the regulations governing the nurse corps. Considerable friction existed at times between these nurses and the members of the hospital corps in regard to division of duties and responsibility, and much tact was required to get the best services from both. The men disliked the idea of being subjected to the authority of a woman nurse in all matters; it was finally arranged that the nurse in the ward should be responsible for the nursing proper, and the acting hospital steward in charge be responsible for the discipline and police, the two to consult together in all matters pertaining to the welfare of the sick in the ward. By this arrangement the ward work was in most cases satisfactorily performed. Divided responsibility, however, is always unsatisfactory and best results cannot be thus attained. With good hospital-corps men as nurses it is believed that the place for women nurses is not on board hospital ships. Their presence requires separate arrangements for sleeping apartments, toilet, and mess rooms, which in the cramped conditions found on ship board works at times disadvantageously. The *Missouri* employed no female nurses, but instead had graduate male nurses whose services were reported satisfactory.

Ten male nurses were at first employed on the *Relief*, but they were relieved after the first voyage and additional hospital-corps men secured. There was constant friction between them and the women nurses and the hospital-corps men, and it seemed best to dispense with the male nurses. Some of these afterward enlisted for service on board and gave excellent service when they understood the requirements as to discipline demanded of enlisted men.

All the cooking on the *Relief* was performed in one small galley. This arrangement was most unsatisfactory, but the plan of the ship did not admit of more galleys. Had it been practicable there should have been at least a galley for the sick and hospital-corps detachment and employees drawing a ration, and another for the ship's crew and officers. This arrangement is suggested because of the sources of the food supplies or subsistence. The sick if not requiring special diet, all the enlisted force and rationed employees are subsisted on the ration, but the others above mentioned are subsisted by the commissary department on such articles of food as may be required, not to exceed a certain fixed per-diem value. It thus becomes necessary to know just the value of the foods consumed by the latter class, that the authorized allowance may not be exceeded. The management of the ration is the same on hospital ships as in shore hospitals. Savings can be made and a fund established to purchase such additional articles as may be desired. Those of the sick requiring special diet are supplied as noted in the beginning of this article from a special forty-cent subsistence fund in lieu of the ration.

The conditions on shipboard differ so much from those ashore that it is economy to employ a competent experienced man as ship's steward and a suitable number of employees as mess men, cooks, pantry men, cabin boys, etc., to constitute the steward's department. This department should be conducted as is done on large passenger steamships, and subdivided under as many assistant stewards as may be required to conduct the separate messes. A mess room should be provided for the hospital-corps detachments, but experience seems to indicate that the sick may be better served by individual service on trays. If the ship be commodious it might be practicable to have mess rooms for the convalescents, but in actual practice on the *Relief* it was found more satisfactory to give each patient, whether up and about or confined to his bed, his meals served on a tray. This tray was prepared at a diet kitchen on the upper deck situated just over the ship's galley from which the cooked food was sent on dumb-waiters. This diet kitchen had numerous steam-heated warming tables where the food was kept hot during its preparation for the tray. This room also had several boilers for making coffee, bouillon, chocolate, and other liquid foods; ample drawer and shelf space was here provided for dishes and cutlery. At mealtime the special diet patients requiring food in bed were first served, then those on the regular diet; each convalescent able to report for his tray came for it at the diet room and passed on to his bunk or any suitable place adjoining to eat his food. Meals were served to one ward at a time; convalescents, when able, assisted the attendants in the distribution of the trays. The soiled dishes were returned for cleansing to the diet room at another window. A nurse was always on duty when the meals were being given out and superintended the arrangement of the trays to make them as inviting as possible. She received lists from each ward showing the number and kind of diets required, supervised their preparation, and kept check on the issues. Japanned trays were first used but were not desirable; they soon became corroded and of unsightly appearance: heavy china dishes and plated silver ware were used. Dishes required constant replenishing owing to frequent accidents. It would be economy to use white enamelled ware for all dishes and trays. It is open to the objection of chipping but is very durable. The main diet kitchen requires an ample force of attendants to facilitate rapid handling and serving of food that it may reach the patient in a palatable condition.

Little supplementary electric diet kitchens in each ward are of great convenience in preparing foods and hot drinks outside of regular meal hours.

The galley had a fixed range, boilers for steam cooking, shelves, racks, etc., for cooking utensils. Adjoining the galley was a bake-shop; the butcher-shop was in a small room next the cold-storage room on the lower deck.

In receiving patients on board a hospital ship it is oftentimes necessary to send ashore the ship's boats for transporting the sick to the ship. Each of these boats will accommodate four patients on litters or about twenty if they are able to sit up. When thus loaded the boats are towed by steam launches, it being impracticable to row when they contain patients. One launch can tow a string of three or four boats and patients can be taken on board very rapidly. Litter squads are detailed as loading parties to accompany the boats; others remain on board and unload and distribute the patients when received. If the ship's construction will permit it much labor may be saved by rigging up block and tackle and lifting the patient on the litter to the deck by means of the steam windlass. The construction of the *Relief* prevented such an arrangement and all patients were received on board by gangways. Of these there were two; they were especially constructed, were broad and long so that when lowered the incline was gradual. The small boat drew alongside, the bearers made ready, and at a propitious moment when the boat was on the crest of a wave or swell, passed the patient over to the other bearers waiting on the gangplank to receive him. In rough weather loading was difficult and at times had to be suspended. The bearers learned to be very expert, and in all the hundreds of patients handled there was never an accident, though at times the up-and-down play of the small boats at the gangway was many feet. The patient was carried up to the main deck and assigned to a suitable ward. Stimulants and hot foods were in readiness when needed. If the condition of the patient would permit he would be given a tub bath; if not, then a sponge bath in bed, and given fresh hospital clothing. His valuables were properly listed and cared for by an officer assigned to such responsibilities. Such of his clothes and such toilet articles as he might have or need might be left in his clothing bag hanging at his bunk. All other clothing was placed in bags designed for patients' effects. These bags were made of strong bed ticking with draw string, and were about three by two feet in dimensions. They were furnished by the medical department and their expenditure was authorized; in other words, they were expendable. Shipping tags were provided and each man's bag had tied to it a tag giving his name and military address, his ward and bed number. These bags were placed in store-rooms so arranged that the tags were exposed, the arrangements being made by wards to facilitate accessibility. Such property as he might have which could not be put in bags—trunks, chests, etc.; volunteers will have quantities of such,—were tagged and put in the trunk room. When the patient was transferred ordinarily he was given the bag which bore his name on the tag and identified it as his in his further movements. If too sick to take charge of it himself, it was simply turned over to some responsible person representing the authority of the hospital to which he was destined. This system was very satisfactory and after it was devised but little trouble was experienced with patients' effects which prior to that time had given rise to an endless amount of trouble and confusion. On the *Missouri* a checking system was devised in which the bag was checked and a duplicate issued for the patient. It proved satisfactory, it is believed, to the authorities on board the *Missouri*, but it is not considered to be as well adapted to the needs of hospital ship service as the method used on the *Relief*. A patient received on board should be accompanied by a transfer slip giving his medical history and a descriptive list. When he is discharged the hospital his new commanding officer should be informed as to his accounts. Great care must be taken to keep proper accounts for each man while on board. The regulations governing muster, payments, issues of clothing, and all matters pertaining to administration must be strictly observed.

The dead should be buried at sea or properly embalmed and placed in metallic caskets; the former is to be preferred, but it is customary as a matter of sentiment to do the latter.

In the past sick and wounded have been moved by boat whenever the seat of war made it feasible to resort to water transportation. Steamers have been used on navigable rivers and sailing vessels and steamers on lakes and the ocean; in some instances canal boats have been utilized when battles have been in localities where canals existed: they were used after the fight at Balls Bluff during the Civil War, and the British have used them in Egypt. Small boats, barges, etc., may at times prove useful in emergency, but their discussion hardly comes within the limits of this article where the hospital ship proper is the subject under consideration.

England seems to have been first in preparing floating hospitals and transports for the sick, but there seems to be very little record of any systematic preparation previous to the Crimean campaign of 1854. During this campaign a fleet of "well-appointed" steamers, the *Orient, Poistiers, St. Hilda, Clifton, William Jackson* and others, carried in twenty-two months 114,668 patients. In 1858 the British fitted up two hospital steamers, *Mauritius* and *Melbourne*, for the use of their forces in China. In the former the lower troop deck was fitted up for the sick and wounded with berths ranging fore and aft. Heat was supplied by the engine-room and by swinging and cabin stoves, and ventilation secured by hatchways, port-holes, and tubes arranged from the galley fires. One thousand gallons of fresh water were supplied daily from the condensers. The *Melbourne* was in a general way fitted similarly to the *Mauritius*. Each had a surgery 15 by 10 feet, and a dispensary. The berths were 6 feet 3 inches by 2 feet 6 inches, with metal bottoms; good bedding and table furniture and good diet were provided. Each steamer had wash-rooms, washing or laundry rooms, and the usual butcher room, bake-shop, and store-rooms. In fitting up it seems to have been intended that these steamers should be used exclusively as hospital transports.

In 1873 England converted the line-of-battle ship *Victor Emmanuel*, a wooden, screw steamer, 5,157 tons, 2,414 horse-power, into a hospital ship and transport for service on the Cape Coast, Africa. The alterations were made at a cost of about $200,000, and accommodations were provided for 142 patients, with an additional capacity on deck for from 60 to 80 convalescents. Fifty-five men were detailed for hospital service on this ship: 16 non-commissioned officers and 39 privates; in actual service at Cape Coast more aid was required. In addition to these there were men employed for general purposes, as bakers, cooks, etc. Reference to Figs. 1192–1195, in Vol. III. of the former edition of this HANDBOOK, will show the arrangement of this vessel.

Spain fitted up two ships for hospital transports in her struggle with San Domingo. These are said to have done good service, but no detailed description of them can be obtained.

The United States used no special boats for the sick in the war with Mexico, 1846–1848, and early in the Civil War the disabled were transported on the ordinary passenger steamboats of the Western rivers. Later these were fitted up as hospital boats, but little alteration being required to make them well adapted for hospital service; they usually had large well-lighted and well-ventilated cabins, and the removal of the thin partitions between staterooms made other wards or rooms suitable to accommodate patients. Col. Joseph R. Smith, to whose writings the writer is indebted for this brief historical review, states that he found records showing that more than 100,000 patients were carried on hospital boats during the Civil War. Of these a great number were carried on the river steamer *D. A. January*, which in forty months handled 23,738 patients. This boat was 230 feet long and 65 feet wide. Its ordinary capacity was considered about 400, though it carried as many as 554 patients.

The hospital steamer *City of Memphis* was 330 feet long and 70 wide and carried comfortably 750 wounded. The *Empress* was 266 feet long and 45 wide, with an ordinary capacity of 500 patients, though she at one time carried

817. These vessels on the rivers frequently passed towns and landing places where supplies could be obtained and did not require the same equipment and stores as are needed for sea-going vessels. In addition to wards each of these vessels had rooms for officers and attendants, store-rooms of various kinds, kitchen and special diet kitchens, pantries, dumbwaiters, linen rooms, dispensary, operating room, bath, water-closets, etc. Water was supplied from a refrigerating apparatus by faucet in convenient places. Medical officers, hospital stewards, ward masters, and nurses were detailed in sufficient numbers. The medical officer or surgeon-in-chief was in absolute control and responsible for the administration. Figs. 1196–1199, in Vol. III. of the former edition of this Handbook, show the arrangement of these boats, the *January* being taken as a type.

In May, 1862, the Medical Director of the Army of the Potomac asked for hospital steamers sufficient to carry 5,000 patients; from this time water transportation was recognized as a method of moving the disabled and a medical officer was placed in charge, known as "medical director of transportation." During the war it is said that as many as thirty well-fitted hospital steamers were used at different times in the East and West.

The best ocean transport of those times was the *J. K. Barnes.* She was a side-wheel steamer, 1,400 tons, 288 feet in length, 35 feet 2 inches in width, 22 feet 9 inches depth of hold. Her total capacity was 477 patients; she was used but ten months, during which time she carried 3,655 patients. Her plans may be seen in Figs. 1200–1202, of Vol. III. of the former edition of this Handbook.

During the recent South African war a hospital ship known as the *Maine* was fitted up by American women. This vessel is a duplicate of the *Missouri* and her equipment was similar. Her operating room was complete, and said to be the best in South Africa. She had accommodations for 218 patients, an *x*-ray machine, electric lights, fans, and diet kitchens, a completely equipped laundry, a steam disinfecting apparatus, refrigerating plant, etc. Her hospital force consisted of six medical officers, five women nurses, eleven male nurses, ten orderlies, and two apothecaries.

The *Trojan, Spartan,* and *Prince of Wales* were other ships fitted as hospital transports; the capacity of all four being about one thousand patients. These ships participated in the China campaign of the allied troops in 1900. During this campaign the Japanese, Germans, and French also had hospital transports, but the details of their equipment cannot be ascertained. It is said, however, that our own hospital ships, especially the *Relief,* were far superior to all others in equipment and facilities for caring for the disabled at sea.

Alfred E. Bradley.

HOT BORATE SPRING.—Lake County, California. This remarkable spring is situated near the town of Lakeport and on the edge of Clear Lake. The spring flows 18,000 gallons per hour, and has a temperature of 124° F. (July, 1888). On analysis it is found to contain the following mineral ingredients:

One United States Gallon Contains:

Solids.	Grains.
Sodium chloride	86.82
Sodium bicarbonate	75.40
Sodium biborate	201.75
Potassium iodide	.12
Potassium chloride	Trace.
Potassium bromide	Trace.
Potassium bicarbonate	4.26
Ammonium bicarbonate	96.20
Magnesium bicarbonate	.73
Calcium sulphate	Trace.
Alumina	2.04
Silica	7.96
Organic matter	9.07
Total	484.35

Free carbonic acid gas, 30.75 grains.

An analysis by Dr. Moore shows a much smaller percentage of borax—103 grains per gallon. The spring is remarkable on account of the excessive amount of borax and ammonium salts which it contains. Professor Whitney states that the water is changeable both in its rate of flow and in its proportion of mineral ingredients. It is used in Lakeport and vicinity for kidney and bladder troubles. It is claimed that the water has dissolved a stone in the bladder.

James K. Crook.

HOT SPRINGS, BATH COUNTY, VIRGINIA.—

Post-Office.—Hot Springs. Hotels and cottages.

Access.—Viâ Hot Springs Branch of the Chesapeake and Ohio Railroad. Connection is made at Covington, Virginia. Through sleepers to Hot Springs are run in the summer. The Virginia Hot Springs Company run a line of first-class stages to the Warm Springs, five miles north, and to the Healing Springs, three miles south of the terminus at Hot Springs. The valley containing the Hot, Warm, Sulphur, and Healing springs of Virginia is located in the heart of the Appalachian Mountains, in the first of several lofty ranges that lie east of and parallel with the main Allegheny divide. Some two miles in width, the valley extends for more than a dozen miles between towering mountains, from the crests of which, 4,000 feet above the sea, villages and farm-houses with intervening stretches of country, over 1,500 feet below, are spread out to the view of the observer as a beautiful panorama. The visitor can drive for miles over new boulevards and carefully constructed roads. The streams formed by the various springs in the valley have pierced the western range and divided it into a series of five tall distinct mountains, narrowly separated from each other by chasms and gorges. Meandering roads and romantic bridle-paths and footways, bordered with ferns and mosses, penetrate these rugged and secluded passes. The altitude of the valley (2,300 feet) and its protection by the surrounding mountains from wind-storms and sudden changes combine to produce a temperature safe in winter and delightful all the rest of the year. The air is clear and dry, mists and fogs being rarely seen. The highest summer temperature observed during a series of recent observations was 87° F., the monthly mean for June, July, and August being 68.5° F.

The Hot Springs have been resorted to for three generations of white men. Physicians of wide reputation and abundant experience have pronounced them equal to the most effective similar waters of the European spas. The drinking-waters are also of great variety, and besides the hot springs there are magnesia, sulphur, soda, and alum springs, each of which is widely recommended for medicinal purposes. The bath-house at Hot Springs is a substantial four-story structure of stone and brick, built in the Colonial style of architecture at a cost of over $100,000. It is fitted up in a sumptuous manner with all the requisites of a modern institution of this kind. All varieties of baths will be found here. The old bath-house has been converted into two large swimming pools, one each for gentlemen and ladies. The hotels at Hot Springs are the "Homestead," a charming house of the true old Colonial style, which has been entirely remodelled and modernized, and the "Virginia," a new hotel built in the latest fashion, and supplied with every comfort and convenience. This hotel is kept open all the year. Ten new cottages cluster close by, each with a broad porch and veranda. This hotel is connected with the passenger station, but so arranged that no noise or annoyance is caused by railroad trains. The waters of the Hot Springs have been analyzed by several well-known chemists. The Spout, Boiler, and Sulphur Springs were examined by Professor Clarke, of the Smithsonian Institution in 1884, and the last two, together with the Soda and Magnesia springs, have recently been analyzed by Messrs. Dickoré and Morgan, of Cincinnati, Ohio. The several results in the examinations of the same waters have been practically identical. Following are specimen analyses:

Boiler (Bath) Spring.

(Analysis by Dickoré and Morgan.)

One United States Gallon Contains:

Solids.	Grains.
Magnesium sulphate	8.48
Magnesium carbonate	3.02
Calcium sulphate	1.89
Calcium carbonate	23.08
Sodium sulphate	3.68
Potassium sulphate	.69
Potassium chloride	.54
Silica	1.95
Total	43.33

Temperature, 108° F.

Soda (Drinking) Spring.

(Analysis by Dickoré and Morgan.)

One United States Gallon Contains:

Solids.	Grains.
Magnesium sulphate	5.90
Magnesium carbonate	2.61
Calcium sulphate	3.22
Calcium carbonate	17.55
Sodium sulphate	2.02
Potassium sulphate	.88
Potassium chloride	.21
Silica	.49
Total	32.88

Temperature, 74° F.

Spout Bath Spring.

(Analysis by Professor Clarke.)

One United States Gallon Contains:

Solids.	Grains.
Silica	1.37
Alumina	.15
Potassium chloride	.54
Potassium sulphate	1.09
Sodium sulphate	1.64
Calcium sulphate	8.32
Magnesium carbonate	7.02
Calcium carbonate	13.96
Total	34.09

Temperature, 106° F.

These waters resemble considerably in chemical composition those of the Hot Springs of Arkansas. They also resemble those of Aix-les-Bains in France, the French spring having a somewhat higher temperature. Both for internal use and for bathing the waters of the Virginia Hot Springs have gained a wide celebrity in the treatment of many of the ills to which human flesh is heir. The baths here are especially to be commended. The excellent thermal waters with the elegant and elaborate methods of using them may be expected to render all the service in diseased states which can be accomplished by this means. It is especially desired that all those who visit the springs with the intention of using the baths consult a resident physician in regard to the use of the waters.

The Healing Springs Hotel, three miles from the railway station at Hot Springs, is reached by a comfortable line of stages. It is connected by telephone with the depot and with the hotels at Hot and Warm Springs. No place in the Virginia Mountains is more pleasant or picturesque. The air is pure, dry and bracing, the temperature being uniform and delightful, throughout the season. The rooms in the hotel and cottages are large and cheerful; they are kept scrupulously clean, and the management throughout is charmingly homelike and in harmony with the surroundings. The supply of water is abundant, being derived from four springs of essentially the same character, and is beautifully bright and crystalline. Its temperature is uniformly 85° to 88° F. The bathing accommodations have been greatly extended and otherwise improved by the erection of a new bath-house, and by the addition of several apartments to those already built. The waters of these springs, as will be seen by the analyses, are almost identical with those of Schlangenbad and Ems in Germany. These were made by Prof. William E. Aiken, of the University of Maryland:

One United States Gallon Contains:

Solids.	Healing Springs.	
	Old Spring. Grains.	New Spring. Grains.
Calcium carbonate	17.90	18.72
Magnesium carbonate	1.24	1.96
Iron carbonate	.07	.28
Calcium sulphate	1.32	1.26
Magnesium sulphate	7.25	7.39
Potassium sulphate	2.21	2.53
Iron sulphate	.18	.10
Ammonium sulphate	.23	.23
Potassium chloride	....	.25
Potassium carbonate	.24	
Sodium chloride	.27	.29
Silicic acid	1.89	1.82
Organic acid (crenic ?)	.86	.88
Carbonic acid	2.20	2.29
Sulphureted hydrogen	Trace.	Trace.
Bromine	Trace.	Trace.
Sodium	Trace.	Trace.
Total	38.56	38.00

The bubbles of gas that rise from the springs contain in 100 parts: nitrogen gas, 97.25; carbonic acid gas, 2.75.

These waters have proved valuable in a considerable range of diseases; they are diuretic, somewhat laxative, and tonic in their effects upon the system. The best results have been observed in chronic congestion of the liver, in irritability of the bladder from cystitis, in enlarged prostate, etc., in the early stages of Bright's disease, and in debilitated states generally.

The *Warm Springs* are located five miles north of the railroad terminus at Hot Springs. The court-house and county buildings are located here. The springs are picturesquely located in a grand old grove and lawn in the centre of a tract of about 1,800 acres, which in width includes the crests of the mountains on either side of the valley. The remarks concerning the scenery, atmospheric conditions, etc., in the description of the Hot Springs apply with equal force to the Warm Springs. An excellent hotel, built in the Colonial style, charmingly situated and well-kept, will be found. There are also a number of comfortable cottages. For three generations the springs have been visited by people from all over the United States, with not a few from foreign countries, and even when it involved a long and tiresome journey in primitive stage coaches they were a favorite resort of the wealth and fashion of Virginia and the South. The grand boulevard recently completed between the Hot and Warm Springs is a magnificent driveway, and passengers will be transported from the Hot Springs station in comfortable carriages in the brief space of forty minutes after a most enjoyable ride. The gentlemen's bath is an octagon forty feet in diameter and holds 43,000 gallons of water. The ladies' bath is circular in shape, with a capacity of 60,000 gallons. These pools are supplied from separate springs discharging upward of 60,000 gallons of water per hour, at a temperature of 96° F., which, charged with myriads of bubbles of sulphureted hydrogen gas, rises naturally from the bottom of the pools, affording a delightful and luxurious bath. There are also private baths of various kinds, and ample provision for the comfort and convenience of bathers. An old analysis of one of the springs, made by Prof. A. A. Hayes, shows the following solid constituents:

One United States Gallon Contains:

Solids.	Grains.
Calcium carbonate	5.22
Calcium sulphate	14.53
Potassium sulphate	1.38
Ammonium sulphate	.36
Sodium silicate Magnesium silicate	1.72
Iron crenate	2.50
Carbonic acid	6.92
Total	32.63

Gases: Sulphureted hydrogen, carbonic acid, and nitrogen.

The water is limpid, has a styptic taste, and the odor of sulphureted hydrogen. The action of the water is sedative, as a rule. Immersion in the bath gives rise to a sense of voluptuous repose and as the hand passes over the body the surface presents a velvet smoothness, as though anointed with some delicate ointment. This unctuous quality has also been observed in the baths of Molitz, in France, and in those of Wildbad near Stuttgart. It has been variously ascribed by European writers to the presence of silicates, to the monosulphuret of sodium, and to an organic matter, the last being the most probable cause. These waters, by reason of their soothing effects, are applicable in chronic and subacute rheumatism, gout, neuralgia, congestive amenorrhœa and dysmenorrhœa, and in nephritic and calcuious disorders. The spout bath, arranged with an ascending douche, is especially useful in the type of dysmenorrhœa named. The baths are also beneficial in the squamous skin affections. *James K. Crook.*

HOT SPRINGS, FALL RIVER COUNTY, SOUTH DAKOTA.—

Post-Office.—Hot Springs. Numerous hotels and cottages.

Access.—Viâ Fremont, Elkhorn, and Missouri Valley Railroad (branch of the Chicago and Northwestern system), or viâ the Chicago, Burlington and Quincy Railroad (Burlington route) direct to Hot Springs, arriving at the same depot by either route. This magnificent new spa is located in the heart of the Black Hills at an elevation of 3,400 feet above the sea level. The advantages of Hot Springs as a health resort are numerous. First as to the topographical features. The scenery in and adjacent to the place is varied and delightful. The lofty pine-clad hills, grand canyons, rippling streams, and beautiful falls of the Minnekahta and Cheyenne, make up a group of attractions difficult to excel.

Second as to climate. By reason of certain peculiar circumstances of location this resort is favored by very mild, equable atmospheric conditions. Summer days are followed by evenings of delicious coolness, while the autumns are unusually pleasant. During the winter months the temperature has maintained an average of 42° F. above zero for the last four years. Situated in the Minnekahta valley and sheltered on all sides by heavily timbered hills, cold winds and sudden changes of temperature are practically unknown. The winter temperature in the valley is from 20° to 25° higher than in localities only a dozen miles distant. It is said that the protection afforded by the hills is supplemented in no small degree by the millions of gallons of hot water flowing through the valley.

The visitor will find the accommodations prepared for his entertainment on a par with the charming scenery and genial climate. The largest hotel, the Evans, is constructed and equipped throughout in accordance with the latest and most approved methods. It is fully up to the standard of the best hostelries of the day. Other excellent hotels are the Gillespie, the Hot Springs, the Catholicon, the Davis, and the Parrott House. Cottages are also on hand for those who desire them. The hills afford attractive spots for camping out.

Adjoining the Evans House, and in full keeping with the elegant and elaborate appointments, is the Evans Sanitarium, containing sixty bath-rooms and embracing all varieties of baths. The Stewart Sanitarium, recently completed, also affords facilities for all kinds of bathing, including an excellent plunge bath. The Catholicon Sanitarium, now under construction, will add another to the attractive retreats of the Hot Springs. This structure, with the bath-house, will have a measurement of 100 × 75 feet, and will contain over 100 bath-rooms. The plunge bath is one of the prominent features of Hot Springs. It is constructed of stone, wood, iron, and glass and has 100 dressing-rooms. The building is 75 feet wide and 250 feet long, heated by steam and lighted by electricity. The water is at a natural temperature of 96° F. the year round. It increases in depth from three feet at one end to eight feet at the other. The springs at this resort are eight in number. The "Minnekahta" is the name given to a great Indian spring, the word being a synonym for health, pleasure, and recreation. It is said that the waters of this spring were in use by the Sioux and other tribes long before the approach of civilization. The natural temperature of this spring is 98° F. It furnishes the drinking fountain of the Evans House, the Evans bath-house, and the Minnekahta bathhouse. An analysis by Prof. Charles B. Gibson, of Chicago, resulted as follows:

One United States Gallon Contains:

Solids.	Grains.
Magnesium sulphate	4.32
Sodium sulphate Potassium sulphate	25.62
Iron peroxide	Trace.
Sodium chloride Potassium chloride	13.79
Calcium sulphate	16.32
Silica	2.46
Total	62.51

These waters are perfectly transparent, have a pronounced alkaline reaction, and contain no organic matter. Following are analyses of two of the other springs:

One United States Gallon Contains:

Solids.	Mammoth Mineral Spring. Grains.	Lakatah Spring. Grains.
Sodium sulphate	23.26	8.82
Potassium sulphate	5.63	3.33
Calcium sulphate	36.11	16.29
Calcium chloride	5.59	8.50
Ammonium chloride	.02	.05
Magnesium chloride	4.11	3.14
Calcium phosphate	....	.31
Magnesium nitrate	.30	.15
Magnesium phosphate	.10	
Magnesium carbonate	3.51	3.04
Iron sesquioxide	.15	.26
Alumina	.27	.02
Silica	1.55	1.83
Organic and volatile matter	12.11	8.05
Total	92.71	53.79

These waters are of the sulphated-saline and calcic variety. According to a report of the National Association of Railway Surgeons, which visited the resort several years since, "treatment by the Hot Springs water may be said to stimulate all the secretions and organic functions; to promote digestion and assimilation, and to favor tissue metamorphosis and excretion, thereby relieving internal congestions, stimulating blood-making, increasing the appetite, and favoring new and healthy tissues at the expense of the old and inactive." This treatment may, therefore, be confidently recommended in "gout and rheumatism after the inflammatory stage; in neuralgia, especially when depending upon gout; in metallic or malarial poisoning, paralysis not of organic origin, and neurasthenia; in the early stages of Bright's disease; in syphilis and functional diseases of the liver and stomach; in catarrhal affections of the respiratory tract . . ., and in chronic diseases especially of the squamous variety."

Hot Springs is the county seat of Fall River County, and is located about seventy miles south of Deadwood. The town has a permanent population of 3,000. Its proximity to extensive pine forests, in addition to the favorable features of location above mentioned, assists in preserving a mild and agreeable climate, and has brought the resort into much favor with persons afflicted with hay fever, asthma, and incipient phthisis.

James K. Crook.

HOT SPRINGS, GARLAND COUNTY, ARKANSAS.—

Post-Office.—Hot Springs. Hotels: Arlington, Eastman, Pullman, Avenue, Park, Bloomington, Josephine, etc. According to Cutler's Guide to the Hot Springs, there are as many as five hundred hotels and boarding-houses in the city.

ACCESS.—Viâ the Iron Mountain Route, the only line running to the Hot Springs. All lines leading into St. Louis connect in the Grand Union Depot with express trains of the Iron Mountain Route. From the south the best route is viâ Cairo, Columbus, Memphis, or Texarkana, connections being made at each of these points with Iron Mountain express trains. The springs are 55 miles southwest of Little Rock, the State capital, and 22 miles from Malvern, where trains on the Iron Mountain connect with the Hot Springs Railroad leading directly to the springs. Sleepers come through without change at Malvern. The Hot Springs are situated on the Mountain Creek and in the valley of the same name. They issue from the western slope of the Hot Springs Mountain, a spur of the Ozarks, at an elevation of from 700 to 800 feet above the Gulf of Mexico. The mountains on either side attain an altitude of 1,200 feet. The climate in this region, as a general rule, is mild and balmy and not subject to extremes of either heat or cold. Sunstroke is unknown, and the summer nights are generally cool and pleasant, light blankets, as a rule, being required before morning. The pure mountain air and constant southerly breezes unite in forming a healthful and invigorating climate. The lowest temperature observed in 1891 was 16° F., the highest 98° F., the average for that year being 84° F., or somewhat higher than the average for a series of preceding years. The rainfall for 1891 was 70.86 inches.

These springs have been known and utilized as a health resort since early in the century, and during that time they have acquired an extended reputation in the treatment of certain diseases. A city of considerable size and containing numerous excellent hotels, sanitariums, bathing-houses, and public buildings has been developed about them. Some of the handsomer and more commodious bath-houses were erected at a cost of from $10,000 to $50,000. Among the more prominent of these are the Eastman, Park, Alhambra, Superior, Palace, Magnesia, Ozark, Horseshoe, Rammelsburger, Lamar, and Maurice pavilions. The discharge of water from the springs amounts to 335 gallons per minute, or 482,000 gallons per day. These waters are nearly all concentrated in large, air-tight tanks, built by the United States Government, and are sufficient to bathe 19,296 persons daily, allowing twenty-five gallons for each bath. The springs are now seventy-two in number, another having recently been added to the list, according to a late annual report of the local board of health. From the United States Engineer's Report to the Hot Springs Commissioners we obtain the following table of temperatures of the springs:

Number.	Temp. (Fahr.)	Number.	Temp. (Fahr.)	Number.	Temp. (Fahr.)
1	77.0°	25	111.0°	49	131.0°
2	76	26	106	50	145
3	124	27	127.5	51	144
4	124	28	145	52	143
5	80	29	80	53	144.5
6	103	30	134.5	54	146
7	115	31	147	55	122
8	121.5	32	124	56	133
9	122	33	140	57	128
10	121.5	34	120	58	Sipage.
11	105	35	135	59	133
12	111	36	110	60	134.5
13	135.5	37	120	61	135
14	137	38	128	62	109
15	134	39	125.5	63	83
16	131	40	112	64	135
17	Sipage.	41	157	65	141
18	93	42	Sipage.	66	87
19	84	43	144	67	Sipage.
20	83	44	Sipage.	68	131
21	106	45	111	69	83
22	122	46	Sipage.	70	89
23	125	47	144.5	71	94
24	113	48	91		

Highest temperature, 157° F.; lowest, 76° F.

Those marked "sipage" are intermittent. All others are constant and unvarying in heat and quantity. All the springs on the east side of Hot Springs Creek flowing from Hot Springs Mountain, except one under the Rammelsburger bath-house, are hot. All on the west side, except the Alum spring, are cold. No complete analysis of the waters seems to have been made since the now some what antiquated one made by Prof. E. Hills Larkin, in 1859. It is as follows:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Magnesium carbonate	0.13
Calcium carbonate	3.97
Sodium sulphate	.38
Potassium sulphate	.23
Calcium sulphate	.11
Sodium chloride	.01
Calcium silicate	.46
Sodium	Trace.
Bromium	Trace.
Iron sesquioxide	.10
Alumina	.45
Silica	1.87
Organic matter	.70
Water (?)	.14
Total	8.55

The water also contains a considerable quantity of free carbonic acid. Persons taking the baths here should always do so under the supervision of one of the local physicians. Those affected with organic disease of the heart or recognizable physical signs of consumption are not allowed to bathe, as the thermal action of the water is liable to be prejudicial to such cases. If the lungs are but slightly involved, careful bathing may be permitted. Furthermore, cases of simple cardiac palpitation are not excluded. As each case must be treated on its merits, and as detailed instructions are given by the local physician, it is unnecessary here to enter into a minute description of the bathing process at Hot Springs. Suffice it to say that patients are usually (not invariably) required to bathe six minutes in water at 96° to 100° F., two to six minutes in the vapor bath-rooms, and five to twenty minutes in blankets according to the time required to induce perspiration. The course here has been found especially beneficial in diseases of the genito-urinary system, especially syphilis, and in gout, rheumatism, and neuralgia. The baths are also recommended on high authority in various skin affections including eczema, psoriasis, urticaria, impetigo, prurigo, rupia, etc.

The city of Hot Springs itself is well drained and well lighted, and has ample police and fire protection. It now claims a population, resident and visiting, of 21,000. About 50,000 persons visit the place annually, and this number is ever on the increase. The United States Government Army and Navy Hospital, recently erected, cost $200,000. It is said that the Arlington Hotel, with its bath-house attached, will have cost over $500,000 when completed. Among other mineral springs within the limits of the city of Hot Springs, or in the neighborhood, are the following: Allen's Alterative Spring, situated on Central Avenue, in the heart of the city; Gillen's White Sulphur Springs, located three miles from Hot Springs; Mountain Valley Springs, situated twelve miles north of Hot Springs, at the foot of Blakely Mountain, in a beautiful Valley extending well up into the mountain range; and Potash Sulphur Springs, located seven miles east of Hot Springs on the Hot Springs Railroad, one mile from Lawrence station. *James K. Crook.*

HOT SPRINGS, MADISON COUNTY, NORTH CAROLINA.—

POST-OFFICE.—Hot Springs. Mountain Park Hotel and boarding-houses.

ACCESS.—From the north and east by through Pullman cars on the Pennsylvania and Southern Railroads; from the west and northwest viâ Louisville, or viâ Cincinnati by the Queen and Crescent route to Knoxville, thence by East Tennessee, Virginia and Georgia Railroad (now a part of the Southern system). The location is 35 miles west of Asheville. The picturesque little village of Hot Springs is situated on the western boundary of North Carolina, only three miles from the Tennessee line, in the heart of Big Smoky and Blue Ridge Mountains, on the banks of the beautiful French Broad River. The location is 1,700 or 1,800 feet above the sea level. The atmosphere is dry and invigorating and the climate mild and equable, there being a very large proportion of clear days. The springs have long been popular in the South, but in recent years they have come into high favor with Northern visitors also. They are about twenty in number, and the temperature of the waters ranges from 96° to 104° F. They form one of the only two groups of hot springs east of the Mississippi from Canada to the Gulf of Mexico. The following analysis was recently made by Professors Chandler and Pellew, of New York:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	1.08
Potassium chloride	.62
Potassium sulphate	1.62
Calcium sulphate	20.04
Magnesium sulphate	7.20
Ammonium bicarbonate	Traces.
Calcium bicarbonate	9.02
Iron bicarbonate	.10
Sodium phosphate	Traces.
Alumina	.04
Silica	3.14
Organic and volatile matter	Traces.
Total	42.86

The waters are quite similar to those of the Arkansas Hot Springs. Several of the springs have been encompassed in the limits of a fine, large bath-house, which is divided into sixteen separate pools, nine feet long by six feet wide and four to five feet in depth. The water pours into these pools directly from the springs. The visitor will find here all of the modern appliances and improvements which go to make up a first-class bathing establishment of the day. Guests are received at all times of the year. With its lovely mountain scenery, its exhilarating climate, its thermal waters, and many other natural attractions, combined with a hospitable and scientific management, this resort is well deserving of the wide reputation which it has obtained. *James K. Crook.*

HOT SULPHUR SPRINGS.—Middle Park, Grand County, Colorado.

POST-OFFICE.—Hot Sulphur Springs. Hotels.

ACCESS.—Viâ Union Pacific Railroad, 50 miles west from Denver to Georgetown; thence by daily stage 50 miles to springs, passing over the Snowy, or main range, of the Rocky Mountains, at 11,250 feet altitude.

These springs are located in the Middle Park on the banks of the Grand River, 7,625 feet above the sea level. This river forms the only drainage outlet to the Middle Park, a mountain basin 90 by 50 miles in extent. The enclosing peaks vary in height from 9,000 to 14,000 feet.

The prevailing weather in this section is clear, with westerly winds. There is considerable snow in winter, with a steady range of temperature of about 32° to 50° F., but occasionally dropping to 20° or 25° below zero. As many as twenty-two of the springs are well situated for improvement, but, according to the latest reports we have had, the baths now in use take water from only three or four. The exact flow of water cannot be stated, but it is believed to be greater than that of the Arkansas Hot Springs. A strong smell of sulphureted hydrogen pervades the neighborhood of the springs, and with a favoring wind may be noticed for a considerable distance up the valley. The channels through which the waters flow are lined with a soft yellowish-white, velvety substance having the odor of sulphur (probably a confervoid growth known as sulfuraria). This substance is evidently not a sediment, as it stands up like the pile of velvet or plush, and is not deposited in layers, while the water itself is as clear and bright as that of any mountain spring. It is said to be very palatable and to rest well on delicate stomachs. The following analyses were made some years ago by Professor Mallett, Jr.:

ONE UNITED STATES GALLON CONTAINS:

Solids.	No. 1—Red sulphur, temp. 109.5° F. Grains.	No. 2—Saline, temp. 91° F. Grains.	No. 3—Alum, temp. 97.5° F. Grains.	No. 4—Little sulphur, temp. 111° F. Grains.	No. 5—Big sulphur, temp. 80.56° F. Grains.	No. 6—Bath spring, temp. 117° F. Grains.
Calcium carbonate	10.08	......	......	8.46	3.68	6.43
Sodium carbonate	58.57	50.45	20.37	29.42	39.37	22.42
Magnesium sulphate	......	......	5.26			
Magnesium carbonate	6.57	4.14	......	2.66	1.93	
Sodium chloride	14.61	......	13.29	12.18	13.97	13.11
Sodium sulphate	8.48	8.97	17.53	14.25	9.85	25.11
Sodium silicate	......	1.46				
Potassium sulphate	.50	.07	1.03	7.03	.96	1.69
Free carbonic acid	2.94	......	8.42	.42	9.49	4.69
Silicic acid	......	......	.61	.54	1.31	1.36
Lithia	Trace	Trace	Trace			
Iron	Trace	Trace	Trace	Trace	Trace	Trace
Ammonia	......	Trace	Trace	Trace	Trace	Trace
Total	101.75	65.09	66.51	74.96	80.56	74.81

The supply of water furnished for this analysis was insufficient to detect solids present in minute quantities. The lithia was discovered by means of a spectroscope in the residue left after evaporating 300 c.c. of the water. No gaseous constituents are shown, as the analyses were made from bottled water, which had been standing for some time after removal from the springs, and it is believed that the sulphureted hydrogen (or other gas) which may have been present had either escaped or been oxidized to sulphuric acid.

The waters are recommended in cutaneous, hepatic, uterine, neuralgic, gouty, and rheumatic disorders, and for the manifestations of tertiary syphilis. As with thermal waters generally, they are contraindicated in most acute diseases, in tuberculosis and cancer, in fatty degeneration of any important structure, in aneurism or organic heart disease, and in predispositions to cerebral, gastric, pulmonary, or intestinal hemorrhage. There are two hotels at the Hot Sulphur Springs and several private houses where guests may obtain accommodations.

James K. Crook.

HOUSE SANITATION.—The primary objects of habitations is to secure protection from the influence of heat and cold, rain, sunshine, and storms, and thus promote the health and happiness, and indirectly also, the morals and culture of the human race. The influence of sanitary houses cannot be overestimated. Dr. Villermé, in an investigation in France from 1821 to 1827, found that of the inhabitants of arrondissements containing 7 per cent. of badly constructed dwellings, 1 person out of every 72 died; of inhabitants of arrondissements containing 22 per cent. of badly constructed dwellings 1 out of 65 died; while of the inhabitants of arrondissements containing 38 per cent. of badly constructed dwellings 1 out of every 45 died. The history of improved dwellings for wage-earners shows everywhere a lessened death rate.

1. *Site.*—One of the first requirements of a sanitary home is a salubrious building site with a thorough exposure to air and sunlight; the top of a small elevation is always to be preferred, because of better natural drainage, purer air, freedom from dampness, and greater safety from inundations. Hippocrates and Vitruvius have referred in their writings to elevation as a desirable factor. The tops of the highest hills are usually too much exposed to the wind, and when chosen in certain climates the house should be protected by trees on the windward side; next to the top of a hill, the slopes should be preferred with a southern, southeastern, or southwestern exposure, on account of the advantages of sunlight and greater cheerfulness. Sites located in depressions which receive the natural drainage from surrounding slopes should be avoided, as they are not only damp, but likely to be surrounded with cold air and chilling mists. It is scarcely necessary to insist that so-called "made soil" and close proximity to marshes and injurious industrial establishments should be avoided.

Next to the topography of the site the character of the soil is important in its influence upon the healthfulness of the home. In a general way a gravelly, sandy, or chalky soil of good depth on a slope makes the best building site, provided soil pollution has not taken place and the deposit is not upheld by some impermeable stratum of clay or rock near the surface. Clay, marl, peat, and made soils should be avoided, because they are damp and the presence of organic matter, apart from favoring the proliferation of disease germs, also tends to pollute the ground air which is in constant communication and interchangeable with the atmosphere. (See Dr. Charles Smart's article on *Air*, p. 159, Vol. I.)

While rock affords easy facility for surface drainage, Mr. T. M. Clark (REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, first edition, Vol. III., p. 423) regards it as very objectionable, as the ledges are full of seams through which water usually flows, and the trenching necessary for the interception of the springs formed in this way is so costly that it is usually neglected, and cellars built on rock are in consequence generally damp.

The temperature of the upper layers of soil, and hence also its dryness, depend largely upon its exposure to the sun; but it is well known that heat is variably absorbed and retained in different soils equally shielded or unshielded by vegetation. The following table by Schubler shows the capacity of different soils of absorbing and retaining heat—100 being assumed as the standard:

Land with some lime..	100.0	Clayey earth	68.4
Pure sand	95.6	Pure clay	66.7
Light clay	76.9	Fine chalk................	61.8
Gypsum	72.2	Humus.......	49.0
Heavy clay............	71.1		

It will be seen, therefore, that sandy soils are warmer and clayey soils are not only damp but also very much colder.

Unfortunately, "ideal building sites" are within the reach only of comparatively few, and steps must therefore be taken to render objectionable sites as sanitary as possible; for the purpose of securing dryness, attention must be paid to the prompt removal of surface water and of subsoil water, the site should be drained by means of suitable drains four to six feet below the floor of the cellar or basement; indeed this precaution should not be neglected even in comparatively dry soils in order to limit the fluctuations of the ground water. In the preparation of the building site it is always desirable to excavate sufficiently deep to get rid of surface pollution, and it is perhaps needless to insist that in grading no soil containing the rubbish and wastes of human life and occupation should be used. In isolated buildings the surface drainage should be directed away from the house and the environments improved, with due regard to light and air, by either favoring the growth of vegetation or by removal and pruning of excess and overproduction.

2. *Building Material.*—The most common materials used in the construction of buildings are wood, brick, sandstone, limestone, granite, marble, iron, steel and other metals, glass, cement, mortar, asphaltum, and concrete. Of these materials, iron, zinc, copper, cement, slate, vitrified brick, and granite are quite impermeable; while others are not; depending upon the degree of their porosity and hygroscopic properties—according to Lang—

	Per cent. of water by volume.	Or, per cent. by weight.
Soft-burned bricks absorb	32.70	19.13
Hard-burned bricks absorb	28.20	16.50
Mortar burned bricks absorb.................	26.00	14.80
Portland cement absorbs.....................	17.80	11.00
Limestone absorbs...........................	17.70	7.26
Dolomite absorbs	14.70	6.50
Sandstone absorbs	10.80	4.34
Porphyry absorbs	2.75	1.05
Slate absorbs...............................	.93	.35
Granite absorbs.............................	.61	.23
Marble absorbs	.59	.32
Serpentine rock absorbs	.56	.22
Vitrified bricks absorb	.00	.00

A wall built of ordinary brick and mortar is capable of absorbing large quantities of water. Pettenkofer has calculated that 10,000 gallons are incorporated in a house built of 100,000 ordinary sized bricks. Bricks burned from clay containing much saltpetre and sulphate of sodium are especially objectionable, as a deposit is formed on the outside of the walls and moisture is attracted.

Galton, in his work on healthy dwellings, has shown that marble and limestone conduct more heat than an equal thickness of glass, bricks, plastering, and wainscoting. This appears to prove what experience has practically demonstrated, that frame and brick buildings are more readily warmed than marble and limestone structures of equal size and thickness of walls.

The hygienic importance of the properties of the building material cannot be underrated. Its porosity largely determines the interchange of air through the walls and the temperature of the rooms, thus greatly influencing ventilation and heating. The pores, as in the soil, contain either air or moisture; if air, the heat is conducted slowly, whilst water conducts heat readily. The hygroscopic properties of the material influence capillary attraction and diffusion of moisture, and consequently also the permeability and heat-conducting powers of the walls. Walls saturated with moisture absorb much heat and render transpiration of air impossible. It is for this reason that a house with damp walls appears much cooler to the inmates in summer than a dry one; but damp walls are decidedly objectionable, because they not only render the air of the room damp and impure and abstract more heat from the inmates, but also favor the growth of micro-organisms.

It will be readily understood that the application of paint, wall paper, and even calcimining will affect, if not completely check, the transpiration of air through the walls. For hot climates, frame and other forms of wooden buildings possess the advantage that they cool off very rapidly after the sun has disappeared, but because of their inflammability, short duration of life, and other sanitary disadvantages, such buildings cannot be recommended. But, as long as they are being extensively used in this country, special precaution should be taken in planning such buildings to prevent the entrance of cold winds at the junction of the wood walls and the stone underpinning. For this purpose Mr. Clark recommends a few courses of brick in mortar to be laid upon the cellar wall just behind the wooden sill; and as regards the exclusion of cold air through cracks or crevices in the cornice, he suggests the construction of a four-inch wall of brick and mortar on top of the plate which forms the top of the wall and supports the floor of the rafters, carrying it up until it meets the roof boarding. This wall, besides its use in keeping out cold winds, is also of some value in checking the spread of fire. Frame houses can be rendered cooler in summer and warmer in winter by double plastering inside and by covering the outside walls first with rough boards and a layer of Cabot's quilt and an exterior finish of clap-boards or shingles.

In spite of certain objections to brick, they are on the whole the most desirable material for ordinary dwellings; they resist fire better than any other material, and a hard-stock pressed brick of a light color is quite impermeable to moisture and makes a pleasing and hygienic outer wall. Next to brick, granite, marble, lime and sandstone are most frequently used, especially in connection with iron and steel in the construction of fireproof buildings. None of these rocks can resist the ravages of fire as well as brick; granite is better than marble, lime, or sandstone in this regard.

Micro-organisms in building material are especially numerous in the filler for ceiling spaces, which is frequently selected without regard to its source, old plaster and other rubbish being used; Emmerich has isolated the pneumococcus in such material, and Bonome found the bacillus of tetanus in mortar.

The latter being a mixture of sand and lime, the inference is that it was derived from sand, and that the spores were not destroyed by the action of the lime. Wall papers, unless very smooth, harbor a large number of microorganisms; we also know the danger of house fungi, especially the "merculius lacrymans," in bringing about the "dry rot" in pine lumber, as well as the frequent occurrence of moulds in dark and damp places.

Construction of the House.—Dryness of the foundation and walls, as already indicated, must be secured by draining the subsoil four to six feet below the cellar or basement and covering the entire floor with a layer of cement concrete six inches thick, rammed solid, and this should be coated with one inch of cement. In this way not only dampness, but the equally obnoxious ground air are excluded. To prevent the dampness of the soil from rising in the walls by capillary attraction, the foundations must be laid in concrete and hydraulic cement and a horizontal course of slate bedded in cement should be interposed between the concrete footings and wall, and another course of slate just as the foundation walls reach the ground level. Since these slate courses are liable to fracture, the last damp-proof course should consist of vitrified hollow brick, which, moreover, possess the advantage of securing ventilation. Some architects recommend damp-proof courses of tarred-felt asphalt or sheet lead (Figs. 2711 and 2712).

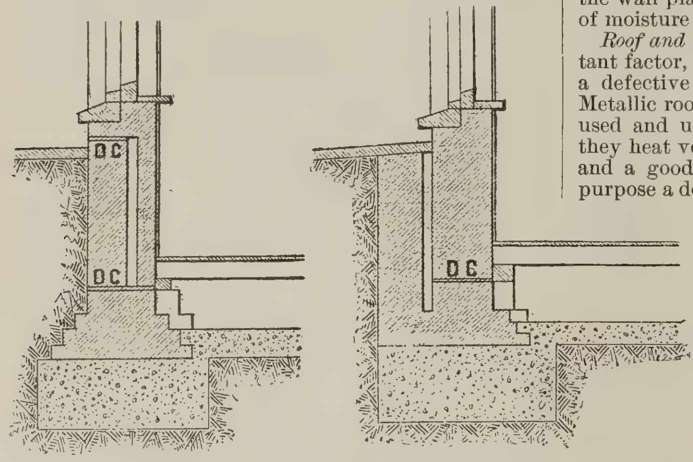

FIG.. 2711. FIG. 2712.

FIGS. 2711 and 2712.—Methods of Preventing Dampness of Walls. Letters *D C* denote location of damp-proof course. (Munson.)

The exterior walls of a house, whenever practicable, should be separated from the ground by an "open area," extending from the foundation upward; but where this cannot be done, a "dry area" may be formed by constructing a hollow wall to the ground level, provided with the usual damp-proof courses, and if springy, also with a subsoil drain at the bottom, at the same time protecting the wall in contact with the ground with a coat of slate embedded in cement. Mr. Clark suggests that if the ground is springy, a strip of tarred roofing felt, a little wider than the wall, should be laid upon the footings just below the cellar floor, and the stonework continued upon it. This, he says, "will prevent moisture from rising in the walls by capillary attraction from below, and with the coal-tar coat on the outside, a cellar with walls of porous material may be made dry and wholesome at small expense," but we cannot vouch for the durability of this procedure.

In localities with considerable rainfall it will be well to protect the side or rear walls of a rough brick building from driving rains with either a coat of cement, mineral paint, tar, or glazed tiles. Such a precaution is unnecessary when hard-pressed bricks are used. Reference has already been made to the fact that during the construction of a building an immense amount of water is incorporated with the bricks, mortar, and plaster. This water should be gotten rid of before the house is occupied, by thorough airing and drying; but not too rapidly, as a rapid evaporation prevents the carbonate of lime from becoming crystallized and the mortar loses its binding qualities. If the house has not been properly dried, the walls are very likely to sweat, which is in part due to their own moisture and partly to the condensation of the respiratory vapors on the damp cold walls. Laveran states, that a building is not fit for occupancy as long as the wall plaster contains more than twenty-two per cent. of moisture (see Examination, p. 768).

Roof and Roofing.—A good dry roof is another important factor, because water often gets to the walls through a defective roof and the whole house becomes damp. Metallic roofs with a sufficient pitch are most commonly used and usually secure this needed protection; but as they heat very rapidly a tin roof should be painted white and a good non-conductor should intervene. For this purpose a double course of boards with a layer of Cabot's quilt, corked or Florian building-paper may be used. The tin, of course, is properly secured to the upper sheating with a layer of felt paper directly beneath the tin. In any event there should also be an air space of two to three feet between the upper ceiling and the roof, and this space should be ventilated with perforated bricks in the walls and circular ventilators at the highest points of the roof. It is also a good plan, in order to prevent rusting, to cover the tin with a coat of mineral paint on the under side. Slate, cement, and tiled roofs, when properly constructed, afford protection against dampness, fire, and heat. In rural districts wooden shingles are still extensively used, and such roofs when treated with creosote and covered with rubber or metallic paint last for about twenty years. Whatever kind of a roof is used, free access to it should be provided by means of stairs or a ladder through a suitable opening, which in summer can be utilized for the escape of hot air. Special attention should be paid to the gutters and rain leaders; the openings of the latter should be protected with a network of galvanized iron, so as to prevent dead leaves, scraps of paper, mortar, birds' nests, etc., from passing through and clogging the conductors. The gutters should be periodically cleaned to prevent accumulation of rubbish and the overflow resulting therefrom. Subsequent leaks and defects should be promptly repaired. A leaky rain spout may keep the entire house damp. Copper or galvanized iron should be chosen instead of tin for gutters and conductors.

Floors.—Hygiene demands that the floors should be impervious to dirt, moisture, and germs, and should therefore be well seasoned, tongued, and grooved, closely matched and laid in white lead. All crevices resulting from subsequent shrinkage should be neatly filled with strips of wood, putty, paint, or wax. There should be a sub-floor of rough pine with a double layer of Florian building paper between; the top floor should not be laid until after the building is trimmed out; it should then be planed off and treated with a mixture prepared as follows: Dissolve by heat one pint of paraffin pared into shavings in two pints of raw linseed oil. To this solution add two pints of liquid dryer and sufficient turpentine to thin it to the desired consistency. This will give a gloss finish. If a dead finish be desired, about one-half of the quantity of paraffin should be used; apply with brush the same as varnish. If a high degree of polish be desired, rub with a polishing brush. One gallon of this mixture will cover approximately two hundred square feet of floor surface.

Oak and other hard-wood parquetry floors are not only attractive but also offer every hygienic advantage. In warm climates cement or "granito" floors may be advantageously used. The latter are really nothing more than a concrete-cement floor, four to six inches in thickness, with chips of marble and granite of various colors embedded in the upper layer and polished. They are practically insect and vermin proof, especially desirable for kitchens, pantries, and bathrooms, and should supersede the use of linoleum and rubber floor coverings. As a filler for the ceiling space, with a view of deadening sounds and as a protection in case of fire, special hollow bricks, dry cinders, clean dry mortar and peat, impregnated with milk of lime, have been used. Metallic laths are preferable to wood.

Stairs.—The stairway should be so constructed as to afford an easy ascent with risers not exceeding seven inches in height and treads from ten to twelve inches in width. For public buildings and tenement houses iron stairs and fire-escapes are demanded; indeed, even private houses would be better off with these safeguards in case of fire.

Halls.—The halls of a house should be roomy, well-lighted by direct light, if possible, and susceptible of ventilation. In a modern private dwelling the hall on the first floor is five to six feet in width and leads into the reception room, from which proceeds an open stairway to the upper floors. The open stairway should be lighted and ventilated by means of a skylight.

Interior Arrangements.—In regard to the size of the dwellings it is always best if they are simply large enough to accommodate one family. Overcrowding should be avoided, as infectious diseases are more liable to spread in consequence of aerial infection and the more intimate contact of the occupants. Körösi, of Budapest, has shown that out of every one hundred deaths from contagious diseases, there were:

20 deaths in dwellings with 1 to 2 persons in each room.
29 " " " " 3 " 5 " " " "
32 " " " " 6 " 10 " " " "
79 " " " " over 10 " " " "

The following table, prepared by Rohé, shows the relation of death rate to density of population:

City.	Mean number of inhabitants to each house.	Average annual death rate per 1,000 inhabitants.
London	8	24
Berlin	32	25
Paris	35	28
St. Petersburg	52	41
Vienna	55	47

It would be unfair, however, to attribute this increased death rate solely to overcrowding; other factors must be considered, since, as well expressed by Ogle, "The more crowded a community the greater, generally speaking, is the amount of abject want, of filth, of crime, of drunkenness, and of other excesses." Nevertheless, these mortality statistics demonstrate the baneful effects of tenement houses. With the present rapid-transit facilities in every city, our voice should be clearly in favor of individual homes; and when this is impracticable, we should insist on broad streets and deep yards. No more than sixty-six per cent. of the lot should be covered by the house, and the height of the building should never exceed the width of the street. No field affords better opportunity for philanthropic work than the removal of slums and erection of sanitary houses for wage-earners at reasonable rentals. Acting upon this, the Washington Sanitary Improvement Company was organized in 1897, and Surgeon-General Sternberg prepared plans in which no detail was omitted which would tend to provide the best accommodations from the standpoint of hygiene. Each house has a frontage of 17½ feet and consists of two independent flats, one on each floor, the special feature being that each flat constitutes a complete home, having a separate entrance and exit, separate yard and cellar. The entrance to the flat on the first floor opens into the front or sitting-room, 13.2 by 14 feet; back of this room is a hallway leading to the bedrooms, 12 by 13.2 feet, bathroom 5.6 by 5.6, and kitchen 10 by 12.4 feet. The entrance to the flat in the second story is by a staircase with access through a doorway on a level with the one opening into the flat on the first floor, but at the other end of the front of the house. Each flat has three large closets, and the kitchens are provided with a range, hot-water boiler, dressers, and sinks. Every room receives direct light and air, and the plumbing is the best. These flats rent for $12 per month, with a rebate of one month's rent every year to tenants whose apartments have not required repairs. The company has paid five-per-cent. dividends from the beginning and accumulated a surplus fund at the rate of two per cent. per annum. No officer receives any compensation, and this promotes the philanthropic aspect of the enterprise by providing the very best accommodation from the standpoint of hygiene, and as to comfort the utmost which a given cost will provide. The company was awarded a gold medal at the Paris Exposition in 1900, the only company in the United States to receive that award.

Basements are always desirable, even in small houses, for store-rooms, heating plants, and kitchens; they should be at least eight feet from floor to ceiling, not over one-half below ground, well lighted, and with all precautions taken to prevent the odors of the kitchen from passing into the upper stories. This can be done by a closed stairway and a deep hood over the range, which should conduct the gases into a flue located next to the smoke flue. In the more commodious houses the first floor usually consists of three large rooms, parlor, reception, and dining-room, to which in double houses a library may be added. When practicable, the kitchen should be located in a one-story wing with pantry intervening between the kitchen and dining-room. This isolates the kitchen and odors from the main house, and is preferable in many respects.

The rooms of the first floor, or parlor floor, should be from 10½ to 11 feet high and liberally supplied with windows, while the upper stories may be 10 and 9½ feet in height. Living and sleeping apartments for obvious reasons should not be tolerated in basements. The largest and sunniest apartment in the house should be chosen for the nursery and living room. The bedrooms should also be bright and sunny, and rooms with northern exposure avoided as much as possible for regular bedrooms. In this connection the stimulating effects of sunlight upon tissue metamorphosis and its destructive influence on micro-organisms should be remembered. No room should have a borrowed light, and this can be avoided by the construction of ample air and light wells in city houses which are three or four rooms deep. The windows should be made to open on top and bottom.

Interior Finish and Decorations.—Hygiene cannot approve of decorations or an interior finish which serve as dust and germ traps. In all houses dust is produced by the wear and tear of domestic activities, and our object should be to prevent its accumulation and facilitate its removal. Cornices and projections on ceilings and walls, the mouldings of door and window frames, wardrobes, carpet and cumbersome draperies all tend to collect dust and micro-organisms; they are not tolerated in hospitals and should be abolished in sanitary houses.

When the floors are neatly polished, it is quite sufficient to have a few small rugs which can be easily taken up and shaken and the floors cleaned with a damp duster. Heavy curtains and draperies should give way to light, airy fabrics, which can be easily washed. The bedroom furniture should be light, simple, and limited to the most necessary articles. Every bedroom should be provided with a commodious closet, supplied with clothes hooks, shelves, and drawers, and if the mirror is sunk in the panel of the door, wardrobes and dressing-cases could be conveniently dispensed with. All corners and angles of the inside of the house should be rounded to facilitate the removal of dust.

Wall Decorations.—The wall coverings should be as smooth as possible, since rough and highly-embossed paper and hangings accumulate an enormous quantity of dust and germs. On the whole, the plain calcimined or painted walls outrank from a sanitary point of view the gorgeous decorations of the palatial homes. Green paint and green-colored wall papers should be rejected; indeed, since arsenic has been found in various colored papers other than green, no paper should be used unless guaranteed to be free from arsenic, as much harm may be done by arseniuretted hydrogen, which tends to produce a chronic form of arsenical poisoning, characterized by conjunctivitis, cough, nausea, and diarrhœa, with colic, cramps, and debility.

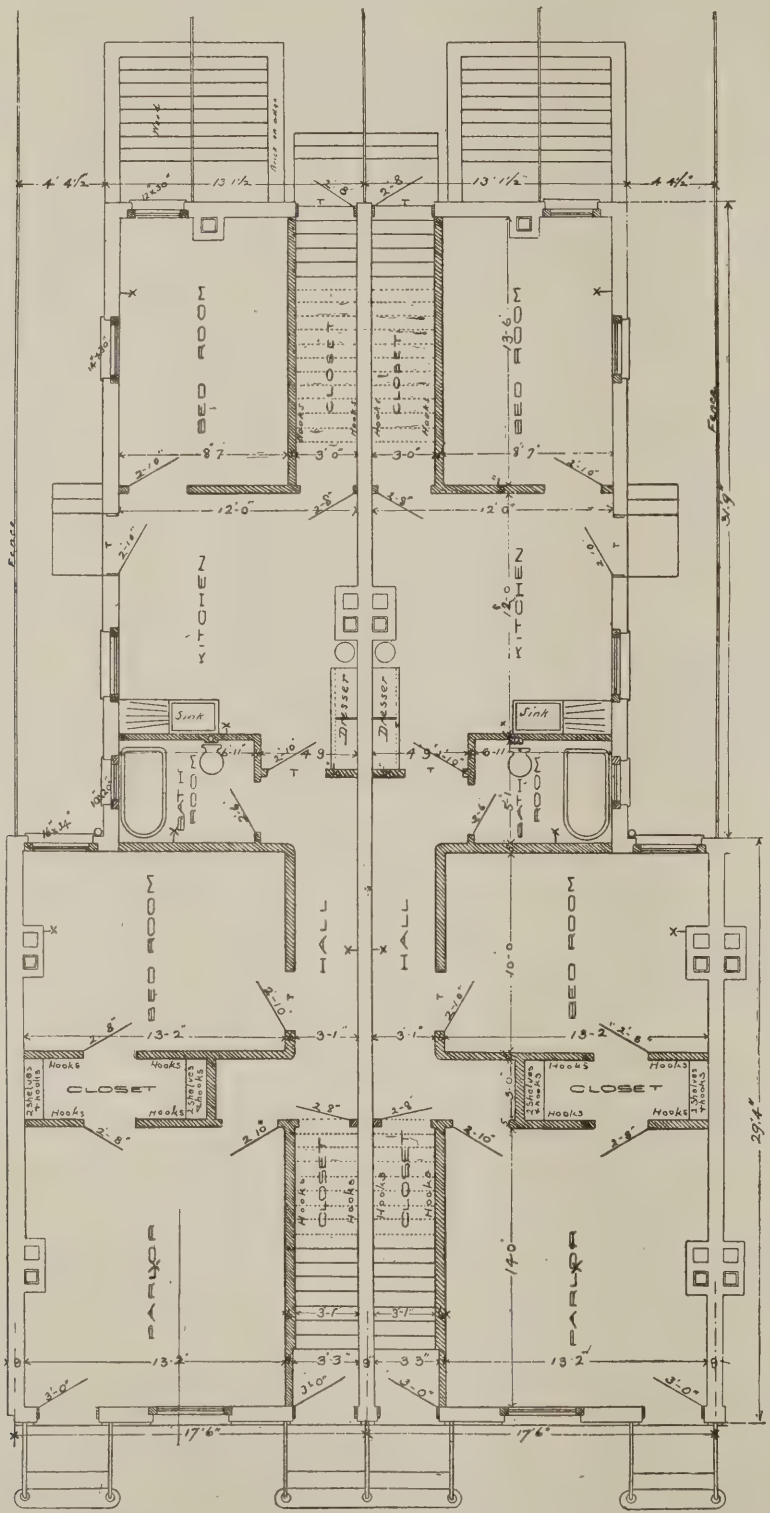

FIG. 2713.—First-Story Plan of Sanitary Houses for Wage-earners in the City of Washington.

The air of habitations differs from the exterior air in this, that unless precautions have been taken it may contain the elements of ground and sewer air; but even in the best-appointed houses the air is vitiated by the products of respiration, combustion, and decomposition of organic matter. As a matter of fact we always find an excess of carbonic acid, as much as 5.88 volumes per 10,000 having been determined in basements, 4.59 on the first floor, 4.50 on the second floor, and 4.19 on the third floor. We also find an excess of organic matter, most probably derived from the lungs, mouth, and skin of the occupants. Some authors deny that the skin and lungs in perfect health give off anything impure, but experience points to the fact that even the cleanest and healthiest persons exhale an organic substance which clings to bedding, clothing, carpets, and walls, and imparts that peculiar close and offensive odor to bedrooms and other inhabited apartments. Indeed, Uffelmann never failed to find ammonia nitrates in the air of his rooms, amounting to from 0.108 to 0.072 mgm. as compared with 0.025 mgm. per cubic metre in the outer air.

We also find more dust and germs than in the open air. If on a wind-still day we expose two glass slides moistened with glycerin, one in the outer air and the other indoors, we shall find at the expiration of twelve hours that the slide exposed indoors will contain a larger amount of dust, and that the organic constituents which in the outer air amount to about thirty per cent. are present to the extent of about fifty-seven per cent. It has also been shown that when the exterior air contained only 6.5 mgm. of dust per cubic metre, the air of even well-ventilated houses contains an average of 16.8 mgm. per cubic metre.

The number of micro-organisms in the air of even the better class of houses is invariably greater than in the open air, and depends largely upon whether the dust has been stirred up or not. Thus Uffelmann found the outer air thirty-nine inches above ground to contain 250 germs per cubic metre; one of his rooms during a perfect calm to contain 7,500 per cubic metre, and one, after shutting two of the doors vehemently, 27,000 per cubic metre.

Cellar air contains usually more organic matter and CO_2, and the degree of humidity amounts often to complete saturation; but the number of germs is less than in other parts of the house.

The *relative humidity* of the air of habitations when not heated is usually quite constant. It is, of course, influenced by the exterior air, but the fluctuations are never so marked as outdoors. This is probably due to the fact that the walls and furniture absorb moisture and give it off to less hygroscopic substances.

The *temperature* of habitations, with the exception of the upper floor, is also very much more constant than that of the open air. The maximum temperature in summer usually occurs five hours later than in the open air; for this reason our houses are hotter about six o'clock in the evening than at twelve or one o'clock. The thickness and construction of the walls determine this to a great extent. Houses constructed with walls having a four-inch air space are cooler in summer and warmer in winter.

Ventilation.—When we consider that an adult individual exhales on an average 14.4 cubic feet of CO_2 during twenty-four hours, and recall the other polluting factors, such as the products of combustion and decomposition, and that the presence of individuals tends to vitiate the air with dust, germs, and organic matter from the skin, mouth, and lungs, while the watery vapor eliminated by the lungs and skin, amounting to about 550 grains per hour, is sufficient to saturate 90 cubic feet of air at a temperature of 60° F., we see at once the necessity for the renewal of air in our habitations. Since it would be neither prudent nor expedient to wait until the air becomes literally unfit to breathe, it is self-evident that the dilution of impure and diffusion of pure air should be constant and gradual. The next question arises, How much fresh air is required to renovate the vitiated air? It has been found by careful observation and experiments that no appreciable organic odors are perceived in the air of inhabited rooms until the volume of CO_2 exceeds six volumes per 10,000. "When the carbonic acid amounts to seven volumes, a want of freshness is observed on entering. When nine, ten, or more volumes are present, the organic odor becomes manifest" (Smart). We know, of course, that this volume, or even double the quantity, of carbon-dioxide is not in itself harmful, but as it goes hand-in-hand with an increase of organic matter it is an index of the amount of organic impurities, and its estimation, according to Smart, affords the best means of testing the efficiency of the ventilation. Our object should be, therefore, to supply a sufficient amount of pure air so that the volume of CO_2 may not exceed six volumes per 10,000. From careful calculations (see Dr. Smart's excellent treatise on *Air*, p. 152, Vol. I.) it has been found that in order to accomplish this result, an average adult requires about 3,000 cubic feet of fresh air per hour. It is evident that the supply of fresh air can be introduced only by a movement of the air, which is brought about either by a diffusion of the gases or by the difference in weight of masses of air of unequal temperature and the pressure resulting therefrom. It is well known that gases have the property of penetrating or spreading and mingling with others in every direction, and this diffusion takes place through all porous substances, even a

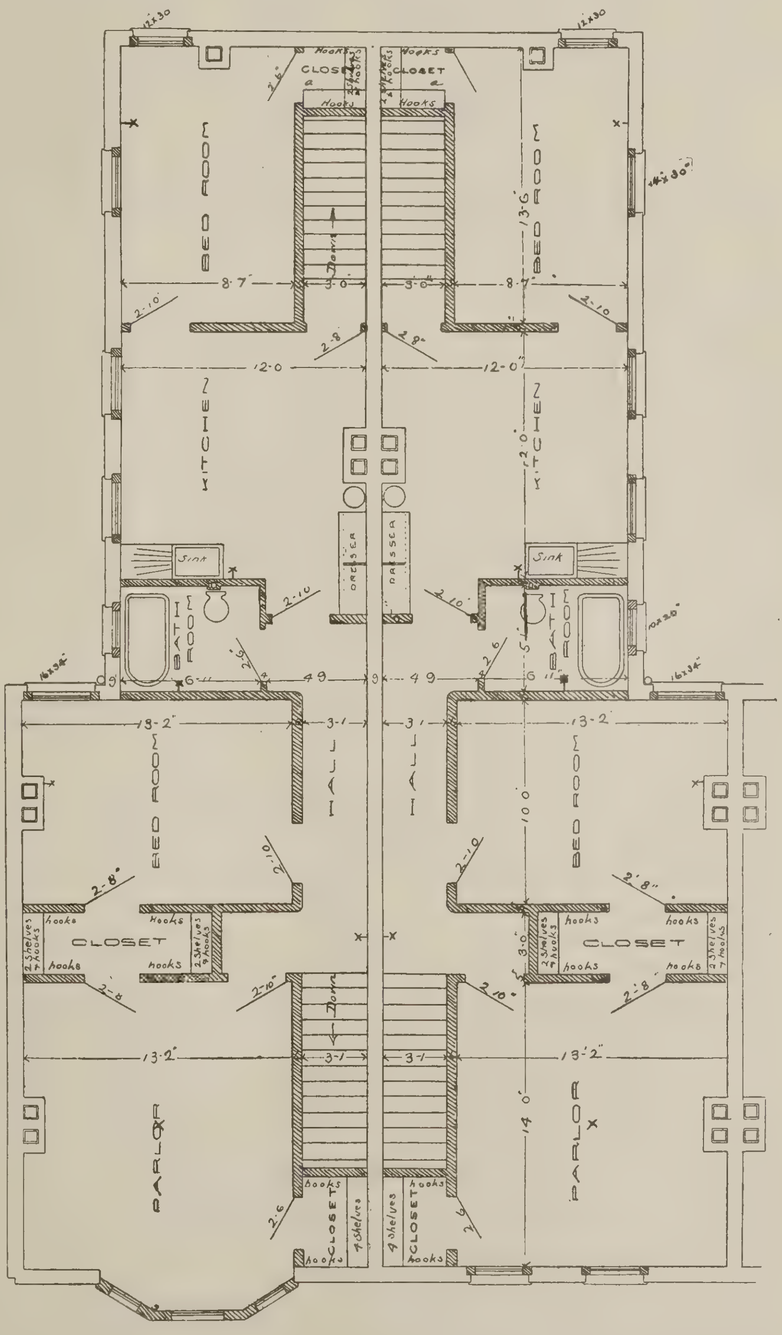

Fig. 2714.—Second-Story Plan of Sanitary Houses for Wage-earners in the City of Washington.

dry brick or stone wall. If it were not for this power of diffusion, CO_2, by reason of its specific gravity, would sink to the lower part of the room.

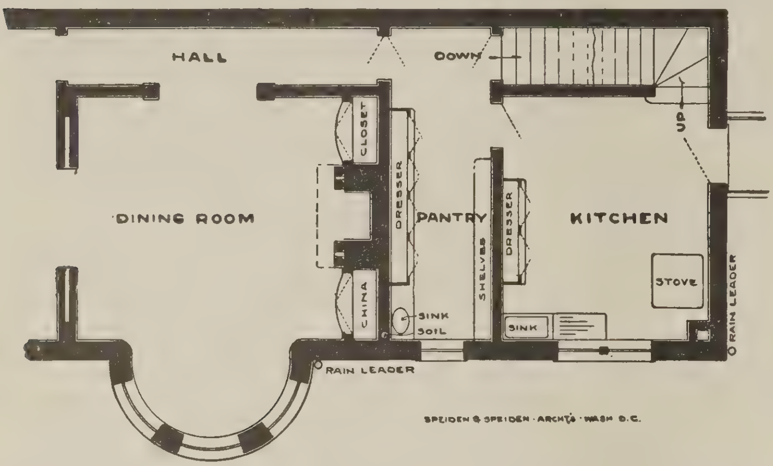

FIG. 2715.—First-Story Plan of a Corner House Showing Location of Pantry, Kitchen, and Dining-Room.

An unequal temperature produces a difference in weight of masses of air. When air is heated it expands; a volume of hot air is consequently lighter than the same volume of cold air. The warm air rises, and to restore the equilibrium the cold air rushes in to occupy its place. This is exactly what takes place in nature. The sun supplies the heat and the air currents, or winds, are thus produced, which in turn serve as powerful ventilating agents in our habitations. The winds act chiefly by perflation, *i.e.* by setting masses of air in motion, driving them onward by an irresistible *vis à tergo;* they also exert an aspirating effect, for when passing horizontally over chimneys or tubes placed at right angles to their course they cause a diminution of pressure within them, the air being practically sucked out, other air from below rushes up to fill the vacuum, and thus an upward current is produced. We see therefore, how ventilation, which means the removal and dispersion of bad air and the introduction of fresh air, may be brought about by all these factors which operate to a greater or less degree in what is commonly called

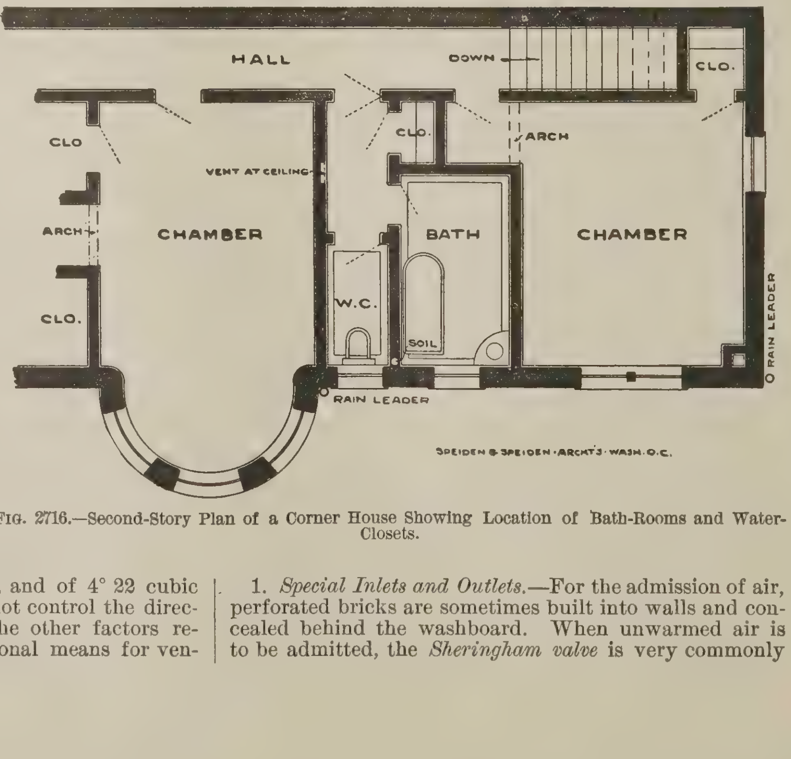

FIG. 2716.—Second-Story Plan of a Corner House Showing Location of Bath-Rooms and Water-Closets.

Natural Ventilation, and which is usually sufficient when each occupant has 1,000 feet of cubic air space and the walls of the house are porous or contain numerous crevices near the doors and windows, and the difference between the inner and outer door temperature is considerable and the winds strike the walls directly or pass with great velocity over chimney flues and other openings. Professor Pettenkofer has shown that by these natural means his library, having a capacity of 75 cubic metres, received hourly at a difference of temperature of 20° 92 cubic metres of fresh air, of 19° 75 cubic metres of fresh air, and of 4° 22 cubic metres of fresh air. But as we cannot control the direction and force of the winds, and the other factors referred to, we should provide additional means for ventilation, and one of the simplest and most efficient plans is to flush the room with fresh air by opening windows or doors on opposite sides of the room. No other method can take the place of this periodical airing for a thorough ventilation of the dead corners and the removal of an immense amount of dust. The objection to this method are the cold draughts in winter, and it should therefore be relied upon chiefly in summer or during the absence of the occupants. In rooms heated with direct radiation, the fresh air should be admitted above the heads of the occupants, either by means of a register in the wall or by the insertion of a louvered or swinging window pane (Fig. 2718) in one of the windows, an upward direction being given to the air so that it may impinge on the ceiling, mix with and be warmed by the heated air in this situation, fall gently into all parts of the room and be gradually removed by means of the chimney flue or any other outlet. Another simple plan is to bore standing holes in the bottom rail of the window sash, or to insert a "Pullman Ventilator" in the bottom rail of the lower sash, or to employ the "Bury Ventilator," which consists of a wooden block interposed between the bottom of the lower sash and the frame. The air passes into the room through the openings in the block which, as in the "Pullman Ventilator," point upward. The separation of the sashes caused by the block also adds to the fresh-air inlet. The use of these devices practically invades the domain of and brings us to the consideration of

Artificial Ventilation, which may be secured by providing, 1. Suitable inlets and outlets; 2. By extraction by heat, or the creation of a decided difference between the inner and outer temperature, and 3. By propulsion and aspiration.

1. *Special Inlets and Outlets.*—For the admission of air, perforated bricks are sometimes built into walls and concealed behind the washboard. When unwarmed air is to be admitted, the *Sheringham valve* is very commonly

used. In this apparatus (Fig. 2719) the air passes through the walls by means of a perforated iron plate and is then directed upward by a valved plate with side checks. This plate being hinged is capable of being more or less completely closed by a balanced weight; it usually measures three by nine inches. *Watson's tube* has two chambers placed alongside of each other, one serving as an inlet and the other as an outlet (Fig. 2720). *McKinnell's ventilator* consists of two cylinders, one inside the other, and of different lengths; the longer tube projects above and below and serves to conduct the impure air, while the outer cylinder having a larger sectional area serves as the inlet. The outlet is protected on the top with a cowl; both tubes can be regulated by valves. They are especially useful for the ventilation of one-story buildings, churches, theatres, kitchens, and pavilion hospitals. The gas burner may be placed immediately under the extracting tube; as the warm air escapes through the inner tube, a corresponding volume is admitted through the interspace between the two cylinders (Fig. 2721).

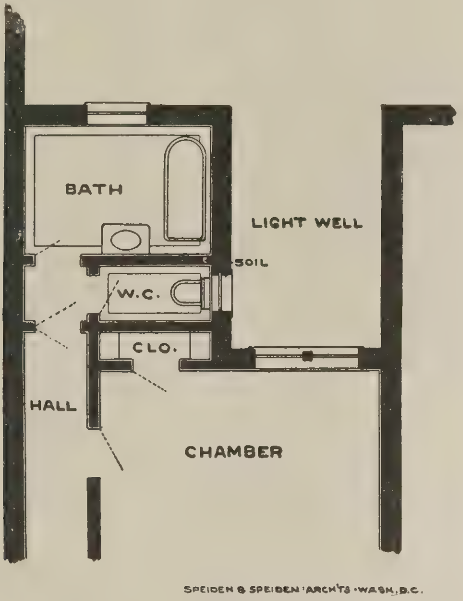

FIG. 2717.—Second-Floor Plan Showing Location of Bath-Rooms, Water-Closets, and Chambers on an Inside Lot.

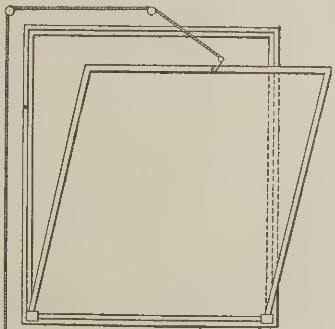

FIG. 2718.—Swinging Window Sash. (Munson.)

The *Ridge Ventilators* consist (Fig. 2722) of openings through the ceiling and roof of one-story buildings, with louvered sides and ends protected with a small roof; the opening of the air shaft in the ceiling is usually provided with a movable shutter to regulate the outlet. The fresh air is admitted by inlets running underneath the floor between the joists and discharging through a register near the stove, or it may be admitted by Sheringham's valves. Of the various methods used in artificial ventilation which contemplate a change of the weight of air without heating, attention is again directed to the perflating and aspirating effects of winds, which are so extensively utilized in the ventilation of ships, and are equally applicable to habitations. Here a large cowl is placed so as to face the wind and the air is thus driven below through a large pipe, whilst another cowl placed to back the wind acts as an aspirator to draw the bad air from below. A great many contrivances seen in connection with house ventilation, some with rotating cowls, others with fixed vanes, are based on this principle (Figs. 2723, 2724, 2725).

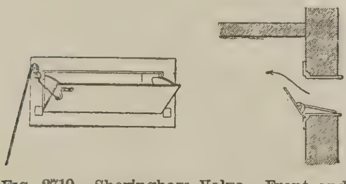

FIG. 2719.—Sheringham Valve. Front and sectional view. (Munson.)

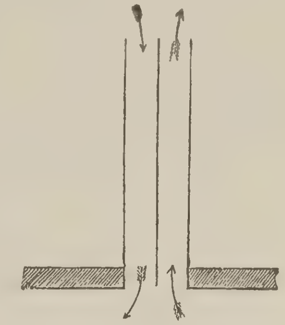

FIG. 2720.—Watson's Tube. (Munson.)

2. *Extraction by Heat.*—The simplest way to produce a difference between the temperature of the inner and that of the outer air is by heating the room by means of a stove or open fireplace, both of which will serve to extract the foul air and secure a thorough renewal of air. In some instances, the outlet can be placed in a separate flue next to the chimney flue; the latter being warmed creates an upward current. Gas jets and lamps may be used in connection with shafts used for the extraction of air by heat (Fig. 2726).

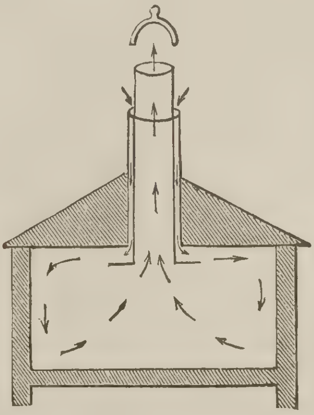

FIG. 2721.—McKinnell's Circular Ventilator. (Munson.)

3. *Propulsion and Aspiration.* — Another system especially adapted for large public buildings is to set the air in motion by the use of fans or air propellers. In other words, the fresh air is forced into and distributed throughout the building while another fan exhausts the foul air. These fans are set in motion by water, steam, electricity, or other motive power. This method presents several advantages: the amount of air delivered and the rate of movement can be regulated with nicety, the entering air can be taken from any desired pure source and can be filtered, washed, warmed or cooled. The Madison Square Theatre, in New York City, according to Dr. D. F. Lincoln (Parkes' "Hygiene," vol. ii., p. 472), is one of the best ventilated buildings of its class. The air is taken at a tower above the roof; is filtered through a conical bag of cheesecloth forty feet long suspended in

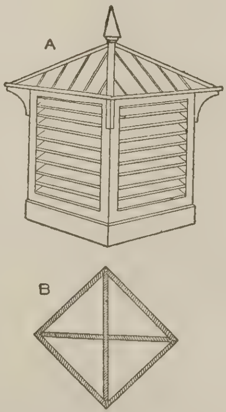

FIG. 2722.—*A*, Muir's Ventilator; *B*, transverse section of same.

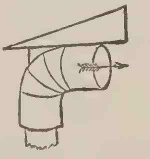

FIG. 2723.—Rotating Cowl for Aspiration. (Munson.)

the tower; it is heated by steam in winter and cooled in summer by passing over ice; heating, cooling, and distributing take place in the basement. One fan at the foot of the tower forces the air into the audience hall, another on the roof exhausts it. The doors and windows are kept closed. The air is introduced by pipes running under the risers; an opening in the riser at each seat discharges a forward current with a velocity of two and one-half feet per second; other jets enter at the front of the footlights and below the balconies the exits are chiefly under the balconies, so that there is a general movement away from the stage. For large buildings, the "Wing disc fan" (Fig. 2727) is usually employed; a four foot fan using one-horse power delivers about 500,000 cubic feet of air per hour, while the larger sizes of the "Blackman wheel," according to Munson, are said to give about 12,000 cubic feet of air per minute (Fig. 2728).

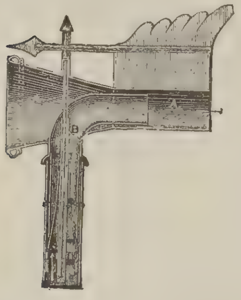

FIG. 2724.—Banner's Rotating Exhaust Ventilator. (Munson.)

Hydraulic ventilators are extensively used during the summer months in Germany; they consist of U-shaped pipes containing spray nozzles under high pressure; the air is sucked in and propelled by the falling spray, the water collecting at the bottom and being discharged by a drain pipe. According to the degree of temperature of the water, the air may also be cooled by this method (Fig. 2629).

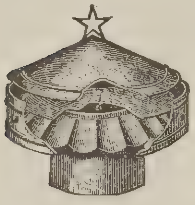

FIG. 2725.—Star Ventilator.

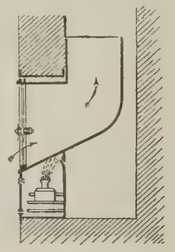

FIG. 2726.—Foul-air Outlet.

General Rules to be Observed in Ventilation.—1. The object of ventilation being to improve the air of the house, we should be sure of the purity of the incoming air. It should not be brought through underground ducts, nor from any point likely to be contaminated by sewer air or other noxious gases. The indication is plainly to select the safest spot for inlets; the inlets should be provided with valves to regulate the amount and protected with fine wire gauze or Hessian jute to exclude vermin and dust. Whenever practicable the air should not only be filtered, but also washed by means of a fine spray in its passage through the inlet. If the fresh air is too cold, it should preferably be warmed before entering the apartments by means of ventilating stoves or grates, or a central system of heating by furnace, steam, or hot water.

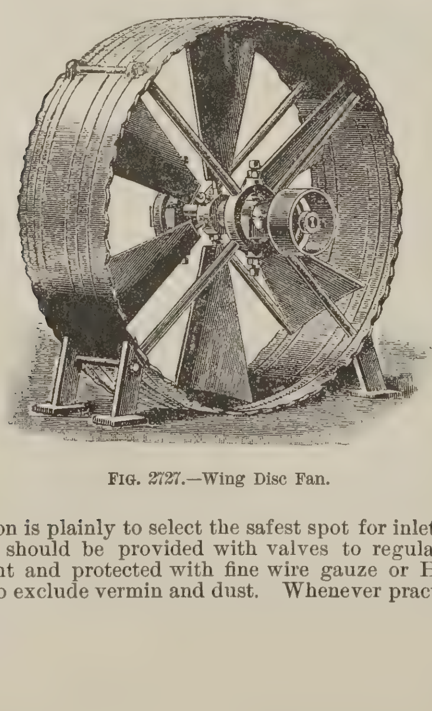

FIG. 2727.—Wing Disc Fan.

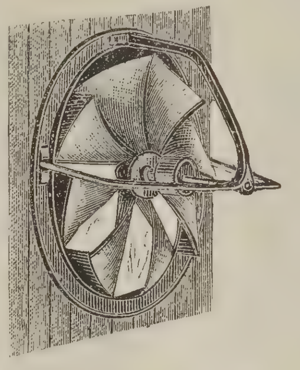

FIG. 2728.—Blackmann's Wheel.

2. The superficial area of outlets should be at least as large as that of the inlets, and in order to insure renovation of air with the least amount of draught, the inlet and outlet openings should not be placed directly opposite but diagonal from each other. It is desirable to place the inlets about the middle height of the rooms and the outlets near the ceilings; they should be supplied with registers to regulate the amount.

3. Since every adult requires 3,000 cubic feet of fresh air, it must be our aim to see that this amount is supplied without discomfort to the occupants. The air of a room cannot be changed oftener than three times in one hour in winter without causing a disagreeable draught; hence every occupant should have a cubic air space of 1,000 feet. Finally this air space must not be furnished in height at the expense of superficial or floor space, for the reason that organic matters are not equally diffused but tend to accumulate in the lower strata; consequently excessive height (*i.e.*, over twelve feet) does not mean a corresponding dilution. In spite of overwhelming clinical evidence, the question of proper air and floor space in prisons, lodging-houses, barracks, and even hospitals has not been practically settled, and the standard adopted is far below the amount required.

In conclusion, it should be distinctly understood that no amount of artificial ventilation can render thorough and frequent house-cleaning unnecessary, or the precautions for the exclusion of contaminated air superfluous, nor can ventilation in winter be maintained without the expenditure of considerable fuel.

Heating.—The necessity for artificial heat whenever the temperature falls below 70° F., notwithstanding the fact that a healthy adult gives off hourly 88 heat units, is fully recognized, and hygiene requires that this artificial heat should be supplied as uniformly as possible, and that the air of habitations, instead of being vitiated by the products of combustion, should be improved by the heating apparatus.

Fuel. — For this purpose materials containing carbon and hydrogen, 1 gm. of which is capable of evolving during combustion respectively 8,080 and 34,462 small calories, are used. Putzey's estimates of the heating value of various kinds of fuel are as follows:

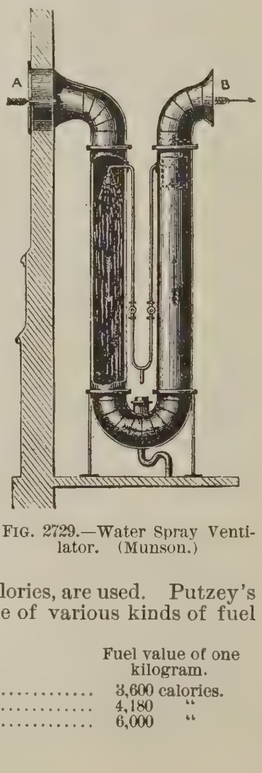

FIG. 2729.—Water Spray Ventilator. (Munson.)

Fuel.	Fuel value of one kilogram.
Dry wood	3,600 calories.
Lignite	4,180 "
Coke	6,000 "

House Sanitation.

Fuel.	Fuel value of one kilogram.
Charcoal	7,000 “
Bituminous coal	7,500 “
Anthracite	8,000 “
Petroleum	17,176 “
Illuminating gas per cubic metre	7,700 “

Of the foregoing fuels, white ash, Lehigh anthracite coal, and gas unquestionably permit of the most complete and ready oxidation of the carbon and hydrogen, which elements supply the heat.

The products of combustion are chiefly carbonic acid and water, although sulphurous vapors and arsenical fumes may be evolved in the combustion of mineral coal. If the amount of oxygen is insufficient for free combustion carbon monoxide, fine particles of carbon in the form of soot, tarry matters, and carburetted hydrogen also escape. The smoke under such circumstances is therefore a mixture of C, CO, CO_2, H_2O, C_2H_2 and may also contain sulphurous and arsenical vapors.

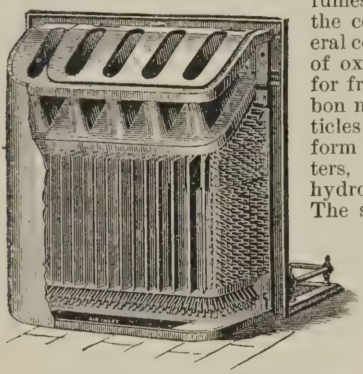

FIG. 2730.—Jackson's Ventilating Grate, Back View. The outer casing is cut away to show space and surface for warming the incoming air.

Rooms may be warmed separately by stoves or fireplaces; this is called *local heating* in contradistinction to the system of *central heating* in which the heat is supplied to a number of rooms or the entire building from a central plant. The latter system offers so many advantages that it is rapidly superseding every other method, at least in cities. The majority of houses in rural districts, however, are still warmed by open fireplaces and stoves. Fireplaces are niches in the chimney supplied with grates in which combustion may be maintained and the products are rapidly carried off through the chimney. The room in this instance is warmed by *radiant heat*, which means the passage of heat from warm bodies to cold ones without raising the temperature of the intervening air directly; the latter is warmed by convection from heated objects. A uniform temperature cannot be maintained by the exclusive use of an open grate, and though a most excellent ventilating apparatus, it is too powerful to be wholesome, and is moreover quite wasteful, as five-eighths of the heat generated escapes up the chimney. The latter objection has been in a measure overcome by controlling the chimney current by a damper, and by a proper construction of the grate and fire-back. For this purpose the width of the grate at the back should be about one-third the width in front facing the room; the side walls of the fireplace should join the back at an angle of 45°, so as to throw as many heat rays into the room as possible, and for similar reasons the whole fireplace should be brought well forward into the room. To minimize these defects, an attempt has been made to surround the back and sides with a space through which air can pass and be warmed by the heat that would be otherwise wasted. An opening below admits fresh air into the chamber where it is warmed and escapes through an opening into the room above the mantle. The Galton, Jackson, and Joly ventilating grates are all constructed on this principle and are therefore a combination of hot air and fireplace heating (Fig. 2730).

Stoves.—There are an endless variety of stoves in which either wood, coal, gas, or petroleum is burned, and in which from seventy-five to eighty per cent. of the fuel is utilized. The great distinction between these and open fireplaces is, that the air which comes in contact with the heated surface is warmed, expands and rises, and its place is taken by a cold air; the currents of warm air circulate through the room and thus every part is equally heated. It is essentially heating by convection, although a very hot stove also supplies radiant heat. Stoves are made of wrought or cast iron, terra-cotta, porcelain, and soapstone; some are ordinary closed stoves, while in others provisions are made for the admission of fresh air from without, which is made to circulate through the stove without coming in contact with the products of combustion, and after being thus heated passes into the same room or the room above, as in our lathrobes, ventilating grates, or the "Cortland Howe" ventilating stove (Fig. 2731). The principle of introducing fresh air can be applied by running a fresh-air inlet from the outer air to near the stove and surrounding the latter with a jacket of sheet iron. The inlet and corresponding outlets should be provided with registers. This is a very simple and effective method of heating and ventilating rural school-houses, etc.

Since gas, both natural and artificial, and coal oil are being extensively used in this country for both heating and cooking purposes, it may be stated on the authority of Notter and Firth that when the combustion is complete and the ventilation is sufficient for the ordinary effects of respiration, their use is not fraught with danger, especially when the more improved patterns are used; but the larger oil stoves or gas stoves which burn more than five feet of gas per hour should be provided with a flue to carry the products of combustion to the outer air. The ordinary gas logs set in fireplaces or the "Backus portable steam radiator" for use with gas should be preferred.

Heating by electricity possesses many hygienic advantages, but the excessive cost has so far prevented its general use.

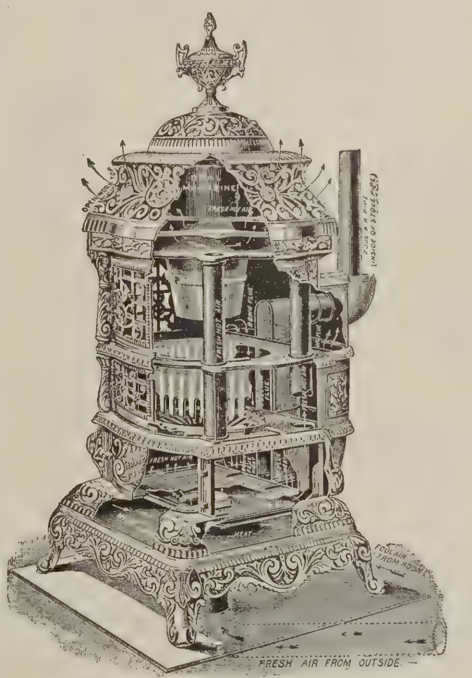

FIG. 2731.—Cortland Howe Ventilating Stove.

Central Heating (*Furnace*).—A very common way to heat a modern dwelling is by the use of a hot-air furnace. In such a case a furnace of wrought or cast iron, brick or soapstone is placed in the basement; the fresh air is admitted from a pure source into the air chamber of the furnace where it is heated and conducted in suitable-sized flues to the different rooms and stories of the house. According to Mr. Edward S. Philbrick ("Man. of Pract.

Hygiene," Parkes, vol. ii., p. 466) a house of more than three large rooms on the floor, however, with one or two stories of rooms above, cannot be properly heated by only one furnace, as it is almost impossible to conduct heated air more than six feet in a horizontal direction from the furnace. The combination of a hot-air furnace and open fireplaces is believed to be a very sanitary way of heating a house, because provision is thus made for both inlets and outlets; the latter are often neglected. An open fireplace is very useful in drawing the furnace air down to its own level, even when there is no fire actually burning in it. All this is important, for apart from the fact that outlets should exist for the extraction of foul air, a windward room cannot be warmed because the furnace air refuses to enter it, and the remedy for this is the open fireplace, or the opening of a chimney flue in the room. Flues from furnaces supplying different rooms sometimes draw against each other, especially when the supply from below is not sufficient for all, either because the fresh-air inlet to the furnace is too small or because after it has been closed in a high wind some one has neglected to open it (Lincoln).

The objection to cast-iron furnaces and stoves is that carbon monoxide is believed to escape through invisible fissures in the plates and joints, while the heaters are red hot; hence they should be lined with fire clay; this precaution may not be necessary for the escape of CO, but it will improve at least the quality of the heat. Soapstone furnaces are highly praised for the quality of the air. Since all heaters are liable to render the air too hot and dry, they should be provided with evaporating pans, or, what is even preferable, a larger heater should be chosen which will not have to be raised to red heat and at the same time furnishes a larger volume of warmed air. If the air is superheated it acquires a peculiar odor, probably due to charring of organic dust; it also becomes very dry and irritating owing to the rapid evaporation of moisture from the skin and mucous surfaces of the inmates and in consequence is apt to produce catarrhal affections, conditions which do not prevail when the temperature of the air delivered does not exceed 90°. There is also economy in running a stove or furnace at a moderate rate, and a reserve should be on hand for colder weather. Dampers in the smoke flues of heaters are always objectionable; the joints of the draft doors should be so good that opening and closing of the lower door or slides is sufficient, but as long as these joints are imperfect, dampers are a necessary evil.

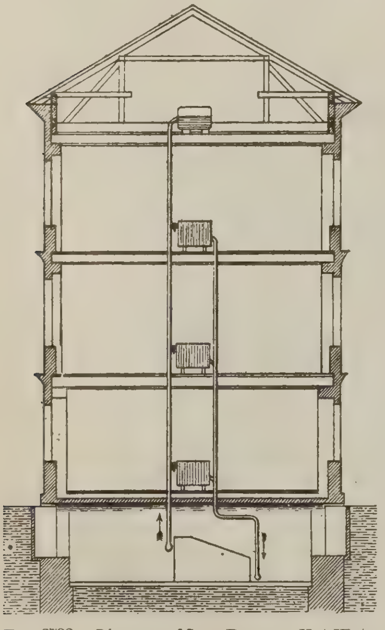

FIG. 2732.—Diagram of Low-Pressure Hot-Water System. (Munson.)

Heating by Hot Water is now extensively employed in modern homes and even larger buildings and while more expensive than the first cost of hot-air furnaces and a steam-heating plant, the advantages are economy in fuel and repairs; the temperature is more agreeable and the heat can be conducted to any desired point. In the *low-pressure system* large pipes, generally four inches in diameter, are connected with a boiler so as to provide a complete circulation. The water after being heated circulates through the pipes and radiators, parts with more or less of its heat to the air, *i.e.*, heating by convection, and returns to the boiler. At the highest point of the system an expansion tank is placed, and a small escape pipe is carried into the outer air to give vent to steam and hot air. The water rarely ever attains a higher temperature at any part of the system than 200° F. (Fig. 2732).

In the *high-pressure system* the pipes are smaller, about one inch in diameter, but sufficiently strong to withstand the pressure incident to a very high temperature, as from one-tenth to one-sixteenth of the coils are exposed directly to the heat of the fire. The water being completely enclosed from the outer air, attains usually a temperature of 300° F. and circulates more rapidly; provision is made for expansion by larger pipes at the top of the system. With the low-pressure system about twelve feet of radiating surface for every 1,000 cubic feet are required to raise the temperature of the room to 65° F. at zero weather, while with the high-pressure system eight or nine feet are sufficient. The volume of water in the high-pressure system is very much less and is heated therefore more quickly than in the low-pressure system, but it will also cool more quickly, and on the whole the advantages are decidedly in favor of the low-pressure system, because the temperature is more uniform and there is no danger from explosions or superheated pipes.

Steam Heating is employed in many public and private dwellings and the waste steam of locomotives is utilized in the warming of cars, ships, and factories. The methods have been perfected and the danger from explosions reduced to a minimum; nevertheless steam plants, as well as other central heating apparatuses, require careful planning and intelligent supervision. Steam heat, like furnace heat, is apt to be excessive in mild weather, but the temperature can be regulated by arranging multiple coils or radiators, which can be shut off in sections. In every case the calibre of the radiator should be larger than the supply pipes so as to favor condensation and consequent liberation of latent heat. Provisions must also be made for the rapid return of the condensed vapor to the boiler by means of return pipes, since any obstruction to the flow of the return steam interferes with a free and rapid circulation and causes not only defective heating but also a most disagreeable thumping noise.

In connection with either hot water or steam heating, we recognize three methods: (1st) the direct; (2d) the indirect; and (3d) the direct-indirect. In the direct system the radiators are placed in the room without any special provisions for ventilation; in the indirect system, the coils or radiators are placed in a suitable chamber in the basement into which fresh air is admitted and from which the heated air is distributed to the different rooms by suitable inlets and outlets. This plan answers very well for ordinary dwellings, but for larger buildings arrangements must be made to force the heated air where wanted, and this is accomplished by the *exhaust system*, or the *plenum system*. In the former the air is exhausted by suction and the pressure of the atmosphere is relied upon to replenish the fresh air, while in the plenum system the air is forced into the room by special fans, and is preferable because the purity and volume of the air can be regulated in the manner already referred to under Ventilation. In the *direct-indirect* system the radiators are placed under the windows and the fresh air is admitted from behind them and is warmed by its passage over the radiators. The fresh-air inlets are controlled by a key in the room connected with a register outside in order to regulate the amount of fresh air, while the foul air is discharged by suitable outlets. The air in steam- and hot-water heated apartments may also become excessively dry and evaporating pans are almost as essential as with furnace heat. With automatic thermoregulators, it is possible to maintain a uniform temperature, and on the whole we may conclude that the indirect and direct-indirect systems—

combining, as they do, a central system of heating with proper ventilation—are the most sanitary. The use of steam gives perhaps more satisfactory results in cold climates than the hot water, but either method is preferable to hot-air furnaces.

Lighting.—Apart from the hygienic importance of sunlight on metabolism and its destructive effect on germ life, every room, whether used for dwellings, workshops, schools, etc., should be so well lighted by windows that the eyes need not be strained even on a cloudy day.

Natural Lighting.—The area of windows exclusive of sash frames should be at least one-sixth or preferably one-fifth of the floor space, and in order that the light may penetrate the deeper portions of the room, the windows should almost reach to the ceiling. After providing the windows we should, of course, not shut out ninety per cent. of the light by blinds and draperies; but if the light is too glaring it may be softened by white, cream, or light gray shades; the color of the window panes should always be perfectly transparent; plate glass possesses the advantage of warmth and durability. The difficulty of securing a sufficient amount of daylight in buildings located on narrow streets surrounded by tall buildings has been partly overcome by glass building blocks 8×6×2½ inches, with an air chamber in the centre, used instead of brick or stone in connection with steel frame construction, but more particularly by the introduction of prisms, which refract and diffuse the light throughout a room that would otherwise be illuminated but partially or not at all.

Artificial light, no matter how obtained, differs from daylight in this, that it does not furnish a pure white light; the prevailing rays are red, yellow, or violet, and the effects of a yellowish-red or violet-blue are produced. Whatever difference of opinion there may be as to the color best suited to our eyes, we know that our vision is most perfect under the influence of a white light, and this ought to be a good criterion. One of the disadvantages of all low-power illuminants is that the light is never as bright as daylight, involving therefore closer application of the eyes and consequent strain of the muscles of the eyeball. These remarks are hardly applicable to the electric arc-light and the Welsbach gas-burner, the rays of which, like the direct solar rays, may indeed be so glaring as to cause undue irritation of the retina. Another harmful effect of artificial illumination is the unsteady or flickering character especially seen in the electric arc-light, and which on account of the abrupt changes is likely to irritate the retina; another disadvantage is that the ordinary illuminants, except the electric light, tend to vitiate the air by the products of combustion and also affect the temperature and humidity of the air by the heat evolved. The requirements of a hygienic light are that it should be as near as possible the color of sunlight, sufficiently ample, but not too glaring; it should be steady and, instead of deteriorating the air, it should as far as practicable be utilized to improve the air; nor should the heat evolved be sufficiently intense to be a source of discomfort to the inmates in warm weather.

From this table we conclude that the electric arc-light is the most suitable for lighting of streets and squares, the electric incandescent light is best suited for public and private habitations, including also steamers, powder works, and mines. It is in every way superior to gas and other illuminants, because there is no danger from fire, there are no products of combustion, hence no pollution of the air, nor are the temperature and humidity of the rooms affected to any perceptible extent. These advantages over gas are of special importance to the inmates of buildings where the question of fresh air and temperature play an important rôle; hence we can readily appreciate that banks and other institutions find it profitable to install electric lighting and save time and money by the prevention of sickness among their employees. Next to electric light, gas, especially in connection with a Welsbach or Siemens burner, offers the next best choice; in the absence of either, kerosene with a high flashing point should be preferred over other illuminants. The flashing point of refined kerosene is defined as the temperature at which a sample of the oil commences to give off sensible quantities of inflammable vapor; it should not be less than 100° F. and a higher temperature is preferable. Explosions may occur in lamps when from any cause the vapor over the oil in the reservoir is lighted by a spark, as for instance when the wick is extinguished by blowing over the chimney and is then depressed in a smouldering condition, or when the chimney of the lamp is broken. The Duplex and Rochester burners and many other safety lamps have reduced these dangers to a minimum. The dangers from the inhalation of carbon monoxide from leaky gas fixtures and pipes are especially great when water gas is used, on account of the total absence of odor. Of the various gas burners, the Welsbach, Siemens, and the argand burner enclosed with a chimney give the best results. Wherever practicable, provisions should be made to carry the products of combustion to the outer air, and thereby aid in ventilation.

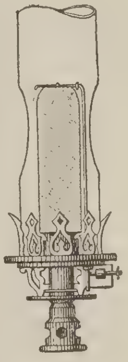

FIG. 2733.—Welsbach Burner.

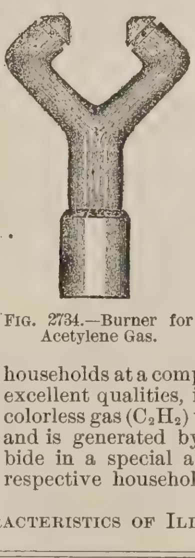

FIG. 2734.—Burner for Acetylene Gas.

Acetylene gas has recently come into deserved prominence, and as it can be generated for individual households at a comparative slight expense, and has many excellent qualities, it is likely to grow in favor. It is a colorless gas (C_2H_2) with a characteristic unpleasant odor, and is generated by the action of water on calcium carbide in a special apparatus, suited to the needs of the respective household or building. Munson states that

SUMMARY OF THE MOST IMPORTANT CHARACTERISTICS OF ILLUMINATING AGENTS.

"a generator capable of thoroughly lighting a company barrack or post hospital need not be greater in bulk than a hogshead, while one capable of illuminating a field hospital of one hundred beds is not larger than a pork barrel." The gas requires a special tip and combustion is usually complete (Figs. 2734 and 2735).

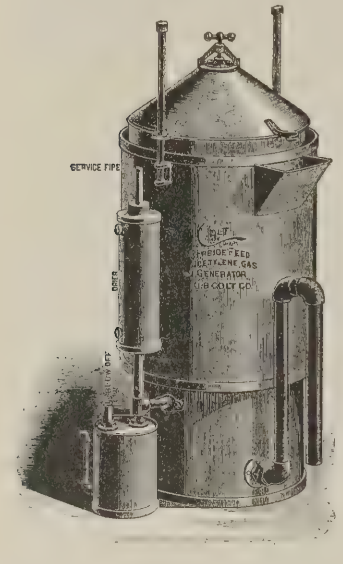

FIG. 2735.—Large Size Acetylene Generator. (Munson.)

Water Supply.—In cities furnished with a general water supply, every floor should be provided with water taps, not only for convenience, but also for greater safety in case of fire. In isolated houses and villages without a general supply or a good spring in the vicinity, our choice will be between artesian, cistern, and well water. On general principles preference should be given to artesian water. (See article on *Water*.)

House Drainage.—The object of the sanitarian is to remove as rapidly as possible all excreta and refuse from habitations, so that the air, water, and soil shall not be made impure. In any event the accumulation must in no case extend so far as to render putrefactive changes evident to our sense of smell. The various methods for the disposal of sewage will be discussed in a separate article, and for the present suffice it to say that the most sanitary disposal of the flow from the water-closets and house drains is a well-devised system of sewerage, which will convey the flow on to farm lands or into the sea, but not into watercourses used for drinking purposes. Since this system begins in the habitations, we shall point out the requisites for proper house drainage, which consist of:

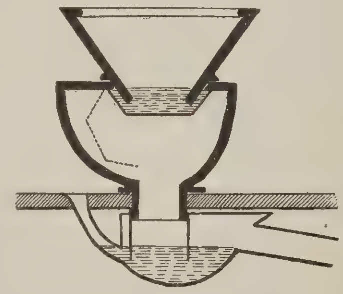

FIG. 2736.—Pan Closet.

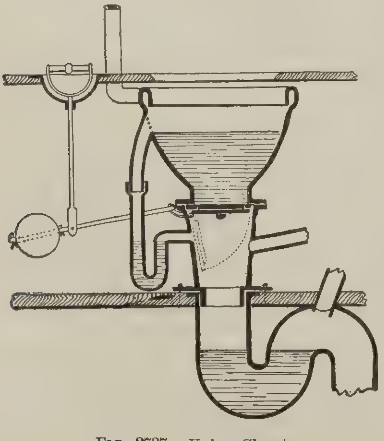

FIG. 2737.—Valve Closet.

1. Water-closets and urinals, wash basins, bath and laundry tubs, and kitchen and slop sinks;
2. A perpendicular pipe known as the soil pipe with which the foregoing fixtures are connected; and
3. The house drain, which is a nearly horizontal pipe, and connects the system with the sewer or cesspool.

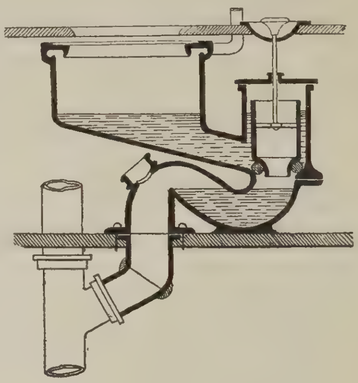

FIG. 2738.—Plunger Closet.

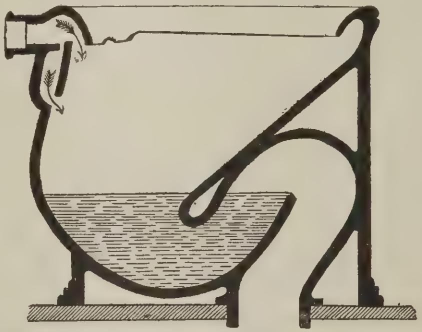

FIG. 2739.—Deluge Closet with Recessed Back. (Munson.)

Water-closets consist of an apparatus for the reception of excreta connected with the soil pipe by means of a suitable trap, and in which water is used to dilute and carry away the excrement deposited therein. They are classified under two heads, viz.: those in which there is no movable apparatus for retaining water in the bowl, and second, those which are supplied with a movable apparatus. Under the first head are included hopper, washdown and wash-out closets, under the second, pan-valve and plunger closets. Space will not permit me to enter into a detailed description of the various patterns, except to say that the pan, valve, and plunger closets (Figs. 2736, 2737, and 2738) are objectionable and should not be tolerated. Among the best forms are the short hopper closets, with a trap which opens into the soil pipe above the floor. This brings the water seal well up in the hopper and reduces to a minimum the surface likely to be fouled above the trap-water. So-called "wash-down" closets are modications of the short-hopper; of these the "Deluge," "Dececo," and the "Century" have given the most satisfactory results (Figs. 2739, 2740, and 2741). All of these fixtures are designed to give a quick and powerful flush of five or six gallons of water from a tank, the siphon of which is put into action by pulling a chain. Where the closet is to be used by servants, children, and others likely to neglect the flushing, the water supply should be made automatic and metred by a waste-saving apparatus. The

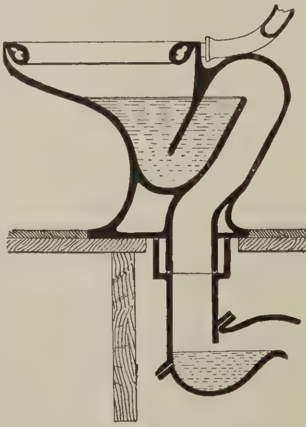

FIG. 2740.—Dececo Closet.

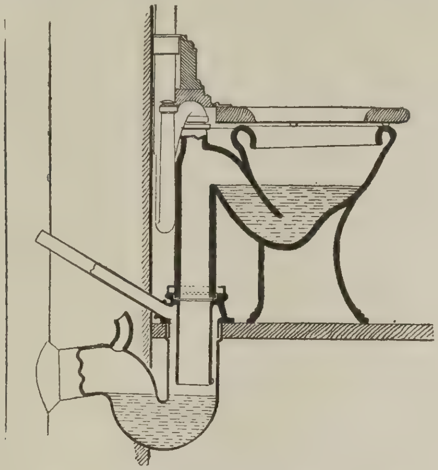

FIG. 2741.—Century "Siphon-jet Closet." (Munson.)

weight of the person on the seat is thus made to lift the valve in the bottom of the tank and when the weight is removed this valve closes and the lower one opens, discharging an ample and definite quantity of water with a sudden dash, which expels all the contents of the hopper below. For public buildings, copious flushes discharged at regular intervals from automatic flush tanks like the "Rogers-Field" are to be preferred. No system should be tolerated which provides for the flushing of the hoppers by faucets, for even if allowed to run for half the time with the consequent waste of water, it does not flush the system like the sudden dash of five or six gallons of water.

Water-closets whenever practicable should be located in a separate room from the bath-room, and preferably in a special projection connected with the house by a well-ventilated lobby; the closet should be provided with a window and other outlets, so that the air may find a ready exit without contaminating the air of adjoining rooms. The exhaust flue already referred to (Fig. 2726) and heated by either a gas jet or lamp is especially indicated in rooms used for water-closets. Each floor of the house, if great convenience is desired, should have such a room and an adjoining room large enough for the bathtub, lavatories, slop sinks, etc. (See plans on page 756.)

Simplicity of the drainage system is of the utmost importance; hence all the fixtures necessary for the comfort of the inmates of the house should be placed in close proximity to the soil pipe, drained and trapped separately into the soil pipe. An error frequently made is to connect a wash bowl waste with a water-closet trap several feet distant by a pipe under the floor, difficult of access and so nearly horizontal as to insure its being soon filled with a deposit of slimy filth. This, like the scattering of fixtures all over the house, is very objectionable. A well-planned, moderate-sized house will show all the bath-rooms, water-closets, pantry, kitchen and laundry fixtures directly above one another and in close proximity to the soil pipe; that is to say, the rooms used for servants' bath-room and laundry in the basement should correspond with the kitchen and pantry on the first floor, and the toilet rooms and water-closets on the upper floors. (See the diagram shown in Fig. 2742.) All the plumbing should be exposed, and since the introduction of nickel-plated pipes the various fixtures present a very attractive appearance. Copper-lined wooden bathtubs and encased wash bowls and water-closets have given way to open elegant and durable fixtures of porcelain, enameled iron or marble, and the ordinary water-closet with hinged seat can be used for a urinal. The bathrooms and other rooms containing plumbing should have an impermeable floor, such as the "granito" floor already referred to, while tile or adamant walls are also desirable.

Urinals should always be of some non-corrosive material, such as china, stoneware, or slate; public urinals should be provided with automatic flushing tanks or a "flush-down spray" (Fig. 2744) and an impermeable floor sloping toward a gutter which discharges into a siphon trap connected with the soil pipe.

Kitchen, pantry, slop sinks, and laundry tubs are usually made of earthenware, porcelain, slate, soapstone, or galvanized iron with or without enamel, and are protected with a strainer to keep the large foreign bodies from obstructing the pipes. Whenever the kitchen and

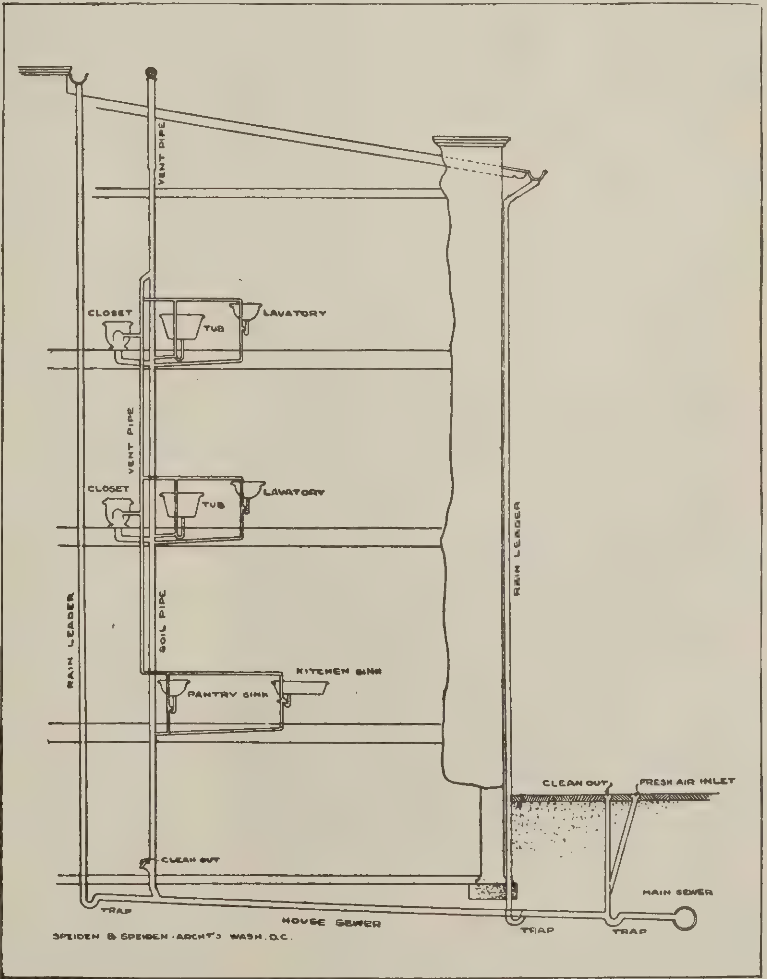

FIG. 2742.—Diagram Illustrating Sewage Plumbing of a House.

pantry drains cannot be provided with a very rapid fall, the congealing of the grease is likely to form a deposit on the inside of the pipe which often obstructs it entirely. To remedy this condition, which will arise no matter how large the drain pipe, the drain should be flushed with a hot four-per-cent. solution of caustic potash or soda several times a week, or, what is far better, so-called "grease interceptors" are placed as near the sinks as possible. The grease congeals in these bowl-shaped stoneware tanks and floats on the surface and can be removed when necessary. The outlet for the waste water being immersed several inches below the surface, the water is allowed to flow off while the grease accumulates on the top of the standing water (Fig. 2745).

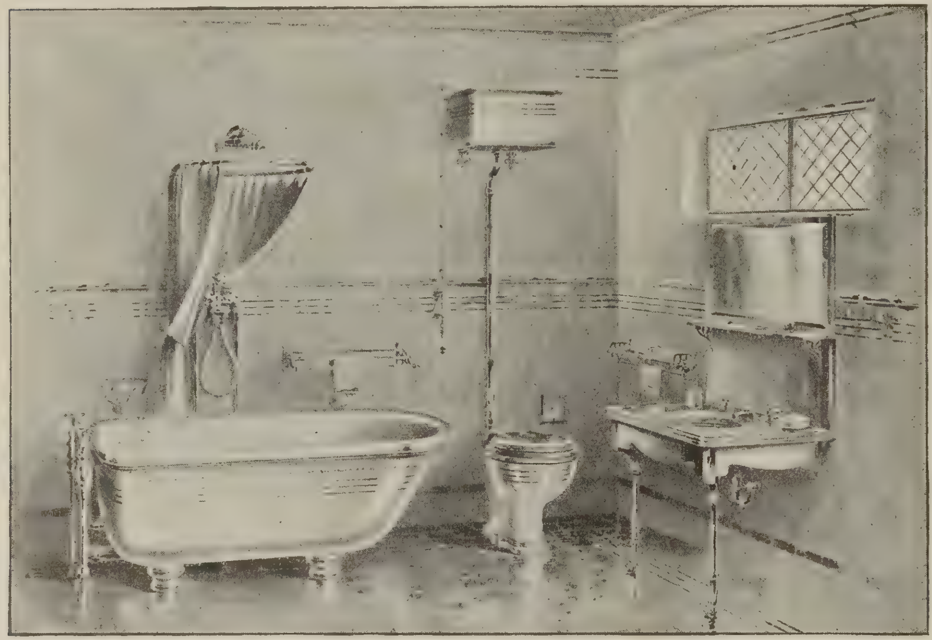

FIG. 2743.—Model Bathroom. (Plate VI.—R, copyright 1900 by the J. L. Mott Iron Works.)

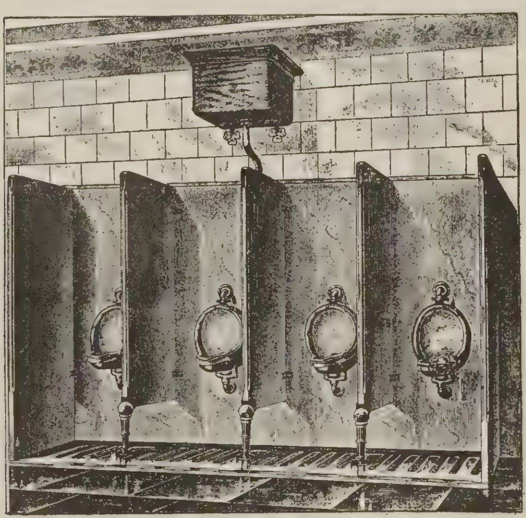

FIG. 2744.—Bowl Urinal. (Munson.)

Soil Pipes.—The soil pipe forms a vertical stack inside of the building, extending from the house drain through the roof where it should terminate ten feet away from all windows and chimneys. The soil pipe receives the sewage from the water-closets and the waste water from all other fixtures; it should never be less than four inches in diameter, made of wrought or cast iron and painted with a coat of tar within and without. Special rules are laid down for the construction of the joints between the different lengths; they may be screwed together, or what is more common caulked with oakum and lead and Spence's metal. Screw joints are preferable. In any event they must be air- and water-tight and free from all defects. The proper security of the soil pipe is a point of importance, for if not perfectly secured it may during the settlement of the walls strain one or more of the connecting joints and produce mischief by leakage. The connection between the soil pipe and house drain should be made by means of a rounded elbow and not by an abrupt right angle (Fig. 2746). At this junction a screw plug should be inserted for inspection and cleaning, as obstructions are most likely to occur at this point.

Traps and Ventilation of Soil Pipes.—It will be readily understood that if the fixtures were simply connected by means of ordinary drain pipes to the soil pipe, the air of the house would certainly be contaminated by sewer air and the more objectionable emanations from the soil and house drains, which are constantly coated with a slimy putrescible mass, giving rise to dangerous and offensive gases.

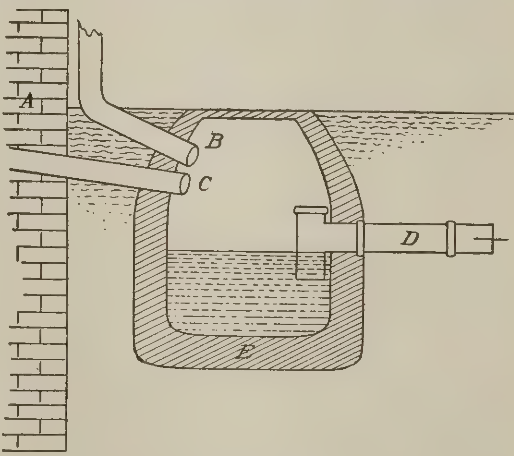

FIG. 2745.—Grease Interceptor. *A*, House wall: *B*, ventilation pipe; *C*, inlet; *D*, outlet.

When houses are artificially heated, this tendency is increased by the diminished density of the air within the house, causing slight inward pressure through all existing openings and fissures. The remedy consists, first, in the use of traps which are certain appliances so constructed as to form a water seal of at least three-quarters of an inch, standing above the highest level of water in the curve of the trap. This water seal prevents the back flow of gases. There are an endless variety of traps in the market, such as the siphon, "Sanitas," midfeather trap, bell traps, etc. (Figs. 2747 to 2753), but of these Figs. 2747, 2748, and 2749 are the simplest and best, because there are no corners or angles for the accumulation of filth and the whole curve is always full of water. The water seal may be broken by evaporation when the fixture is not in constant use; this in warm weather may occur within a few days, and to reduce the danger to a minimum Mr. Putnam invented the "Sanitas trap" which has given excellent results. Evaporation may also be prevented in unoccupied houses by pouring a little oil into the fixtures. It is desirable, however, upon re-occupying a vacated house to flush all the fixtures with water and air the rooms, as sewer air may have entered. Traps may also be emptied by reason of capillary attraction, which is liable to occur if bits of rags and strings have found access to the trap, and one end passes over the further bend while the other remains immersed in the water seal. The water seal may also be broken by a heavy rush of water through it from its own fixture ("*siphonage by momentum*") or by a rush down the soil pipe from a fixture on a higher level, "*siphonage by suction.*" As an additional precaution against the entrance of sewer air and the unsealing of traps by siphonage, the soil pipe and traps should be ventilated. For this purpose the soil pipe is carried above the roof, the top being left open or protected with wire gauze or a ventilating cap, and fresh air is freely admitted to the drain at its lower end on the house side of the trap which connects the system with the sewer. The fresh-air inlet terminates above the ground and must be protected by a perforated iron plate to prevent obstruction, and as the air of the house is generally warmer a constant upward current is thus secured, except when the closet is used, when the current is reversed on account of the sudden rush of water downward through the pipe. For this latter reason and on account of the frequent obstructions placed in the fresh-air inlet by playing children and the obstructions found in the running trap, there has been a disposition to abandon the fresh-air inlet and running trap altogether, and Mr. Charles E. Ball, Inspector of Plumbing of the City of Washington, states that in two outlying districts of the city the concurrence of three conditions—viz.: new clean sewers, recently constructed house plumbing, and the separated location of the dwellings—has justified the omission of the house running trap; indeed, he holds that the objection to open connections with the sewers has little force if the plumbing within each house thus connected has tight joints. The present method of inspections and tests of our plumbing work assure this result in most cities. If the houses are constructed of uniform height, as is usually the case in modern city blocks, or if they are isolated from each other as in suburban localities, emanations from the soil pipe openings cannot injuriously affect the occupants of neighboring premises.

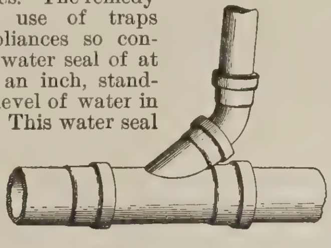

FIG. 2746.—Method of Connecting Soil Pipe with House Drain.

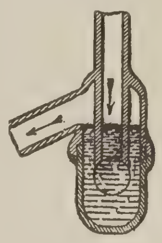

FIG. 2750.—Bower's Trap.

That even more radical opinions than those here expressed are entertained by eminent sanitary authorities is evidenced in a report of the Sewerage Commission of the City of Baltimore, rendered in November, 1896, by Mess. Rud. Hering and Samuel M. Gray, who say:

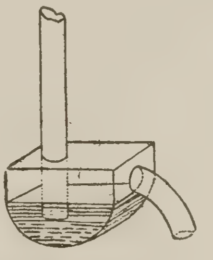

FIG. 2751.—D-Trap. (After Notter and Firth.)

"The problem of sewer ventilation resolves itself into a provision for maintaining a direct communication between the air in the sewers and the atmosphere and in causing the entrance of pure air and its circulation through the sewers to be as free as practicable.

"The most perfect way of accomplishing the above conditions is to ventilate public sewers through the house drains and soil pipes of the buildings, to omit the main trap along the house sewer which also acts as a retainer of foul matter, and to have perforations in the manhole covers of the public sewers.

"In this way an abundance of air can enter the system not only from the outfall, but through the manhole covers and circulate through the sewers and out through every premise sewer to above the roof of the buildings.

"Such a method of ventilation, however, requires that the entire plumbing in the house is planned and constructed by responsible parties, so that the work will be first class. It is also necessary to have the house pipes tested after the plumbing is finished so as to be assured of tight joints. This method has been tried in several cities in our country and is the common one on the continent of Europe, but it is not the usual one in our country, for there is in the minds of many a fear that if the public sewer should be ventilated through the soil pipe of their house, some danger might arise through a leak in their own pipes of contracting a disease, the germs of which are supposed to come from the public sewer.

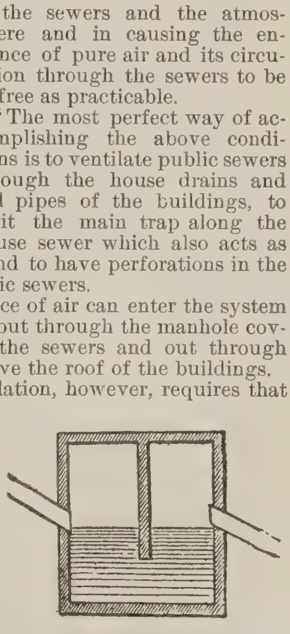

FIG. 2752.—Mid-feather Trap. (Notter and Firth.)

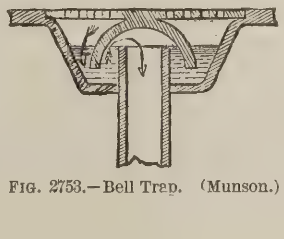

FIG. 2753.—Bell Trap. (Munson.)

"From experience in our country and in Europe, these fears are not well grounded and there are no facts on record to justify them. On the other hand, the advantages of a thorough draft through the house pipes is considerable and keeps them much cleaner than where a trap is placed between the house and the sewer, thus disconnecting the two.

"It has been said that air coming out of soil pipes below windows of adjoining houses might cause offence. But offence could also be caused if there were a main trap and the house pipes were fouled, which they generally are not when used for ventilating the public sewers."

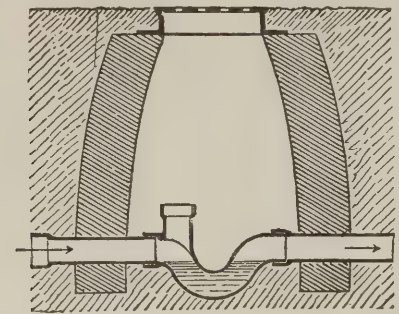

FIG. 2754.—Main Trap and Air-hole for House Drain.

There is much to be said in favor of both sides of the question, and for the present we prefer the more conservative views of Mr. Ball.

The need of draft through every part of the house drainage is not the only reason, for, as pointed out by Mr. Philbrick, it is impossible to retain the water seal in the best forms of traps, unless the atmospheric pressure is freely admitted just below the water seal. The partial vacuum that follows a charge of water as it descends a vertical line of pipe is such that without a free admission of air below every trap, the pressure on the house side of the trap would force the water through them and leave them unsealed. It becomes necessary, therefore, to apply branch vents to each separate trap, for waste pipes more than eight feet in length and less than four inches in diameter. These vents should be extended from the drain below and above the roof or at least be extended and connected to the main soil pipe above the highest fixture. Mr. Putnam and others insist that trap venting does not cure siphonage and simply favors evaporation and necessarily increases the cost of plumbing, and to overcome this fault and still prevent the danger of siphonage, he prefers the "Sanitas trap."

Down spouts from the roof should never be used as soil pipes or ventilators, for apart from the danger of frost in certain climates, during heavy rains, when generally it is most necessary to give a safe exit on account of sewer air pressure, they will be absolutely useless as ventilators and foul air may be forced into the houses.

The *house drain* receives the discharge from all waste and soil pipes and conducts it to the sewer; formerly they were made of terra-cotta in two-feet lengths and about six inches in diameter laid in cement, but owing to so many fractures caused by the settlement and weight of the walls, the insinuation of roots of trees between the joints, rat burrows, etc., the building regulations very properly require that they also shall be made of cast iron, well-jointed, the diameter depending upon the number of soil pipes and rapidity of the fall. The fall for a four-inch drain should if possible be not less than one in forty, of a six-inch drain one in sixty, and of a nine-inch drain one in ninety feet; this will insure a velocity of flow in each case of between three and four feet per second. A direct line from the house to the sewer should always be chosen; if a bend is necessary a suitable curve should be described; the place where the drain emerges from the house must be well cemented to exclude rats from the sewer. All branch drains should be made to connect with a **Y**, so that the branch current may be flowing as nearly as possible in the direction of the main current; these branches, if the plumbing is properly planned, will be necessary only for large houses. The water from the rain leaders should when practicable discharge at the head of the house drain, so that the drain may be thoroughly scoured during each rain storm. When drains discharge into a sewer liable to flooding, it is necessary to provide a tide valve between the sewer and drain, and for house drains with insufficient fall it is advisable to place an automatic flush tank at the head of the drain.

General Considerations.—It is perhaps needless to insist that sanitary plumbing involves a carefully planned system, good material and workmanship, simplicity and exposure of the work. Even the soil and drain pipes should be exposed when practicable, or at least should be accessible by panel work and covered channels in the basement. No soil pipe should be carried on the outside of the building in climates subject to frost, and to render a house safe from the contamination of sewer air it is necessary, first, that the soil pipe and all traps be ventilated; second, that the water seal in the traps be maintained and the house drain be disconnected from the sewer by the introduction of a running trap and fresh-air inlet in the manner already described, with the exceptions noted on page 765; and third, that the entire system be free from leaks or defects.

Testing of Plumbing.—Soil pipes and the general plumbing should be tested for leaks before the house is occupied. This may be done by pouring into the highest point one ounce of *oil of peppermint* in a bucket of hot water. Another person who has not come into previous contact with the oil should inspect the respective floors after a lapse of ten minutes, when the leak will be discovered by the presence of the volatile oil. The man who handles the peppermint must remain on the spot until the investigation has been made below; it requires extreme caution, as a single drop emitted elsewhere will destroy the value of the test. Special glass grenades charged with the oil of peppermint or other pungent chemicals have been prepared for use of sanitary inspectors. The system may also be tested before the water-closets are connected by soldering over the apertures where the traps are connected with the soil pipes and then filling the pipes with water. This is a severe test, but very certain, as any subsidence in the level of the water indicates a leak which can be searched for as long as the "stack" of soil pipes and drain is exposed to view.

Sometimes the "smoke test" is applied from below; the smoke, being forced up the pipes by means of a small bellows or smoke rockets, will be emitted through the leaks and thus lead to the discovery of the defects. Of course all openings known to exist must first be closed and the smoke test should be connected with the lowest possible point. This test is not so reliable as the others named. The *gas pipes* should also be tested before lathing and plastering is begun, otherwise great damage may be done. For this purpose all the outlets are capped except one, to which is attached a tube connected with an air pump and mercury gauge. Air is pumped into the whole system and the stopcock turned, and if after working the pump for some time and stopping it the gauge shows in the course of thirty minutes no signs of sinking, the pipes may be taken as in a safe condition; but if the mercury in the gauge falls, owing to the escape of air from the gas pipes, there is a leak somewhere, which may be discovered by pouring a little ether into the pipes near the gauge and recommencing pumping, while another person searches for the leak at the various joints or outlets. Very minute holes may be detected by lathering the pipes with soap and water and making use of the pipe and pump to create soap bubbles. Similar tests are applied after the gas fixtures have been connected, so as to detect the presence of defective joints and keys; in this instance every burner is turned off except one to which is attached a tube connected with the air pump and gauge.

Sewage Disposal for Villages and Isolated Houses.—When we consider the fact that over seventy per cent. of our population reside in rural districts and occupy homes without sewer connections, we see at once why wells and outhouses are often dangerous neighbors. Mr. Philbrick, of Boston, has described a system of sewage disposal by irrigation which must commend itself as safe and practicable for all small villages and isolated houses, where the land has sufficient slope to afford the requisite grade. The requisites for this system, as stated by him in Parkes' "Manual of Practical Hygiene," vol. ii., p. 484, are as follows:

"First, land adapted to grass nearly level or gently sloping at the rate of one-fourth of an acre for a single family, or an acre for a combination of eight to ten families, if provided with a constant water supply under pressure. If the water supply is limited to what may be pumped by hand one-half of the above area will be ample.

"Second, the highest part of the land devoted to this purpose should be at least five feet below the level of the top of the drain where it leaves the house.

"Third, the soil should be thoroughly under-drained, if not resting on a dry and porous subsoil by nature. Under-drains are often needed in clayey or retentive soils and should be laid at least four or five feet below the surface, at intervals of about twelve feet, with a free outfall.

"Fourth, the land should be graded, unless tolerably smooth beforehand, so as to avoid sudden inequalities. A surface that is adapted to smooth mowing by hand is good enough for this purpose.

"Fifth, the soil must be entirely free from roots of trees and shrubs. These would choke the pipes in a few weeks. . . ."

If house drainage is conducted directly into porous tiles laid under the surface, the fluid parts will escape at every joint while the solid matter is apt to cling to the interior and gradually fill them, so as to render them practically useless, hence arrangements should be made to discharge the sewage by means of properly trapped and ventilated drains into a water-tight cesspool, where it will macerate and liquefy, and to discharge the contents periodically with such a rush as to fill the whole system of distributing pipes at once and brush away slight obstructions which may have been left by former discharges. This can be accomplished by providing a stopgate in the outlet pipe where it leaves the tank to be opened by hand when the tank is full and closed again when empty, or by providing a siphon or float to discharge the tank automatically whenever filled.

Mr. Philbrick has modified Field's siphon to be used in connection with these sewage tanks. One of the objections to this plan of subsoil irrigation, while excellent in principle, is the possibility of the roots entering the porous tiles and choking them; there is also danger from frost, and if laid deeper than one foot the vegetation cannot assimilate the very matter we wish to dispose of; for these reasons the writer favors the disposal by surface irrigation along the furrows of growing vegetation or in winter on the same garden spot.

Fig. 2755 shows such a method which Mr. Philbrick says has been in use for several summers at a house used only as a summer resort, and has been attended with complete success. There is an overflow pipe from the cesspool which is perfectly tight, indicating when it is full. The gate in the outlet pipe is then opened, and the whole contents are distributed on the kitchen garden in ten minutes. If an opportunity is selected when the wind is blowing from the house to the garden, no offensive odors are perceived and the growing crops soon absorb the fluid, much to their advantage.

When a proper slope cannot be had, we must of necessity fall back upon either the earth closet, tonneau, or pail system for the collection of excreta, while the kitchen slops and refuse waters from the house should be conducted to some garden spot if practicable and disposed of by irrigation. The ordinary privy pits and open-box privies should never be tolerated; the undue prevalence of typhoid fever in rural districts is largely due to the use of these makeshifts and neglect in the disinfection of the excreta. The history of every sewered city shows a lessening of the typhoid death rate subsequent to the construction of the sewers and that the typhoid rate is always higher in sections supplied with privy pits and open receptacles. The only reasonable explanation for this is, that sewers carry away the filth and germs that otherwise would contaminate the soil and ground water. But even if there were no wells these makeshifts are still a source of danger, in so far as they favor the transmission of the infection by means of flies; nor can the possibility be ignored that the germs in leaky or overflowing boxes may reach the upper layer of the soil and with the pulverized dust gain access to the system. These conclusions were enunciated by the writer in 1895, and appear to have found ample support in the experience of the late Spanish-American war.

House Diseases.—Special reference should be made to some of the insanitary factors likely to produce disease.

Dampness of the basement and walls is certain to render the air of the house damp; this not only leads to undue abstraction of animal heat, but also influences the cutaneous functions and favors the development of micro-organisms. The air of habitations may be vitiated not only by the products of respiration and by exhalations of the skin and mouth, but also by the products of combustion, by putrid gases from decomposition of organic matter (more especially sewer air), and last, but not least, by the household dust. Dr. Charles Smart, in his able article on air and its impurities, pp. 147–155, Vol. I., has fully set forth the nature and effects of these impurities. Severe outbreaks of acute tonsillitis, marked by great inflammatory swelling of the tonsils, foul tongue, gastric derangement, severe headache, intense depression and high temperature, have been attributed by some authorities to the entrance of sewer polluted air into the habitations. Cases of typhoid fever, gastro-enteritis, diarrhœa, and dysentery have been attributed to the same cause, and Parkes tells us that in general and lying-in hospitals in which the air of wards was liable to pollution from drains, surgical fever, erysipelas, pyæmia, septicæmia, and puerperal fever were quite prevalent and fatal. Since sewers receive the excreta of patients suffering from intestinal infections and also the wash-water and secretions from persons and clothing of other infectious diseases, it may be presumed that they contain the carriers of many diseases, but it is not so easy to explain the liberation of micro-organisms from the sewage. Some believe that there is always a possibility of particles of sewage becoming dried and as particles of dust gaining access to the air, while others contend that during evaporation or from the bursting of bubbles of gas when the sewage is putrefying, the germs may be projected from the liquids into the sewer air, and may then in consequence of defective traps or joints in the drains be blown into the house. While there is ample room for speculation on the subject, in the present state of our knowledge we may conclude at least that whether sewer air contains specific organisms or not, its constant inhalation cannot fail to lower the power of the system to resist the invasion and effects of pathogenic germs, and that the emanations from choked house drains are more injurious than those from sewers. The inhalation of household dust, apart from the mechanical irritation of the mucous membranes produced thereby, may also be the means of carrying infection; since the tubercle and influenza bacillus and the pneumococcus are doubtless often conveyed from dried and pulverized sputum or mucus deposited in the room. When we recall the bad effects of deficient sunlight, of dampness, impure air, and excessive summer heat, we can appreciate why some of

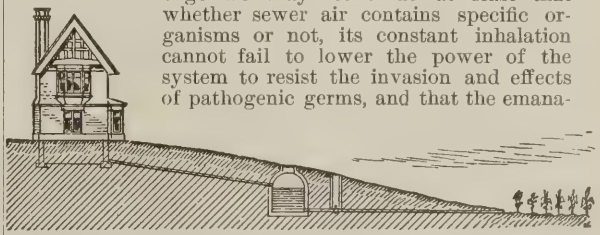

FIG. 2755.—Disposal of House Drainage by Surface Irrigation.

these factors should be especially potent in unsanitary dwellings in the production of certain typical house diseases.

Scrofula, or more correctly speaking a chronic form of tuberculosis of the glandular system, is especially common among children brought up in dark, gloomy, and damp habitations. These children are anæmic and as puny as plants reared without the stimulating effects of sunlight. Add to this fact that dampness favors the development of catarrhal conditions which render the system more vulnerable to tuberculous infection, and we have a reasonable explanation why this disease, as well as *pulmonary tuberculosis*, prevails especially among inmates of damp and dark basements and back-to-back houses. The death rate is often double and treble that of other localities, and while there are doubtless other factors which determine this frightful mortality, none are more potent than deficient sunlight and ventilation, especially in view of the fact that the ubiquitous tubercle bacillus clinging to floors and walls in carelessly expectorated sputum, may retain its vitality and even proliferate in damp and badly lighted rooms. For similar reasons *diphtheria* and *cerebro-spinal meningitis* are also more frequent in unsanitary dwellings. *Acute* and *chronic rheumatism* and *bronchial affections* are likewise of more common occurrence in damp houses, and in recently constructed houses which have not been sufficiently dried and aired. Here again the continued abstraction of animal heat lowers the vitality of the inmates and favors the development of these affections, and a bronchial catarrh thus produced may render the mucosa vulnerable to the invasion of the tubercle bacillus.

Infantile diarrhœa is more frequent and fatal among the inmates of the upper stories; this is doubtless due to the enervating effects of heat and the more speedy decomposition of food, especially the milk, in the heated atmosphere; at all events, Meinert has shown that the mortality from cholera infantum, at Dresden, was 11.27 per cent. in the top stories as compared with 9.13 on the second and 3.98 on the first floors. Similar observations have been made at Berlin, which also developed the fact that still-births occur in a larger proportion among the occupants of the upper stories of houses. Whether this condition is due to the causes already mentioned, to sociological conditions, or to stair-climbing, remains to be determined.

Sanitary Inspection of Buildings.—The eradication of preventable diseases is the highest aim of scientific medicine, and the time may come when the public is willing to compensate the physician "to prevent by watchful foresight so far as is consistent with the progress of human knowledge" the outbreak and extension of such diseases. Indeed even now it is the duty of health officers and medical officers of the public services to examine into the cause of outbreaks of contagious and infectious diseases, and it is therefore desirable to point out some of the subjects to which an intelligent sanitary inspector pays special attention. Such an examination should include the character of the site and soil, the building plans, material and construction, ventilation, heating, lighting, plumbing, water supply, and the collection and disposal of refuse, and presupposes a knowledge of the causes of propagation and best methods of prevention of infectious diseases; also a knowledge of sanitary chemistry, microscopy, and bacteriology in order to determine the impurities in air, water, soil, food, etc., the prompt and accurate diagnosis of disease and the efficient use of disinfectants;—in fact, a good sanitary inspector must possess a general knowledge of the subject under discussion, good common sense, the habit of accurately observing facts, and the power for reasoning from causes to effects and by way of exclusion.

Before beginning the examination of a building or locality proper it will be well to gather all the information possible from all persons likely to throw light on the subject of bad water, offensive odors, and many other details, for, as remarked by Mr. Frederick N. Owen, "he will often find that this testimony will be uniform in a certain direction and will save him much time and labor in the investigation he is about to make, by directing his attention to some one point as the probable cause of the trouble." There are thousands of houses, clean and well-kept inside, which are steeped in the foul exhalations rising from cesspools and vaults in the immediate vicinity; if, therefore, offensive odors are noticed only when the wind is from certain directions, the inspector would do well to look for the nuisance in that direction. The inspector should be systematic in his methods and all the observed facts should be carefully noted in a memorandum book.

1. The examination of the site should include its relations to sources of soil, water, and air pollution, such as proximity to marshes, factories, and other nuisances, the presence of ponds and stagnant pools with special reference to mosquitos as carriers of malaria. Attention should be paid to the elevation of the site and its relation to adjoining lands as regards drainage; to the amount and duration of sunlight, prevailing winds, and the character and amount of dust; and to the influence of trees close to the house in causing dampness by shutting off sunlight and air. The examination should also be directed to the cleanliness of the yards, outhouses, and the character of the diseases in the neighborhood. The writer in 1895 recorded a number of house epidemics of typhoid fever in which the infection was doubtless carried from privies to the food supply of neighboring houses by the agency of flies.

2. The examination of the soil on which the house stands, with special reference to dip of strata, porosity, and soil pollution, height and fluctuations of the ground water as determined by the water level in neighboring wells. A porous soil like sand, unless upheld by a stratum of clay, is usually dry and salubrious; clay and rock are impervious to moisture, and the water usually flows along the surface to some lower point; situations at the base of a hill are especially objectionable, as the ground water from higher levels generally comes here near the surface and renders the soil and air by capillary attraction and evaporation more moist than at any other point, and this dampness may extend to the walls of the house unless special precautions have been taken in the manner described on page 752 ("Construction of the House").

3. The examination of the plans, number of stories, construction and interior arrangement of the house should include the permeability and hygroscopic properties of the building material. Our general knowledge of the relative permeability of different kinds of building material will enable us to form an opinion, but for exact determinations the use of a poroskop, or gasometer and manometer becomes necessary. The capillary attraction may be determined by drying a suitable piece of the material, placing the lower end in water, and noting the height to which the moisture ascends. The effective humidity of certain building materials is determined by weighing a certain sample and after drying it at a temperature of 100° C. to weigh it again. The loss in weight indicates the amount of moisture. The relative capacity of certain building materials for parting with their moisture can be determined by placing two equal-sized pieces in water until completely saturated, and then, after wiping them off rapidly, exposing them to a uniform current of perfectly dry air. From the length of the time consumed in drying, the capacity for evaporating moisture may be calculated. The material, character, and condition of the roof, gutters, and rain leaders should receive careful attention.

4. The examination of the air in the interior is important. Here we should remember that whenever the volume of CO_2 amounts to seven volumes per 10,000, with a proportionate increase of organic impurities, a want of freshness is observed, and when nine or more volumes are present the organic odor becomes quite perceptible, although, as pointed out by Dr. Smart, Vol. I., p. 153, the continued occupancy of an apartment may give rise to organic odors, clinging to the walls and other surfaces, when CO_2 may not be present in large quantity. Before

entering into a systematic examination of the air for the determination of its impurities (see *Air*, pp. 147–155, Vol. I.) as regards carbonic acid, organic matter, ammonia, hydrogen sulphide, carbon monoxide, micro-organisms, and humidity, and for the determination of cubic air space for the occupants, it will be well to note the character and habits of the inmates as regards cleanliness, the amount of household dirt and dust which has accumulated on the walls, floors, and furniture, and to examine the closets, slop-pails, garbage, and ash receptacle, as well as the condition of the water-closets. The latter are often found with no connection with the outer air, being located in the middle of the house. Most of the private dwellings have no other way of changing the air than through doorways, windows, transoms, and the seams of imperfect workmanship.

5. We should study the arrangement of rooms, their length, breadth and height, floor and cubic air space for each occupant, distribution of light, number of doors, transoms and windows, sufficiency of ventilation, the size of fresh-air inlets and outlets, their cleanliness and freedom from obstruction. We should also test the humidity of the air in different stories by means of a reliable hygrometer, remembering that a humidity of 60°, saturation being 100, is the limit for healthy dwellings in this country. If the house is found to be noticeably damp, we may find the cause in imperfect cementing of cellars or basements, in the absence of damp-proof courses in the walls to prevent capillary attraction, in leaking downspouts, house drains or water-pipes, in ash heaps piled against the wall, absorbing and retaining moisture, in obstructions to air and sunlight, etc.

6. The methods of heating, as by stoves, open fireplaces, steam, hot water, or hot-air furnaces. If the house is heated by a furnace, the position of the fresh-air inlet with reference to sewer drains, underground ducts, and other impure sources should be noted. The very place which should be well cemented to exclude ground air—namely, right under the furnace—is frequently neglected. Basements and cellars must be cemented to exclude not only dampness but the equally objectionable ground air with its excess of CO_2 and other impurities. We should also note the character of fuel, the provision of dampers and presence of coal gas, the amount of heat obtained, and the quality of the air.

7. The question of natural and artificial light should receive consideration, and the average amount and duration of sunshine should be noted. Thus, for example, the proportion of window to floor space should be one-sixth or one-fifth, and in temperate climates direct sunshine should reach, when practicable, all parts of the room. The sufficiency of artificial lighting may be approximately determined by observation, and quite accurately by the employment of Bunsen's photometer. In this country, the unit adopted for the measurement and comparison of lights is a No. 6 sperm candle, burning 8 gm. per hour and giving out a light known as "one-candle-power." Such a candle, according to Munson, contains, on analysis, carbon 80 per cent., hydrogen 13 per cent., oxygen 6 per cent. The quality of the air and the temperature of the room lighted with ordinary illuminants should also receive attention.

8. The inspection of the plumbing is one of the most important features of a sanitary inspection. If an offensive odor is perceived in the basement it will suggest the possibility of a leaking drain pipe; and if inquiry reveals the frequent presence of rats, we may infer that the house drain is in direct communication with the sewer and that the traps and lead bends are likely to be gnawed and leaky. Unfortunately, in most buildings the pipes are hidden behind woodwork and underneath floors, and the owner never appreciates the importance of exposed work until the workmen have to tear up floors and walls to permit of the necessary inspection and repairs. Of course this should not be done until a general examination and the tests for plumbing already referred to indicate defective work. Very often, too, the owner has not the faintest idea of the location of the house drains and soil pipes, and this suggests the necessity of a law compelling every householder to preserve a set of drawings, showing the location of drains and vertical soil pipes.

The inspection of plumbing should begin with the main drain and proceed upward to all the ramifications, special attention being paid to imperfect caulking of joints, open connections, putty joints, holes plugged with corks, rag-patches, spots of corrosion, lead pipes gnawed open by rats, etc.

The fixtures should be carefully examined and their traps or water seals tested in order to learn their efficiency against the entrance of sewer air; this unsealing, unless special precautions have been taken, is sure to occur if the fixtures remain unused for a certain time and the water in the traps has evaporated. To make this test Mr. Owen suggests that "all the basins, baths, and other fixtures above the traps to be tested and on the same line of piping should be filled with water and then discharged simultaneously, care being taken that all the pipes are free from obstruction. The fixtures below the trap should then be filled and discharged in the same way. If the trap retain its seal under these tests, it is safe to assume that it is an effectual barrier to the entrance of sewer air." For the detection of pin holes in the pipes, etc., which cannot be seen by the naked eye, the "peppermint," "smoke test," or some other pungent chemicals should be employed in the manner described on page 766.

The following list of defects in plumbing and drainage have been encountered by Mr. Owen, and numerous specimens illustrating these defects have been observed by the writer in the Museum of Hygiene, in the City of Washington:

1. Earthen-pipe drains, either broken or with leaky joints, laid under the cellar floor, saturating earth with sewage. 2. Section of earthen pipe drains completely obstructed by the insinuation and growth of the roots of trees. 3. Pipe drains without sufficient grade or with the fall in the wrong direction. 4. Drains without running traps admitting sewer air from sewer or cesspools to the pipes in the house. 5. Drains without a free current of air. 6. Rat burrows from sewers and along drains undermining floors and admitting foul air to the house. 7. Section of soil pipe, the lumen of which was completely obstructed by urinary deposits, because of the exposure of the soil pipe on the outside walls of the house in cold climates. 8. Soil or waste pipes without any or sufficient ventilation. Defective connections between fixtures and waste pipes. 9. Lead pipes and traps gnawed by rats. 10. Water-closets, cistern with overflow joined to soil pipe or drain. 11. Safes under closets or basins connected to soil pipe or drain. 12. Two or more fixtures with unventilated traps on the same line of pipe, siphoning each other when used. 13. Sink overflow pipes joined to soil pipes untrapped or with trap liable to siphon. 14. Overflows from fixtures connected with waste pipe on sewer side of trap admitting foul gases to rooms. 15. Faulty traps and fixtures without traps. 16. Water supplies to sinks taken from water-closet or other contaminated tanks and used for drinking purposes. 17. Rain leaders used as soil pipes or ventilators to drains, delivering foul air to bedroom windows or under eaves or roofs. 18. Ash pits near larders and pantries, or liable to soak moisture to walls. 19. Defects of drainage and rat burrows from neighboring houses, especially from those located on a higher level. 20. Cesspools near houses, wells, or cisterns, polluting the drinking-water.

If an outbreak of contagious or infectious disease is being studied, and up to this point the inspector has not reached any conclusion, it is desirable to consider the possibility of the germs being carried by flies, mosquitos, and other insects. Our investigation should, of course, extend to the water supply, milk, food, and even the ice supply.

The general principles set forth in the foregoing pages are equally applicable to the inspection of public buildings, schools, hospitals, prisons, barracks, asylums, etc. (For inspection of dairies, etc., see *Milk-Borne Diseases*.)

George M. Kober.

HOWARD SPRINGS, LAKE COUNTY, CALIFORNIA.—

Post-Office.—Putah. Hotel and cottages.

Access.—From San Francisco, Sacramento, or Woodland to Calistoga, thence by stage. These springs are fourteen in number and are picturesquely located in a mountainous pine region 2,240 feet above the level of the sea. Following is a quantitative analysis of the principal springs by Prof. W. T. Wenzell, California College of Pharmacy:

One United States Gallon Contains:

Solids.	No. 1—Excelsior. Grains.	No. 2—Twin Springs. Grains.	No. 3—Eureka. Grains.	No. 4—Neptune. Grains.	No. 5—Soda. Grains.
Sodium chloride	101.67	30.96	35.70	29.61	9.38
Potassium chloride	1.13	19.71	25.65	14.64	12.81
Lithium chloride	8.35	.03	.09	.06	
Sodium bicarbonate	34.10	73.97	82.35	......	37.72
Magnesium bicarbonate	2.81	114.10	110.25	73.34	59.32
Calcium bicarbonate	6.30	10.88	5.84	32.14	35.62
Iron bicarbonate	1.85	1.14			
Alumina	.03	.15	.10	.19	.13
Oxide of iron	......	......	4.95	.20	.09
Silica	34.10	9.24	3.40	8.34	6.95
Organic matter	.14	.32	.20	.25	.26
Total	190.48	260.50	268.53	158.77	152.28
	Cu. in.	Cu. in.	Cu. in.	Cu. in.	Cu. in.
Free carbonic acid gas	134.00	77.50	150.00	120.00	117.00
Temperature of water	75° F.	102° F.	110° F.	85° F.	60° F.

It will be observed that the "Excelsior" spring is quite similar to some of the Saratoga springs of New York. The percentage of sodium chloride, however, is much less than that of its Eastern namesake, the Saratoga Excelsior, while the amount of sodium bicarbonate is about twice as great. The water is mildly purgative, and on account of the considerable quantity of lithia which it contains is useful in a number of urinary complaints, especially calculus and gravel. The "Twins" No. 2, although only six feet apart, show a remarkable difference of temperature, one being cold at 50° F., the other thermal at 102° F. The water of the hot spring is a very efficient cathartic, and is used in habitual constipation, chronic dyspepsia, and in certain diseases of the liver and kidneys. On account of the large quantity of iron contained in the "Eureka" spring, No. 3, it has gained great celebrity in the treatment of anæmia, debility, etc. The "Neptune," No. 4, is also quite rich in iron, besides containing considerable quantities of magnesia, lime, and sodium. The water is tonic and mildly laxative in its action. The "Soda" spring, No. 5, being very rich in carbonic gas, forms a pleasant cooling effervescent draught, if the water be taken directly from the spring. It contains a little iron and has mild tonic properties.

James K. Crook.

HOWARD SPRINGS, LAUDERDALE COUNTY, ALABAMA.—

Post-Office.—Florence. Hotels at Florence.

The springs are located one mile and a half from the Tennessee River, and half a mile from Florence at the junction of the Memphis and Charleston, and Louisville and Nashville railroads. The river is navigable for ten months in the year. Florence has a population of 8,000 and possesses abundant hotel facilities.

The climate in this section is mild and equable and the weather is not subject to sudden changes. In 1890 it is said that the highest temperature was 89.5° F., the lowest 64° F. The average summer temperature ranges from 79° to 84°, and the nights are almost always cool, requiring light blankets. The usual winter temperature ranges from 54° to 59° during the day, and from 40° to 48° at night. The coldest weather ever known in Florence was in January, 1893, when the mercury fell to 9.5° above zero. The elevation here is about 1,100 feet above the sea level, and the surrounding country is gently undulating. The springs are three in number. No quantitative analysis has been made, but according to an old qualitative examination by Professor Tuomey, State Geologist, Spring No. 1 contains:

Hydrochloric acid.
Sulphuric acid.
Calcium carbonate.
Iron carbonate.
Sulphurous acid.
Sulphuric acid.
Alum.
Magnesia.

Another spring is said to contain ferric alum in large proportions, and has a considerable reputation in the treatment of diarrhœa and dysentery. The third spring, about 500 feet distant from No. 1, contains sulphur, and is used in skin diseases. The waters of No. 1 have an extensive reputation in the treatment of Bright's disease, diabetes, and other disorders. For various reasons these springs have been more or less neglected since the Civil War.

James K. Crook.

HUANUEO BARK. See *Cinchona.*

HUBBARD SPRINGS.—Lee County, Virginia.

Post-Office.—Jonesville.

Access.—Viâ Louisville and Nashville Railroad to Hubbard Springs station, thence a walk of two hundred yards to springs. These springs are located seven miles from Jonesville in southwest Virginia. The surrounding country is rugged and broken in character, the springs being in a charming valley at the foot of the Cumberland Mountains. The elevation is about 1,450 feet above the sea level. There are four springs located in a space of thirty feet square, and known respectively as the "White Sulphur," the "Black Sulphur," the "Chalybeate," and the "Frustom." An analysis has been made, but the results are not known at this time. The waters are stated to be much valued in rheumatism and in disorders of the liver, kidneys, and gastro-intestinal mucous membrane. No special accommodations are provided for visitors, but board and lodging may be obtained in the neighborhood.

James K. Crook.

HUDSON HOT SPRINGS.—Grant County, New Mexico.

Post-Office.—Hudson. Hotel.

Access.—Viâ Atchison, Topeka, and Santa Fé Railroad (Silver City branch to Hudson, thence by coach to springs). The location is twenty-five miles from Deming, at the junction of the Southern Pacific and Atchison railroads. At present the accommodations for guests are limited, the hotel having been destroyed by fire and not rebuilt. Plans are completed, however, for the erection of a hotel of fifty rooms with all modern conveniences, and it will no doubt be ready for occupancy before this work is printed. The location is 5,000 feet above the sea level, and is in a broad valley open on the south for many miles, and surrounded on other sides by mountains distant from ten to fifteen miles. On the east, four miles distant, flows the Mimbres River, whose valley, from one to two miles in width, is dotted with a succession of fine farms and orchards. The variations of temperature are never extreme in this region, the air being pure and dry and the rainfall light, occurring almost entirely in July and August. The flow of water from the springs has not been measured, but it is sufficient to irrigate eight acres of land. The following analysis of the Hot Springs was made by Prof. W. D. Church, chemist:

One United States Gallon Contains:

Solids.	Grains.
Silica	1.55
Oxide of iron and alumina	.50
Calcium carbonate	4.45
Magnesium carbonate	2.62
Soluble sulphates and carbonates of sodium and potassium	13.55
Sodium chloride	2.27
Total	24.94

Temperature of water, 142° F.

It is said that certain of the diseases of the blood, liver, kidneys, and stomach are much benefited by the hot-water baths conjoined with the internal administration of water of the cold spring. On account of the equable climate it is safe to visit this resort at any season of the year. *James K. Crook.*

HUNTER'S HOT SPRINGS.—Gallatin County, Montana.

Post-Office.—Springdale. Hotel and sanitarium.

Access.—Viâ Northern Pacific Railroad to Springdale, where stages connect with the springs, three miles distant, the road crossing a magnificent iron bridge on the Yellowstone River. Hunter's Springs are situated at the base of the foothills of what is known as the Crazy Range of mountains. The location is 1,000 miles west of St. Paul and 920 miles east of Portland, Ore., and has an altitude of 4,480 feet above the sea level. The surrounding scenery is of the grand and romantic character commonly found in the Rocky Mountains. The climate is dry and salubrious, and severe storms are unknown. The thermometer seldom reaches as high as 98° F. in summer or as low as zero in winter. The springs boil up from a rocky ledge in the bottom of a little valley or basin enclosed by gently undulating hills. They are twenty-seven in number and are arranged in three principal groups, varying in heat from 148° F. to 168° F., with a combined outpour of about 90,000 gallons per hour. The water is clear and sparkling and remarkably soft. At present only the waters from the upper springs are used for the baths of the sanitarium. The baths for ladies and gentlemen are in separate buildings, each fitted with a plunge, tub, and vapor baths, and heated by the hot waters. About eighty rods from the bath-house is an outdoor summer bath, about one hundred and five feet square and from four to six feet deep, supplied with water from the lower group. This is said to be the largest bath of hot mineral water in the United States. The sanitarium connected with the springs has recently been enlarged and is adequately prepared for the reception of various classes of patients. Cases of rheumatism, liver disorder, bronchial catarrh, asthma, gout, and uterine diseases have been benefited or cured by a sojourn at this resort and the use of the waters and baths. An analysis by Professor Noyes, of the Minnesota State University, resulted as follows:

One United States Gallon Contains:

Solids.	Grains.
Silica	4.52
Alumina	.07
Iron carbonate	Trace.
Calcium carbonate	.23
Magnesium carbonate	Trace.
Lithium carbonate	Trace.
Potassium carbonate	.32
Potassium iodide	Trace.
Potassium bromide	Trace.
Sodium chloride	1.44
Sodium sulphide	.85
Sodium sulphate	.61
Sodium phosphate	Trace.
Sodium biborate	Trace.
Sodium carbonate	8.79
Ammonium (free)	.02
Albuminous ammonia	Trace.
Total	16.85

James K. Crook.

HUNTER'S PULASKI ALUM SPRINGS.—Pulaski County, Virginia.

Post-Office.—Sassin. Hotel.

These springs are located eight and one-half miles north of Pulaski City, from which point they are reached by carriages and stages. The location is very pleasant and picturesque, being about 2,000 feet above the sea level, and surrounded by beautiful mountain scenery. The average summer temperature at Pulaski Springs is 71.6° F., and malarial disorders are said to be unknown. Immediately surrounding the springs are shady lawns and charming walks and drives, which, with the pure air and romantic landscapes, render the place very attractive during the summer months. Excellent fishing and hunting may be had in the vicinity. The springs are two in number. They have been analyzed by Dr. William H. Taylor, State Assayer and Chemist, with the following results:

One United States Gallon Contains:

Solids.	Grains.
Potassium sulphate	0.31
Sodium sulphate	.32
Lithium sulphate	Trace.
Calcium sulphate	.99
Magnesium sulphate	1.26
Aluminum sulphate	16.40
Iron sulphate	1.99
Manganese sulphate	Trace.
Sodium chloride	.11
Silica	3.87
Free sulphuric acid	.63
Total	25.88

The chemist states that his analysis was not complete, and that further tests would show the presence of additional mineral ingredients. The water is recommended in dyspepsia, diarrhœa, and dysentery, and locally in catarrhal states of the mucous membranes. It is used commercially. *James K. Crook.*

HYALIN.—This is the chief organic constituent of the walls of hydatid cysts, and is related chemically to chitin. The walls of the older transparent cysts are composed of pure ash-free hyalin; those of the younger cloudy cysts are albuminous and contain various salts. Hyalin has been found only in echinococcus cysts. From the older cyst walls it is obtained in water solution under high pressure.

Pure hyalin is opalescent, transparent, insoluble in cold water, alcohol, and ether, but soluble in over-heated water (150° C.). It is not soluble in acetic acid, and only slightly in cold hydrochloric and nitric acids, but dissolves completely in hot solutions of the latter two. In concentrated potassium and sodium hydroxides it is slowly and incompletely dissolved. According to Lücke its composition is as follows: C. 44.1–45.3, H. 6.5–6.7, N. 4.5–5.2, O. 43–44.7 per cent. From the water solution it is precipitated by alcohol, acetate of lead, and mercuric nitrate, but not by acetic acid and potassium ferrocyanide or mercuric chloride. By the latter reactions it is distinguished from albumin. Neither tannic acid nor chlorine water precipitates it. If the water solution is boiled with dilute sulphuric acid reducing substances are formed, which with yeast yield alcohol and carbonic acid, and are strongly dextrorotatory, proving to be grape-sugar. It has been estimated that the older cyst walls yield fifty per cent. of their weight of this substance. From chitin, to which it is most closely related, hyalin is distinguished by its solubility in water at 150° C.

Aldred Scott Warthin.

HYALINE DEGENERATION.—Under this head there is classed by various writers a large number of pathological processes of widely differing origin and nature, characterized in common by the production of a clear, homogeneous, refractive material to which the name hyalin is applied. The most comprehensive use of this term is that employed by von Recklinghausen who defines hyalin as a homogeneous, refractive, albuminous body, staining well with eosin, carmine, picrocarmine, and acid fuchsin, resistant to water, alcohol, acids, and ammonia; in these respects resembling amyloid, but giving none of the specific amyloid reactions with iodine or the aniline stains. In accordance with this definition, he classes as hyaline substances epithelial colloid and keratohyalin (*epithelial hyalin*), the hyaline products of connective-tissue cells and intercellular substance (*connective-tissue or conjunctival hyalin*), hyaline products of coagulation (*blood hyalin*), hyaline inflammatory exudations on surfaces, into tissues, urinary tubules, etc. (*exudation hyalin*), and tissue necroses presenting a hyaline appearance (*hyaline necrosis*). Further, the hyalin formed in connective tissues is to be divided into two classes: that formed by a secretory process on the part of the connective-tissue cells, and that resulting from a degeneration or infiltration of the interstitial substance. Since these various substances are of different origin and are not chemically identical, as shown by their great difference in staining, the above classification, resting as it does only upon a common physical property, has not been accepted by the majority of pathologists, who class the greater part of these processes under other heads than that of hyalin, and restrict the term hyaline degeneration almost entirely to the hyaline changes occurring in connective tissue.

Hyaline Degeneration of Connective Tissue.—The group of changes occurring in connective tissue, in which the fibrous basic substance becomes structureless and homogeneous, is at the present time usually understood by pathologists when the term hyaline degeneration is used. In the earlier stages of this degeneration the connective-tissue fibrillæ become swollen and are gradually transformed into coarse, irregular hyaline strands or even into nodular masses; in other cases they may become confluent, forming uniformly homogeneous masses; or masses of hyaline substance may be formed between the fibrillæ, the latter gradually disappearing. Neither the hyaline material into which connective tissue may be transformed nor that by which it may be replaced has yet been shown to be a distinct chemical entity. In both cases the substance closely resembles amyloid, but differs from it in that it has no specific reactions with iodine and the aniline dyes. There are, however, reasons for believing that the chemical relationship of these substances is very close, inasmuch as it has been shown that the two are frequently found in combination and that under certain conditions amyloid may lose its specific reactions and become changed into hyalin. The formation of hyalin, similar to that of amyloid, in many cases partakes more of the nature of a *deposit* than a *true degeneration*.

The most characteristic staining reaction of hyalin is with acid fuchsin. This is best brought out by the methods of Van Gieson and Pianese. By means of this reaction it may be distinguished from amyloid, colloid, mucin, though its behavior with this stain is not always constant. The staining variations are, however, largely dependent upon the age and density of the hyaline substance, and the ease with which it is penetrated by the staining fluid. Recently formed hyalin stains light rose-red; old hyalin a very deep red when penetrated by the stain, but with Van Gieson's method it often stains yellowish, the acid fuchsin not having penetrated. It is very probable, however, that the hyaline changes in connective tissue are not identical, but represent a class of closely related conditions.

As in the case of amyloid, hyalin is most frequently found in the walls of blood-vessels, but differs from the former in being found in connective tissue without showing any relation to the vessels, particularly in the case of glandular stroma. Physiological hyalin occurs in large masses in ovarian corpora fibrosa, where it constitutes a normal formation in the process of obliteration of the corpus luteum. The formation of hyalin in the blood-vessels in old age is also to be regarded as of the nature of a physiological process. Under normal conditions the blood-vessels of the ovary are the first to show this change, and this organ at the menopause shows extensive hyaline change in the walls of its arterioles. A similar change is found at this time in the uterine vessels.

The pathological formation of hyalin may occur in apparently normal connective tissue, or in that altered by pathological processes, in newly formed connective tissue following inflammatory processes or that developing in tumors. Hyaline degeneration occurs most frequently in the walls of the blood-vessels, heart valves, endocardium, kidney glomeruli, lymph glands, splenic follicles, connective tissue of the thyroid, parotid, lachrymal and mammary glands, tunics of the testis, periosteum, bursæ and tendon sheaths. In the connective tissue of tumors it is of very frequent occurrence, particularly in the case of the endotheliomata of the serous glands and meninges. The reticulum of tubercles is often hyaline in character, and hyaline connective tissue is not infrequently formed about old tubercles, in old scars, granulomata, etc.

Hyaline change is rarely massive enough to be visible to the naked eye. When present to such an extent it is manifested by whitish, semitranslucent, hard and dense areas resembling scar tissue, replacing the normal structure. It is usually whiter and less translucent than amyloid. In blood-vessels showing much change the walls may be thickened, stiffened, and the lumen partially or wholly blocked. From the hard and dense character of the process hyaline degeneration is usually spoken of as sclerosis; in blood-vessels, either arterio- or phlebosclerosis.

Sclerosis of veins is not nearly so common as that of arteries, but is of quite constant occurrence in organs and tissues affected by chronic inflammatory processes. The sclerosis of arteries may be considered pathological when it occurs at an early age or to an excessive degree. The small arterioles of the splenic follicles, kidney glomeruli, brain and spinal cord, and the intima of the larger arteries are particularly subject to hyaline change. In many cases the hyaline substance is formed immediately beneath the endothelium in a manner similar to that of amyloid; in other cases there is first a proliferation of connective tissue beneath the endothelium, the new tissue gradually losing its nuclei and becoming converted into hyalin. Not infrequently the formation of hyalin takes place only in the outer coat of the vessel. The small arterioles of the splenic follicles and the kidney glomeruli are often the first vessels in the body to show sclerotic change. The extent and location of this change are, however, very variable; in some cases it may be confined to the coronary arteries, while in others the small arterioles of the central nervous system may alone be affected.

The connective tissue of fibromyomata very often undergoes hyaline change. Similar processes occur in the endothelial tumors of the brain, meninges, and serous glands. In these tumors the chief part of the growth may sometimes consist of hyaline material. When formed into cylinders or columns about the vessels the tumor is designated a cylindroma. In the mixed endothelial tumors of the serous glands hyaline material is formed after the manner of a secretion on the part of the endothelial cells lining the lymph spaces. A similar formation of hyalin at the expense of the interstitial cells occurs in the connective tissue of the conjunctiva and thyroid. In the latter the formation of hyalin in large amounts causes atrophy and compression of the glandular elements, so that not infrequently there is but little functionating gland structure left, the entire organ becoming changed into a hyaline mass in which the glandular remains are with difficulty made out. The basement membrane of Bowman's capsule and of the acini of the mammary gland, as well as that of the tubules of kidney and testis under certain conditions, becomes hyaline. Atrophy of the parenchyma usually follows this change. Hyaline glomerular scars (obliterated glomeruli) are almost constantly found in the kidneys as the result of the destruction of the glomerular parenchyma; a similar sclerosis of the areas of Langerhans in the pancreas may occur in association with advanced general arteriosclerosis.

Fibrinous exudates upon serous membranes may become organized and the newly formed connective tissue suffer hyaline change. Such hyaline formations are not infrequently seen upon the surface of the spleen, liver, pericardium (so-called soldier or milk spots), and pleura. Old pleuritic and pericardial adhesions may be entirely composed of hyaline material, all cells having disappeared. The hyaline bodies called rice bodies or corpuscula oryzoidea found in pathological conditions of the tendon sheaths and bursæ are for the greater part composed of loosened masses of organized fibrin which have undergone hyaline change. In cirrhosis of the liver and in chronic nephritis the new connective tissue frequently is hyaline in character. Old infarct scars show a like change. After complete organization of obturating thrombi, blood-vessels may become replaced by hyaline cords. Similarly in chronic obliterative appendicitis the appendix may become changed into a hyaline cylinder in which even all traces of the muscle coats may have disappeared.

In lymphatic glands large masses of hyalin are frequently found, particularly in the atrophic glands of old age, or in association with chronic inflammatory processes. Here the change seems to be more of the nature of a deposit or infiltration. Large deposits of hyalin occur also in the hæmolymph glands. Rarely, a progressive hyaline degeneration of many organs occurs—heart, vessels, serous membranes, spleen, lymph glands, intestinal wall, etc.,—involving these either simultaneously or one after the other. In these cases portions of the hyaline substance may give an amyloid reaction. From this it may be inferred that there is a form of hyaline degeneration which is closely related to amyloid.

Of the nature of hyalin practically nothing is known. The disappearance of the nuclei, the subsequent retrograde changes in the hyaline substance, and its sequestration from normal tissue stamp the process as being essentially degenerative in character. The causes of the thickening and homogeneous transformation are entirely obscure. It has been believed by some writers to be due to a coagulation of proteid material after the death of the cells, or that it is due to a local disturbance of metabolism. According to the latter theory the cells are unable to make use of the proteid material brought to them; this becomes precipitated or infiltrated into the interstitial substance. The cells are thus pushed apart, and gradually atrophy. In many cases the formation of hyalin just beneath the endothelium of the blood-vessels points, as in the case of amyloid, to a secretory action on the part of these cells in removing certain substances from the blood. In the cylindroma and also in the mixed endotheliomata of the parotid, the formation of hyalin appears to be due partly to a secretory action on the part of the tumor cells and partly to a degeneration of these cells. In the case of the lymphatic glands the appearances more often suggest a deposit than a degenerative process. While not bearing the same relation to tuberculosis, chronic suppurations, etc., that amyloid does, hyaline degeneration is most frequently associated with chronic intoxications. Syphilis, lead poisoning, alcoholism, over-eating, etc., are conditions favoring or leading directly to hyaline change in the blood-vessels. It is probable that hyaline material can be reconverted, absorbed, or removed. The corpora fibrosa of the ovary undergo contraction and decrease of size until they come to consist of a narrow line of hyalin only. Further, hyalin is very unstable, being frequently calcified, converted into myxomatous tissue, or undergoes complete disintegration. The hyalin of sclerotic vessels frequently suffers a fatty change with later formation of cholesterin. The effects of hyaline change upon the tissues are similar to those of amyloid.

Hyaline Bodies.—In this connection should be considered also the so-called hyaline bodies (fuchsinophile bodies, Russell's bodies, etc.) which are frequently found in normal tissues as well as in a great variety of pathological processes. They are globular, hyaline bodies of varying size, often occurring in mulberry-like conglomerations. They may be found both within cells and free in the stroma. With acid fuchsin they stain red, and with Weigert's fibrin-stain a deep blue. They are found particularly in glandular proliferations of the stomach mucosa, chronic inflammatory processes, lymphadenoid tissue, and in malignant tumors. They may occur in either epithelial or mesoblastic cells. Their frequent presence in malignant tumors has led them to be regarded as parasites, either blastomycetes or protozoa. They are almost constantly present in the hæmolymph glands where they undoubtedly represent products of the disintegration of red blood cells. In pernicious anæmia phagocytes filled with these bodies are found in large numbers in these glands. Many of the bodies give an iron reaction. In other cases the granules may arise from the oxyphile and basophile granules, the process partaking of the nature of a coagulation. The exact chemical nature of hyaline bodies is not known.

The hyaline bodies found in the central nervous system are more closely related to colloid and the corpora amylacea. Under certain conditions in gliomata arising from the spinal cord glistening hyaline masses are formed from degenerating glia cells. The condition is known as *degeneratio micans*. In other varieties of tumors arising from the central nervous system, hyaline masses staining red with fuchsin are frequently found. In the majority of cases they are probably obliterated blood-vessels that have become hyaline. *Aldred Scott Warthin.*

HYDRACETIN.—*Acetyl-phenyl-hydrazin,* C_6H_5, NH,-NHC_2H_3O. Hydracetin is a derivative of hydrazin in which two atoms of hydrogen are replaced by the phenyl and acetyl groups. It differs from acetanilid only by the presence of an imido group (NH). *Pyrodin* of commerce is an impure form.

Hydracetin occurs as a white, odorless, and almost tasteless, crystalline powder. It is soluble in fifty parts of cold water, more soluble in hot water, and very soluble in alcohol. Dose, from one-sixth to three-quarters of a grain. It was brought to the notice of the profession by Saltman (*Pharm. Central.*, May 16th, 1889) as an antipyretic and analgesic. It was thought to be of much service in rheumatic fever, phthisis, and typhoid fever. Its employment has not become general owing to its intense action and the frequency of toxic symptoms. It is a very decided blood poison, exerting a destructive action on the corpuscles and giving rise to hæmoglobinuria. Seven and a half grains are sufficient to kill a rabbit. It produces marked depression, coldness of the extremities, cold sweating, and enfeebled respiration and pulse. A ten-per-cent. ointment has been used for psoriasis and other skin diseases, its value being due to its reducing power, but this has also caused toxic symptoms (*Lancet*, 1890, ii., 38). *Beaumont Small.*

HYDRAMNION, HYDRAMNIOS.—The normal quantity of amniotic fluid at full term is from 400 to 1,000 c.c. An excessive accumulation of this fluid is known as hydramnion; ten to fifteen times the normal amount may be present. A slight excess is probably of frequent occurrence, and passes unnoticed, but an increase over 2 litres is very likely to give rise to symptoms. In the majority of cases the formation of the fluid is slow at first, but toward the end of pregnancy it increases at a more rapid rate. Occasionally the fluid may accumulate very rapidly, giving rise to serious symptoms from the sudden distention of the uterus (acute hydramnion). The condition is said to occur in one of every one hundred cases of pregnancy. It usually develops in the fourth to sixth month. Hydramnion in itself is not a disease, but is to be regarded as a secondary condition to many widely differing processes, both of the fœtus and the mother.

No constant pathological changes in the amnion itself have been found in this condition; fissuring of the epithelial layer, fatty degeneration of the epithelial cells, etc., have been described. Hypertrophy of the decidua and hyperplasia of the chorionic villi have also been found in cases of hydramnion, but the connection between these conditions has not been proved. Neither physiological nor chemical investigations as to the composition of the fluid, have yielded positive information as to its source.

The etiology of hydramnion is in many cases obscure. Inasmuch as the question of the origin of the normal amniotic fluid remains unsettled, we are not yet in a position to solve the more complicated problem of the manner of formation of the fluid under pathological conditions. The view most generally held at the present time that the normal fluid is the product of both fœtal and maternal structures is borne out by the fact that hydramnion is produced by or at least accompanies pathological changes in both mother and fœtus. We may therefore distinguish two classes of hydramnion, one of fœtal origin, the other of maternal.

Hydramnion of Maternal Origin.—Hydramnion due to pathological conditions of the mother is of much less frequent occurrence than that associated with diseased processes of the fœtus. It occurs particularly in anæmic, dropsical, tuberculous, leukæmic, and syphilitic women. In pneumonia, hepatic cirrhosis, failure of compensation in valvular lesions, and all other conditions leading to venous stagnation in the maternal body, hydramnion may occur. In such cases the condition is usually chronic, but acute heart failure with sudden development of ascites or general œdema may lead to an acute hydramnion. Loss of tone of the uterine wall is also said to favor the production of an excessive amount of amniotic fluid. Hydramnion is very likely to recur in successive pregnancies of the same individual.

Hydramnion of Fœtal Origin.—Hydramnion occurs frequently in connection with ascites and general œdema of the fœtus caused by cardiac and renal disease, and syphilis of the lungs and liver; less commonly in cases of obstruction of the ductus Botalli, stenosis of the umbilical vein, twisting of the cord, velamentous insertion of the cord, fœtal tumors interfering with the circulation, tumors of the placenta, placental hypertrophy, hydrocephalus, anencephalus, etc. In general, any condition raising the blood pressure in the umbilical vein and placenta may give rise to hydramnion.

Hydramnion has also been explained as being due to a persistence of the vasa propria of Jungbluth, but the presence of these vessels in the late stages of pregnancy is considered by some writers to be secondary to an increase of blood pressure in the umbilical vein. Excessive urinary secretion in fœtal diabetes and cardiac hypertrophy, increased activity of the fœtal skin, serous inflammations of the amnion, deficient absorption of the amniotic fluid, and increased activity of the chorion are other causes assigned by various authors. Both fœtus and mother may under rare conditions contribute to the formation of the increased amount of fluid. This occurs most frequently in cases of syphilis of both mother and child when both are dropsical.

A more recent theory for the explanation of hydramnion is based upon the hypothesis that there is in the fœtal blood a substance which causes an increased passage of fluid from the maternal vessels to those of the chorion, so that the fœtus becomes plethoric. As a result of the plethora the heart's action is increased, and this in turn leads to increased urinary secretion. The lymph-forming substance, being excreted in the urine, passes into the amniotic fluid. When the latter is swallowed by the fœtus the substance is again absorbed into the fœtal blood and a vicious circle is thus set up. This hypothetical substance in the end produces toxic effects upon the liver and kidneys leading to fœtal dropsy.

Hydramnion is not infrequently associated with unioval twin pregnancy, in that in the case of one fœtus there is a normal or lessened amount of amniotic fluid while in the case of the other there is hydramnion and hypertrophy of the fœtal organs. This has been explained in various ways, but none of the theories presented is adequate. According to Küstner one of the twins receives more abundant nourishment than the other, and this over-nutrition leads to increased heart action and resulting cardiac hypertrophy. Increased urinary secretion into the amniotic sac consequently follows and causes an increase in the amniotic fluid. Ultimately insufficiency of the heart occurs with venous stasis and liver cirrhosis, both of which factors add to the hydramnion already existing. According to Schatz one fœtus transfuses more blood into the circulation of its twin than the latter gives back to it, whereby the heart of the latter becomes hypertrophic and increased urinary secretion follows. Against both of these theories may be raised the objection that in the circulation of the twins a condition of equilibrium must ultimately be reached so that in one case blood must transfuse from the circulation of the stronger to that of the weaker; and in the other, as soon as the hypertrophic heart becomes insufficient, the normal heart of the weaker fœtus must act relatively with much greater strength than the insufficient hypertrophic one. In the case of twins arising from two ova either one or both sacs may become hydramniotic.

SYMPTOMS.—In acute hydramnion the sudden distention of the uterus causes intense pain, and there are extreme dyspnœa, cyanosis, frequent and severe vomiting and fever. In chronic hydramnion the symptoms are very much like those of cystic ovarian tumors. As the uterus becomes more and more distended it may give rise to pressure symptoms, dyspnœa, pain in the sides, œdema of legs and genitals, varices, etc. In cases of very gradual development the uterus may attain a very large size without causing much discomfort.

PROGNOSIS.—The pressure symptoms may be so severe as to endanger life, but inasmuch as the process may be controlled by the production of abortion the prognosis, in so far as the mother is concerned, is a favorable one. In the majority of cases the fœtus is either under-developed or malformed, only about one-third of the children surviving. Hydramnion of moderate degree may produce no symptoms and does not endanger either fœtus or mother.

TREATMENT.—Against the formation of hydramnion there are no therapeutic measures of avail. When the fluid accumulates in such large quantity or so rapidly as to produce serious symptoms, relief by evacuation is indicated. This is accomplished by rupturing or puncturing the membranes and allowing the amniotic fluid to escape. Premature labor usually follows this procedure and the fœtus, in case it has not reached a viable age, is lost. In the mild cases no treatment is necessary, but it is to be remembered that in such cases abnormal presentations of the fœtus are of frequent occurrence.

Aldred Scott Warthin.

HYDRANGEA.—"Seven Barks." The dried root of *Hydrangea arborescens* L. (fam. *Saxifragaceæ*). This is a medium-sized shrub with softish stems, opposite, glabrous, ovate, serrate, bright green leaves, and flattish cymes of greenish flowers. It is a native of the middle, and especially of the southern United States. The root is very much and crookedly branched, from a knotty crown an inch or two in diameter, and is usually cut into pieces from one to several inches in length before marketing. The largest of these roots are usually of about the thickness of the little finger. The color is a very pale grayish-yellow, with rusty yellow patches and streaks, but the bark has a great tendency to peel off, leaving the nearly white, very smooth wood exposed. The wood is light, tough, and splintery, and is tasteless and inactive. The bark is first sweetish and feebly aromatic, then slightly acrid.

It contains starch, a little resin, saponin, and a crystalline glucoside (hydrangin, $\frac{1}{10}$ per cent.). It has had some employment in urinary disorders, especially those accompanying "gravelly deposits," and is mildly diuretic. Dose from 2 to 4 gm. (gr. xxx. ad ʒ i.).

Henry H. Rusby.

HYDRASTIS.—GOLDEN SEAL. "The rhizome and roots of *Hydrastis canadensis* Linné (natural order, *Ranunculaceæ*)." (U. S. P.).

The *Hydrastis canadensis* is a small herbaceous perennial plant with an erect, simple, pubescent stem, from six inches to one foot in height. There are usually but two leaves, one at the top of the stem, the other attached a short distance below. The leaves are pubescent, roundish, generally five-lobed. The flower is solitary and rises from the base of the upper leaf. It is whitish or purplish and consists of a colored calyx which falls very shortly after the flower expands. The fruit is a globose, compound berry, somewhat resembling a raspberry. The rhizome is of oblique growth, 2.5 to near 5 cm. (1 to nearly 2 in.) long, and 0.5 to 1 cm. ($\frac{1}{5}$ to $\frac{2}{5}$ in.) thick, cylindraceous, usually with a few short branches longitudinally wrinkled, but plump, somewhat annulate, externally brownish-gray, often with a yellow tinge or yellowish patches; fracture short and sharp, waxy, golden-yellow or bright reddish-yellow, with a thickish bark, about ten short and narrow wood wedges and broad medullary rays; roots, if present, rather coarse, brittle, with a thick bark and somewhat quadrangular wood; odor slight, characteristic; taste very bitter, but not disagreeable, producing a somewhat astringent effect.

The plant is indigenous to North America and grows abundantly in the north and west of the United States and Canada. Only one other species of hydrastis is known, *H. Jezœnsis* Sieb., which is found in Japan.

The therapeutic properties of hydrastis depend upon the active principle *hydrastine*, which is separated in white crystals, without odor or taste, and insoluble in water. With acids it forms salts which are freely soluble in water. Much trouble has arisen from the confusing of this name with *hydrastin*, an "eclectic" extract, which is made up of the various alkaloids and resin, and is many times weaker. It is a yellowish powder. *Hydrastinine* is an artificial alkaloid formed by the oxidation of hydrastine, which breaks up into hydrastinine and opianic acid. The hydrochlorate is official in the United States Pharmacopœia, and occurs as light yellow, amorphous granules, or as a pale yellow, crystalline powder, odorless, but with a bitter, saline taste. It deliquesces upon exposure and is very soluble. *Berberine* is also present and the tonic properties of the plant are, in a manner, due to its action.

Hydrastis exercises, both locally and after absorption, an action upon the system which is beneficial in all states of congestion and hyperæmia. The results of physiological experiments with hydrastine show that it increases the activity of the nerve centres. Both the sensory and motor functions are stimulated and reflex action becomes very marked. The tone of all muscular tissues is particularly raised, the striped, unstriped, and cardiac cells being influenced, as a result of which effect there is produced an acceleration of the heart's action and of the circulation throughout all tissues. A like effect is manifested upon the uterine tissue, and this effect, if the uterus is in the pregnant state, may prove sufficient to cause abortion. There is also produced an increased activity in all the secreting organs, the flow of saliva, bile and other intestinal secretions being greatly augmented. The urine is also increased, and the alkaloid may be detected in the urine within twenty-five minutes of its hypodermic injection.

In excessive doses the action of the drug somewhat resembles that of strychnine. There are excessive motor activity with cardiac distress, and convulsions which may prove fatal. In the latter event death results from extreme depression followed by respiratory failure. In a case reported[1] two doses of twenty drops of the liquid extract produced most alarming cardiac distress in a case of bronchitis with copious expectoration. The lethal dose is given by Cerna as 0.5 gm. for each kilogram of body weight.[2] Phillips and Pembrey[3] during experimental work upon animals found that death followed 15.4 grains when given to a full-grown cat.

The action exerted upon the blood-vessels has led to its employment as an hæmostatic. Attention was directed to its use for this purpose, in Germany, in 1883, by Dr. Schatz, at a meeting of the Association of Physicians and Naturalists. He reported decidedly in its favor for the treatment of chronic hyperæmia and chronic inflammation of the internal genital organs attended by losses of blood. Since that time it has been extensively employed with very general satisfaction. In menorrhagia and metrorrhagia without organic disease, as in the various forms of metritis and endometritis, it is said to check the flow more rapidly than any other remedy. In the hemorrhages occurring at the climacteric, and the excessive menstruation of young girls in which the tissues are relaxed and congested, it has proved itself particularly useful. It also relieves all conditions of congestion of the pelvic organs, ovarian pains, dysmenorrhœa, and other distressing symptoms arising from this cause. Its effect when the hemorrhage is due to myomata appears to be uncertain, some observers claiming for it decided curative properties, while others have failed to derive any benefit from its employment. It should be administered with care during pregnancy on account of its tendency to provoke abortion, although many claim to have used it without any ill effect. One of the earliest applications of hydrastis was as a cardiac tonic, and its effect upon the heart makes its action very similar to that of digitalis. It is not equal to the older drug, but has been found very serviceable when a change from digitalis is necessary.

As a local remedy hydrastis exerts a marked action upon mucous membranes whenever altered by local congestion. It is astringent and tonic, lessening the congestion, and promoting a freer and better circulation in the part. It is employed in all catarrhal conditions of the vagina, urethra, rectum, nose and pharynx, in their subacute or chronic stages. It also exercises the same local effect upon the mucous membrane of the stomach and bowels when administered internally, and has proved of benefit in all catarrhal conditions of these organs, its local action being assisted by the increased secretions of the liver and other intestinal secretions. In hemorrhoids it is thought to act with much advantage.

The fluid extract is the preparation looked upon with most favor for local use. When diluted with water it makes an undesirable-looking mixture, but it offers the advantage of depositing the insoluble resinous material directly upon the mucous surface, which is considered most necessary if its full effect is to be secured. The strength of the solution should be from ten minims to two drachms to the ounce. For rectal and vaginal use it may be applied in the form of suppositories. For internal use the dose is from one-half to one fluidrachm.

Hydrastine has been used as a wash, in the strength of two to five grains to the ounce, as a substitute for the extract, but has not proved as serviceable. For internal use it is to be preferred, as it possesses the hæmostatic and tonic action of the drug, and is of a more definite strength. The dose is from one-eighth to one-half grain, and may be given in all conditions in which hydrastis is indicated.

The eclectic remedy, hydrastin, has been employed for many years as a stomachic, tonic, and antiperiodic, but is never used for any hæmostatic action.

Hydrastinine hydrochlorate is probably the most desirable preparation for internal administration. It acts rapidly, and reports indicate that its action is more trustworthy than is that of hydrastine or the fluid extract. The dose is from one-half of a grain to one grain and a half, every three to six hours. It may also be given hypodermically in a ten-per-cent. solution in distilled water.

Beaumont Small.

HYDRIODIC ACID.—Hydriodic acid (HI) is a gaseous body, freely soluble in water. The aqueous solution, however, is very unstable, constantly tending to disengage free iodine. Accordingly the United States Pharmacopœia makes official *Syrupus Acidi Hydriodici*, Syrup of Hydriodic Acid, wherein the acid is preserved from change by the presence of sugar. The syrup is clear and colorless, or slightly straw-colored, and contains one per cent., by weight, of absolute hydriodic acid. It has a sweet, acidulous taste.

Syrup of hydriodic acid has similar general properties to the other diluted sour mineral acids (see *Sulphuric Acid*), but its special employment in medicine is, because of the iodine of its composition, as a substitute for the alkaline iodides. It seems beyond question to possess the general medicinal properties of the iodides, and may be given in doses of from one-half to one teaspoonful, well diluted, several times daily. *Edward Curtis.*

HYDROA VACCINIFORME.—This affection was first described by Bazin in 1855, but for a long time thereafter was generally lost sight of. In 1888 Hutchinson described what is undoubtedly the same affection, under the title "summer eruption." A year later, Handford published in the *Illustrated Medical News* a series of cases which he proved were identical in nature with both Hutchinson's summer eruption and Bazin's hydroa vacciniforme. Since then numerous cases have been reported by English, German, and American writers, and it has been shown that the disease, although rare, is not so uncommon as had been supposed. In France, strangely enough, the affection escaped recognition after Bazin's original description, but of late it has been again described by Brocq and others.

The affection usually begins in the first years of life and has been found to be much more frequent in the male sex. The parts of the body chiefly affected are those that are unprotected and exposed to the rays of the sun, although in a number of instances it has been seen on other parts as well. The bridge of the nose, the cheeks, and the ears are most prominently affected, and next in order come the backs of the hands. Other parts of the body, if exposed to the sun, will be equally affected, as in one instance in which it appeared on the legs of a boy who went about with trousers rolled up. In a case seen by the writer, however, no lesions ever appeared on the lower extremities, although the child went barefoot during the summer. The affection comes in attacks, usually in the summer season and on exposure to the sun, although this cannot be laid down as an absolute rule, as in some instances there have been quite numerous attacks in winter. There is no itching, as a rule, yet in one of the writer's cases it was marked.

At the outset of an attack there may be slight constitutional disturbance. The first appearances are either vesicles or small red papules which rapidly become transformed into vesicles and bullæ of varying size and which often become confluent. A marked feature, which has given the affection a part of its title, is the umbilication that occurs in many of the lesions, so that a vaccination vesicle is closely simulated. The depressed centre is usually surrounded by a ring of fluid, while there is a red areola at the periphery. The centre is dark blue or black, due to the hemorrhagic and necrotic condition of the corium, which is seen through the overlying vesicle. The lesions frequently become purulent. As a rule the attacks last several weeks, but may be much prolonged by exacerbations. The centre of the lesions dries into a thick, black crust, extremely adherent, and which finally on dropping off leaves a distinct pit. In many of the cases the scarring is quite severe, and reminds one forcibly of that left by a severe variola. The tip of the nose and the edges of the outer ear are in some cases much deformed. The attacks become milder and less frequent toward puberty and usually cease by the time adult life is reached.

Histologically, according to the writer's examination, which has since been essentially confirmed by Mibelli, the small primary vesicle is shown to have its seat in the middle layers of the rete Malpighii. The upper portion of the rete is somewhat reticulated, but the fluid divides the middle from the upper layers so that a large chamber without network is produced. In the fully developed lesion, with dark umbilicated centre, there is found a necrosis of the central portion of the nodule. The outer horny layer is unbroken and stains well, while the lower horny layers have become necrotic. The middle and lower layers of the rete are converted into a reticular tissue, forming a network filled with granular detritus and leucocytes, and this network has become necrotic. This necrosis extends downward through the entire corium, ceasing just above the subcutaneous tissue. The corium has a distinctly abnormal appearance, the connective-tissue cells having lost in great part their capacity for receiving stains. The connective-tissue fibres are broken up and forced apart and contain in their interstices deeply staining granules and detritus. In the papillary layer are large necrotic blood-vessels filled with blood cells, together with some free hemorrhage into the tissue. The necrosis ceases abruptly at the sides and base of the lesion. There is some increase in thickness of the epidermis adjacent to the necrotic portion.

From these appearances it is seen that the disease begins with an inflammation in the rete and upper portion of the corium in a circumscribed area, and quickly produces a vesicle in the rete. Immediately after this a necrosis sets in, which affects the epidermis and almost the entire corium. The dilated and necrotic blood-vessels can be seen through the transparent vesicular covering, and give rise to the dark red hemorrhagic centre seen clinically.

The cause of this peculiar dermatosis is unknown. The most plausible theory is that of a vaso-motor neurosis, which in certain individuals causes, when they are exposed to the sun's rays, a circumscribed inflammation followed by necrosis.

White has described several instances which probably belong in this group, which presented some unusual features, so that it seems probable that the classical description ought to be enlarged somewhat. The exceptional features in these cases were the cessation of all activity during the warm months for ten consecutive years in one case, the continuance of the attacks throughout the whole year in another, together with failure to be influenced by exposure to sun or weather, and an extensive distribution of lesions covering a large portion of the body, instead of a limitation to the portions exposed to the influence of the sun. The lesions in these cases were also very large, and the scars left very prominent and disfiguring.

Dr. McCall Anderson has recently (1898) published two cases of this disease in brothers, in which the urine contained hæmatoporphyrin. In the other cases in which this symptom has been looked for it has not existed.

It is very difficult to classify hydroa vacciniforme, although there are several affections which seem to be somewhat related to it. Boeck's acne necrotica has numerous points in common with the affection we are considering, such as the circumscribed necrosis, the umbilication, and the enlargement of the blood-vessels with hemorrhage. The histological appearances in a case reported by Touton were also similar. It is still a matter of discussion whether acne necrotica and acne varioliformis are the same disease, so that the relationship of hydroa vacciniforme and acne varioliformis is also indicated. We have also a peculiar congenital bullous dermatitis, first described by Hallopeau and characterized often by the persistence of scars and epidermic cysts, which offers some analogy to hydroa vacciniforme, chiefly in the repeated occurrence of bullæ followed by scars and the fact that a favorite but by no means exclusive seat is the head and the backs of the hands. It may also sometimes be excited by the action of the sun.

It is possible that the chemical rays of the sun may play some part in this affection as they have been supposed to do in eczema solare, etc. Hutchinson has described cases of recurrent papular, pruriginous, and eczematous eruptions occurring chiefly on the exposed parts of the body during the summer months. Hence we have evidence that the sun's rays may cause not only superficial inflammatory cutaneous changes, but deep sharply bounded necroses.

TREATMENT.—The importance of prophylaxis is apparent—to guard the patient from the sun's rays, or from wind and storm. Protecting and soothing applications are indicated when the eruption is active. Veils of red and turmeric, which are supposed to neutralize the chemical rays, have been recommended by Unna in eczema solare and may be employed in this affection. Crocker recommends the trial of arsenic, quinine, and belladonna internally. *John T. Bowen.*

HYDROBROMIC ACID.—Hydrobromic acid, HBr, is a gaseous body which, in ten-per-cent. aqueous solution, constitutes the preparation official in the United States

Pharmacopœia under the title *Acidum Hydrobromicum Dilutum*, Diluted Hydrobromic Acid. This preparation is "a clear, colorless liquid, odorless, and having a strongly acid taste. Specific gravity about 1.077 at 15° C. (59° F.). Miscible, in all proportions, with water and alcohol. By heat it is completely volatilized "(U. S. P.).

Diluted hydrobromic acid ranks among the sour mineral acids, and is perfectly competent to fulfil the purposes described under diluted sulphuric acid. Its special application in medicine, however, is not the utilization of its sour qualities, but its employment on the one hand as a *bromide*, in substitution for the alkaline bromide salts, and on the other as a vehicle for quinine, claimed to lessen the disagreeable by-effects of the alkaloid, while not interfering with the medicinal activities of the same. As a bromide-bearing medicine, the diluted hydrobromic acid has proved itself efficient if given in adequate dose, and to have less tendency than the bromides to produce acne and the other symptoms of bromism. In using the acid for its bromine influence, its comparatively feeble strength must be borne in mind, and the dose made to correspond, in proportion of bromine represented, to the average dose of the alkaline bromides. This correspondence is no less than about seven to one, so that it takes nearly seven parts of the pharmacopœial acid to equal, in bromine strength, one part of potassium bromide. To get, therefore, the bromine effect of the moderate daily allowance of 4 gm. (ʒ i.) of potassium bromide, from six to seven teaspoonfuls of the acid would require to be given. Such doses, however, are liable to irritate the stomach, and accordingly the medicine is used most commonly in association with some bromide salt, in cases in which a full bromine effect is wanted. The acid should be diluted, for administration, ten- or twelve-fold, and the mouth well rinsed after each dose. *Edward Curtis.*

HYDROCELE. See *Testes, etc.*

HYDROCEPHALUS, CHRONIC.—(Synonyms: Internal hydrocephalus; congenital hydrocephalus; hydrops ventriculorum cerebri.)

DEFINITION.—An affection which may be defined as an abnormal accumulation of serous fluid within the cerebral ventricles, tending gradually to increase in amount, and to give rise to undue pressure on the cranial contents; in infancy and early childhood leading also to gradual enlargement of the head with separation of the cranial bones.

The term *external* hydrocephalus is sometimes employed to denote an abnormal accumulation of fluid in the subarachnoid space. It is a condition only rarely met with, and either is secondary to cerebral hemorrhage or pachymeningitis, or is associated with a congenital atrophy or defect of the brain. The effusion in this case is of a passive character, and does not give rise to pressure symptoms.

ETIOLOGY.—In the great majority of cases hydrocephalus makes its appearance in early infancy; sometimes, however, it is congenital, and the enlarged head presents a serious obstacle to the birth of the infant. Out of one hundred and three cases collected by Ruffer, in nine the enlargement was present at birth, and in ninety-three it began before the patient was six months old. As this list does not include infants born dead or destroyed during labor to save the mother, it is not to be regarded as representing the absolute relative frequency of the two classes of cases.

Instances occasionally occur in which an abnormal accumulation of fluid in the ventricles makes its appearance in adult age. These cases, however, form but an insignificant percentage, and in them there is seldom any enlargement of the cranium or separation of its sutures.

Many explanations have been offered for the presence of fluid in such abnormally increased amount in the ventricles, but we are still much in the dark and for the present it is better to regard hydrocephalus as a mere symptom associated with, or consequent upon, certain diseased conditions rather than as a distinct disease.

It has been likened to ascites, an affection in which we meet with either a direct obstruction to the venous return of the blood or a chronic inflammation of the peritoneum, and in confirmation of this theory we were told that in some cases the fluid which distends the ventricles is clear, resembling transudation fluid found in other serous cavities, while in other cases it is turbid and contains fibrinous flakes and even pus. In the latter case the lining membrane of the ventricles will be found more or less thickened and its vessels distended. On this account Huguenin proposed to make the fluid itself the test as to whether the action was of a passive or of an inflammatory character. With increased knowledge, however, this comparison is not at present regarded as entirely satisfactory.

Many years ago Hilton advanced the theory that this affection was due to an obliteration by inflammation of the channels of communication between the fourth ventricle and the subarachnoid space interfering with the outflow of fluid from the ventricles of the brain, and in recent years this view has received much support. Halliburton (*Jour. Physiol.*, vol. x., p. 232) has demonstrated that normal cerebro-spinal fluid is a clear, colorless, faintly alkaline fluid with a specific gravity of about 1.005, and is to be regarded as a distinct secretion differing from the mere transudative fluids met with in other serous cavities, in the presence of a distinct copper-reducing agent, at one time thought to be sugar, but now regarded as pyrocatechin, and in the character of its proteids which he found to consist of globulin, albumose, and occasionally peptone, rarely of albumin and never of fibrinogen. More recently Vaughan Harley examined the fluid present in hydrocephalic cases and stated that in many it closely resembled cerebro-spinal fluid in its specific gravity and in its reactions. In others, however, indications of a distinctly inflammatory process were superadded, albumin was present, and the specific gravity had risen to 1.008 or 1.009.

Following out the thoughts suggested by these investigations, Drs. Barlow and Lees regard the choroid plexuses as a special apparatus for the secretion of the cerebro-spinal fluid, and in proof of their view point to the following facts: Each ventricle is provided with its own vascular plexus, those in the lateral ventricles having a double arterial supply indicating a function of special importance, and the epithelium of the ventricles, where it covers these plexuses, changes its character from columnar to one similar in structure to that of a secreting epithelium. From these plexuses a continuous secretion, they think, takes place of the bland fluid on which the delicate structures of both brain and spinal cord rest. As this secretion is constant, means must be provided for the removal of any excess, either by absorption or by drainage. Absorption through the plexuses would appear impossible, for the supply of blood in the arteries must be kept at a higher pressure than that of the ventricular fluid, else circulation would cease; and the veins are far withdrawn into the interior of the velum interpositum. To provide drainage, therefore, communication is provided from the lateral ventricles, through the third into the fourth ventricle by means of the several foramina; thence into the subarachnoid space through the foramina of Magendie and the lateral foramina, and along the lymphatic sheaths of all outgoing nerves. The small diameter of these passages insures that the outflow shall not be too rapid. The careful experiments of Key and Retzius would indicate that this is the only way of escape for fluid from the ventricles.

In what way is obliteration of these channels of communication brought about? In the opinion of these writers it is invariably the result of some inflammatory action and not infrequently of a previous attack of basic meningitis. Attacks of posterior basic meningitis, in their opinion, may occur at a very early period of infancy, and in some cases the symptoms may be of so indefinite a character as to be overlooked or forgotten.

In illustration the authors mention the following case: George A——, seen first when ten months old, with large hydrocephalic head; was an eight-months' child. When one week old had jaundice and frequent convulsions; at three weeks would not allow his head to be raised and was comfortable only when lying; at two months the head was observed to be abnormally large, and since then it has progressively increased in size. They state that in many cases of congenital hydrocephalus the post-mortem examination has revealed the presence of adhesions, evidently of inflammatory origin, blocking the channels of exit. In some of these cases constitutional vice, more especially syphilis, plays an important part. Dr. Lewis Smith referred many of his congenital cases to this cause, and a recent writer considers that the greater number of them are due to chronic inflammation of syphilitic origin.

In a small percentage of cases compression of the veins by a tumor, either in the cerebellum or in the neighborhood of the aqueduct of Sylvius, appears to play an important rôle. Drs. Barlow and Lees consider that mere compression of the veins, without blocking of the channels of exit, cannot by itself account for the accumulation. Both Gibson and Collins, however, within the past few years have reported cases in which a tumor pressing on the aqueduct of Sylvius was apparently the chief cause of the hydrocephalus.

Although an occlusion of these foramina of exit is the very frequent condition met with in hydrocephalus, a few instances have been reported in which this affection has existed, and yet the post-mortem examination, although revealing traces of what appears to have been a previous meningitis, has not shown the presence of any obstruction. No thoroughly satisfactory explanation of these cases has yet been given. Drs. Barlow and Lees advance the suggestion that owing to the previous inflammation a paretic dilatation of the basilar and its branches has taken place, leading to an augmented blood supply to the choroid plexus and, as a consequence, to a more rapid secretion of fluid than can escape through the foramina of exit.

As a very exceptional cause of hydrocephalus in the adult, we may mention the case reported by Kratz in which hemorrhage from an aneurism in the internal carotid artery closed the foramen of Magendie by causing an adhesion of the telea choroideæ to the floor of the fourth ventricle.

Morbid Anatomy.—The results of such an increasing intraventricular pressure will be modified by the amount of resistance presented by the cranial bones, and by the quantity of the fluid present. In congenital cases, and in those in which the hydrocephalus began soon after birth, the resistance offered by the sutures is slight, and great enlargement of the head may result. In these cases, the effusion may reach the amount of several pints. In the majority of instances, however, it does not exceed a pint. As a result of the pressure exerted by this fluid the cranial cavity is expanded in all directions, but the parts entering into the formation of the vault suffer most; the fontanels become prominent, the sutures are gradually opened, and the vertical plate of the frontal and the upper part of the squamous, parietal, and occipital bones are increased in size and become thin, even to the point of transparency. To the hand of the observer the head feels soft and fluctuating, and with electric light may be seen to be distinctly translucent.

The enlargement goes on slowly, but is not always continuous. Periods of quiescence may occur, during which nature may attempt to cover in the open places not only by new growth along the edges of the bones of the vault, but also by islets of new bony tissue which are occasionally found filling in the fontanels.

The bones at the base of the brain are seldom much affected. A few instances are reported in which the bones of the middle fossa have been displaced, and in extreme cases the orbital plates of the frontal bone are not infrequently depressed by the fluid, thus altering the direction and position of the eyeball.

Though the face in these cases looks small, on account of the enormous distention of the skull, Ruffer states that it will generally be found to be quite as large, if not larger than normal.

On the soft structures of the brain the effect of this pressure is disastrous, the convolutions become flattened, the sulci obliterated, and the cerebral substance owing to compression is gradually absorbed. This absorption and thinning is especially noticeable toward the vertex, where in extreme cases it may be found not more than a few lines in thickness. The lateral ventricles are enormously distended, their ependyma is thickened, and the choroid plexuses are engorged. The structures at the base of the brain suffer in general less than those of the cortex, but in advanced cases the large ganglia, the pons, and the cerebral peduncles are altered in shape and their nutrition is impaired.

A hydrocephalic cranium is always an unsymmetrical one; measurements show that one lateral half of the head is always larger than the other. Keen and Robinson have reported cases in which the hydrocephalus was partial and the distention limited to one side. In some the anterior half may be increased out of all proportion to the posterior, or vice versa, and instances are recorded in which the expansion has been limited to one or more bones.

Associated with congenital hydrocephalus it is not infrequent to meet with other vices of conformation. One of the most frequent is spina bifida. Among other deformities occasionally encountered are hare-lip, cleft palate, and the various forms of talipes.

Symptoms.—In some cases the first symptom to attract attention is the slow, gradual enlargement of the head, which may go on for some months before any indication of pressure on or irritation of the nerve ganglions makes its appearance. Bastien reported a case in which the head had gone on enlarging for eighteen months without the intervention of any other notable morbid symptom. In other cases, however, symptoms of irritation of the nerve centres are present from the very beginning and sometimes even precede the enlargement of the head. West states that in twelve out of forty-five cases, recurring convulsions were the earliest symptom; in four more the enlargement was preceded by other indications of irritation such as squinting, severe headache, and nystagmus. In a third class the affection begins with symptoms resembling cerebellar disease, and in a fourth class the symptoms are acute from the onset.

As the disease advances, however, the prominent feature in all becomes the gradually enlarging head, the fontanels, instead of closing, increase in size, the sutures open, and the head assumes more or less a spherical shape. The amount of the enlargement is indicated by two measurements: that of the maximum circumference, and that over the vertex from the centre of one auditory meatus to the centre of the other. As a guide to the amount of the enlargement the following average measurements obtained from the heads of eight healthy male infants may be taken:

	Circumference.	Over vertex. From meatus to meatus.
At birth	13½–14 in.	9 in.
At two months	15 –15½ in.	10 –10½ in.
At four months	16¼–17 in.	11 –11½ in.
At six months	17 –17¼ in.	11½–11⅞ in.
At twelve months	18 –18½ in.	12 –12½ in.
At two years	20 –20½ in.	13 –13½ in.

Owing to the enlargement of the bones of the vertex the face assumes a triangular appearance with the base at the forehead and the apex formed by the chin; the root of the nose is flattened and broadened, and the upper eyelids are stretched. The nutrition of the hair follicles suffers owing to the continuous tension of the scalp, and the hair becomes scanty, and through it can be seen the large veins ramifying over the scalp especially in the region of the temples.

While the enlargement of the head goes on, other symptoms show themselves. The general nutrition becomes defective even though the appetite may remain good and symptoms of indigestion be wanting. The development of the body is retarded, growth is stunted, and the muscular system becomes soft and poorly nourished. Efforts at walking are long delayed, and if at last the endeavor is made, the infant's gait is more than ordinarily tottering and uncertain. The increased weight of the head throws an abnormal strain on the poorly nourished muscles of the neck. In young infants the power to raise it from the pillow may be altogether lost and assistance may be required even to turn it. Older children frequently rest the head by supporting it with both hands.

Loss of control over the sphincters and complete paralysis are of rare occurrence. Sometimes at the onset of the affection a more or less spastic condition of the limbs may exist. Pain in the head is not an infrequent complaint, and judging by the moaning and crying of the child is often severe.

Clifford Allbutt regards ischæmia papillæ as an early symptom; nystagmus and strabismus are often seen in advanced cases. Blindness the result of complete atrophy is, however, infrequent. When depression of the orbital plates takes place, the direction of the eyeball is altered and more or less exophthalmos may be observed. Convulsions occur as an occasional symptom; in some instances they are limited to one side, but more frequently they are bilateral. Not uncommonly they are followed by a temporary paralysis.

As the disease progresses to its close symptoms of pressure become more manifest, drowsiness may set in, and finally coma, from which the child cannot be roused, may end the case. Hydrocephalic children, however, offer but a feeble resistance to infection, and death is more frequently due to intercurrent disease, such as pneumonia, bronchitis, intestinal catarrh, or to one of the eruptive fevers.

When the disease runs a prolonged course, all degrees of impairment of the mental powers may be met with, from slight backwardness to more or less complete idiocy. In nearly every case periods of remission are noticed. The cephalalgia seems to cease, general nutrition improves, and for the time the head ceases to enlarge. The duration of these periods varies much. Sometimes they are so prolonged that the anxious mother indulges the dream of permanent recovery. In a few instances this does appear actually to take place. The effusion remains stationary, the sutures ossify, and the fontanels close by means of additional plates of bone, while growth increases and nutrition improves in the trunk and the extremities. Such patients may live many years. Dr. Bright's patient, Cardinal, died at the age of twenty-nine. His mental faculties shortly before his death were said to be "very fair"; his memory was tolerable. He was able to read and write and was fond of society. A few cases are reported in which a spontaneous evacuation of a large quantity of watery fluid has taken place from the nose with immediate relief to the symptoms which may have become very grave. In one or two cases the relief has been permanent. In one case in which the child eventually died, a small passage conducting from the cranium to the ethmoid bone was found at the autopsy.

In *hydrocephalus of later years* the symptoms are very obscure. It would appear to be almost impossible to distinguish between it and other chronic affections of the brain. The enlargement of the head, which in the hydrocephalus of infancy makes the diagnosis comparatively easy, is in these cases absent. Among the symptoms that have been recorded are the following: vomiting, more or less persistent headache and slow pulse, numbness of the hands and feet, attacks of petit mal, strabismus, dilated and sluggish pupils, and optic neuritis. Unconsciousness sometimes supervenes suddenly and death takes place by coma. The post-mortem appearances are similar to those of the hydrocephalus of infancy, with the exception that the amount of fluid rarely exceeds eight or twelve ounces.

DURATION.—The duration of the disease is very variable. The course is sometimes a rapid one and fatal symptoms supervene in the course of a few months. Few congenital cases survive two years. Many cases in which the affection made its appearance in the later months of infancy or in early childhood live for four or six years.

PROGNOSIS.—The prognosis in this affection is necessarily very unfavorable, but if the quantity of fluid is not great and the tendency to accumulate has at no time been very active, it may happen that one of the periods of remission may be prolonged, the general nutrition may improve, and as the body grows the size of the head may become less disproportionate. Cases of permanent recovery are, however, extremely rare, and in some of them in later life symptoms of grave mental trouble develop. We should remember, however, that a few instances of complete and permanent recovery from the earlier stages of the disease have been recorded.

DIAGNOSIS.—In the absence of any enlargement of the head hydrocephalus cannot be diagnosed with certainty. On the other hand, when the head becomes distinctly enlarged, with widely separated sutures and open bulging fontanels, there can be no room for any uncertainty. When the head is only slightly enlarged and the sutures are not distinctly opened, it may be difficult to distinguish it from the enlarged head met with in rachitis. The following points may assist us: In rachitis the head is square rather than round, the vertex is flattened, the frontal eminences are prominent, but the frontal bones themselves are not bulging and the sutures are closed; there is no deviation in the direction of the eyeballs, and palpation fails to communicate any sense of fluctuation. In hypertrophy of the brain the increase is very gradual, the skull is firm and unyielding, and the enlargement is more marked at the vertex than elsewhere. Occasionally we have a thickening of the bones of the skull cap due to syphilis, but no great difficulty should be experienced in distinguishing this.

In hydrocephalus of adult life the diagnosis must always be extremely difficult. Martin Prince lays much importance upon the variation in the intensity of the symptoms from day to day in this affection as compared with their uniformity in cases of brain tumor.

TREATMENT.—In a disease such as this, in which the prognosis is so grave, it is impossible to speak with any confidence of the treatment by drugs. In congenital cases in which there is a distinct syphilitic history the administration of mercury and potassium iodide has in a few cases appeared to be of much service. Their administration should be commenced as early as possible and pushed energetically, and it is to be remembered that young children bear both of these drugs proportionately much better than do adults.

External compression of the skull by means of strips of adhesive plaster may in congenital cases produce some slight diminution in the circumference of the skull, but its employment without aspiration of some of the fluid appears to be irrational and is not free from danger. Aspiration of the lateral ventricles, if performed antiseptically and the fluid drawn off slowly with the head well depressed, is an operation which does not appear to be attended with much danger, and is one which in many cases will be followed by temporary improvement. With the infant under an anæsthetic a small trocar may be thrust downward and inward into one of the outer corners of the anterior fontanel, care being taken to avoid the longitudinal sinus. This little operation often gives good results in those cases in which the symptoms of compression are advancing rapidly, but have not existed for a long period, removing the tendency to convulsions, relieving pain, and leading to a general improvement of both bodily and mental functions. The chief dangers associated with it are the introduction of infectious material and the possibility of inducing a state of collapse, both of which may be avoided with care. After the aspiration it is well to use some compression over the vault. Ewart, of London, at the meeting of the British Medical Association (1901), advised the introduction of aseptic air into the ventricles at the same time that the fluid was drawn off. This he accomplished by the introduction of two cannulæ into the right sphenoparietal region, allowing the fluid to escape by the one, and permitting carefully filtered air to enter by the other. He claimed for this method a more complete evacuation of the ventricular fluid, and an avoidance of the danger resulting from the sudden and complete removal of pressure. In one of the cases which he reported he removed in ten separate tappings fluid amounting in all to eleven pints. At the time the report was made the condition of the child was greatly improved. Any such operation, however, rarely affords more than a temporary benefit.

Lumbar puncture, advocated in this affection some years ago by Quincke, has in a few cases appeared to be of some benefit, but it offers a hope of service only in those rare cases in which there is no blocking of the channels of exit. Considering the excellent temporary results obtained in many cases by aspiration during the past few years, efforts have been made by some surgeons to establish permanent drainage of the ventricles by establishing an artificial communication between them and the subarachnoid space. Sutherland and Cheyne report three cases in which a small opening was made in the dura, and one end of a number of strands of catgut tied together was passed into the ventricle while the other end was retained in the subdural space. The results, however, were unfortunate, although temporary improvement followed in two cases. Drs. Barlow and Lees, however, report one case treated in this way as a remarkable success.

More recently Mr. McAdam Eccles reports continuous improvement in a case on which he operated, using horse hair instead of catgut as a drain, passing one end of the strands under the dura mater and the other into the right lateral ventricle. The possibility of thus replacing the natural channels of exit from the ventricle into the cavity of the subarachnoid or even into the subcutaneous spaces appears, by the results obtained in these operations, to be feasible, and we are hopeful that with improved technique we may yet be able to do much in the way of relief for this very unfortunate class of cases.

HYDROCHLORIC ACID.—Muriatic Acid, HCl. Under the title *Acidum Hydrochloricum*, Hydrochloric Acid, the United States Pharmacopœia recognizes "a liquid composed of 31.9 per cent., by weight, of absolute hydrochloric acid, and 68.1 per cent. of water." Such grade of acid is "a colorless, fuming liquid, of a pungent odor, and an intensely acid taste. Specific gravity: about 1.163 at 15° C. (59° F.). Miscible, in all proportions, with water and alcohol" (U. S. P.). Hydrochloric acid must be kept in glass-stoppered bottles and protected from the light.

The physiological effects and therapeutic applications of hydrochloric acid so closely resemble those of nitric acid that a separate description is unnecessary (see *Nitric Acid*). For medicinal use, proper, the following official preparation is established by the United States Pharmacopœia:

Acidum Hydrochloricum Dilutum. Diluted Hydrochloric Acid.—This preparation is a simple dilution of the strong acid of the Pharmacopœia with distilled water. It represents ten per cent. of absolute hydrochloric acid, is a colorless and very sour fluid, irritant though not corrosive, and of the specific gravity 1.050. Dose, from ten to thirty drops, largely diluted with water, and the mouth to be rinsed well after the taking of each dose.

Edward Curtis.

HYDROCOTYLE. See *Umbelliferæ.*

HYDROCYANIC ACID.—Hydrocyanic, or, as it is so commonly called, *prussic* acid (HCN), is, in pure or anhydrous condition, a thin, colorless, very volatile, very unstable, and fearfully poisonous fluid. Being so unmanageable in the concentrated state, the acid is used in medicine only in dilute solution in water or in alcohol and water. In continental Europe solutions of various strengths are to be met with, ranging from two to twenty-five per cent. What is known as *Scheele's* acid is an aqueous solution from four to five per cent. in strength. Under the title *Acidum Hydrocyanicum Dilutum*, Diluted Hydrocyanic Acid, the United States Pharmacopœia establishes "a liquid composed of two per cent., by weight, of absolute hydrocyanic acid, and ninety-eight per cent. of water." This preparation is made by distilling a mixture of potassium ferrocyanide and diluted sulphuric acid, receiving the distillate in a receiver containing water. The product is finally brought to standard strength, as determined by assay, by the addition of distilled water. Diluted hydrocyanic acid may also be prepared extemporaneously by the following process, officially authorized: "Silver cyanide, 6 gm.; hydrochloric acid, 5 c.c.; distilled water, 55 c.c. Mix the hydrochloric acid with the distilled water, add the silver cyanide, and shake the whole together in a glass-stoppered bottle. When the precipitate has subsided, pour off the clear liquid." In this process double decomposition ensues between the silver cyanide and the hydrochloric acid, with the formation of hydrocyanic acid which remains in solution, and silver chloride which precipitates.

Diluted hydrocyanic acid is "a colorless liquid, of a characteristic odor and taste, resembling those of bitter almonds. As it is very poisonous, great care should be taken in tasting it. It is completely volatilized by heat" (U. S. P.). The acid is more or less prone to decompose, thereby losing strength, and in such decomposition commonly turns dark, even getting in time to look like a thin ink. This decomposition will certainly and rapidly go on under exposure to the air in an open vessel, and is also hastened by the action of light. The preparation must, therefore, be put up in small, dark, amber-colored vials and kept in a cool place protected from the light. An important point is to have the vials *cork*-stoppered, and not *glass*-stoppered, since, for some reason, the preparation deteriorates much faster in glass-stoppered bottles than in those closed by cork. The acid will keep better, furthermore, according to Squibb, if, in dispensing, quantities be drawn from the stock bottle by a pipette instead of by pouring.

Physiologically, hydrocyanic acid is remarkable for deranging, swiftly and strongly, the functions of nerve apparatus, apparently irritating and quickly exhausting certain nerve centres, and also tending to destroy the conducting power of nerves and the contractility of muscles generally. Probably by virtue of these actions, hydrocyanic acid is a peculiarly speedy and powerful poison. (See *Hydrocyanic Acid: Toxicology.*)

The application of hydrocyanic acid in *therapeutics* does not amount to much. By reason of its poisonous nature, the medicine can be used only in insignificant doses, and the only medicinal virtues that such doses possess are to allay pain or irritability of the stomach, and, less certainly, the irritability of the air passages in disease that leads to dry cough. The local use of hydrocyanic acid solutions as lotions in skin disease, to allay pain and itching, is not without danger of inducing constitutional poisoning by absorption through unobserved abrasions.

Hydrocyanic acid in the form of the dilute solution of the United States Pharmacopœia is commonly prescribed in doses of from two to four drops only, but there certainly is no danger in doses of 0.50 gm. (♏ vij. or viij.), and such doses are used by many practitioners. Furthermore, since the effect of the drug is very evanescent, and there is no evidence of any so-called cumulative action, there is no objection, physiologically, to the repetition of even a full dose so often as every hour. The dose may be administered in water, or syrup and water, and may be combined with alkaloidal salts, but not with salts of the metals. For a skin lotion, the pharmacopœial acid is variously diluted from ten- to fifty-fold by different practitioners.

Quite recently there has been published * an account of some interesting experiments by Jacques Loeb and Warren H. Lewis in the Hull Physiological Laboratory of the University of Chicago, on the prolongation of the life of the unfertilized eggs of sea-urchins by potassium cyanide. Ordinarily such eggs, kept in sea-water at a temperature of about 20° C., lose their power of development, on fertilization, in from twenty-three to forty-eight hours, or less. But if to the sea-water be added a certain percentage of potassium cyanide (one part of an "$\frac{n}{10}$" cyanide solution to 100 parts of sea-water), the time during which the capacity for fertilization persists is very materially lengthened—from one hundred and twelve to one hundred and sixty-eight hours, according to degree of development attainable. And such prolongation obtains for parthenogenetic as well as for sexual development. The experimenters account for these results by the theory that normal death of the unfertilized eggs is due to "specific mortal processes" which "are checked or modified by the process of sexual or osmotic fertilization," and which also may be checked by potassium cyanide, "which substitutes for the destructive action of these processes a condition of suspension of life ('vie latente' of Bernard)." *Edward Curtis.*

HYDROCYANIC ACID. (TOXICOLOGICAL.)—As the various cyanic poisons—hydrocyanic acid, the cyanids, impure oil of bitter almonds, cherry-laurel water, etc.—all owe their poisonous qualities to the presence in them, or liberation from them, by the action of the liquids of the economy, of hydrocyanic acid, their action is in the main the same. The rapidity of their action depends upon the proportion of hydrocyanic acid which they contain, and is modified somewhat in kind by the nature of the substance with which the acid is combined, as in the case of potassium cyanid.

Although Dioscorides casually mentions the poisonous nature of bitter almonds, and Madden, in 1731, called attention to the toxic powers of cherry-laurel water, the toxicological history of hydrocyanic acid itself begins with the year 1803, when its poisonous nature seems to have been first recognized by Schrader. The existence of the acid had been discovered twenty years earlier (1780) by Scheele, whose death has been frequently attributed to accidental inhalation of its vapor. It would seem, however, from the account given by Crell at the time (*Annalen,* 1787, i., 192) of Scheele's last illness, that his death was due to disease and not to poison.

According to Stillé, Borda (1804) first suggested the use of the artificially prepared hydrocyanic acid as a remedy in cases in which cherry-laurel water had been previously used. A few years later (Hufeland's *Journal,* 1813, p. 113) occurred the first case, of which we have been able to find record, of death of a human subject by the action of this poison. This was the case of a child who swallowed a quantity of the dilute acid which a physician had prescribed for the mother. Within the few succeeding years deaths occurring in a similar manner, from misadventure, or by reason of the varying degree of concentration of the medicinal acid used, became very numerous, and in consequence the drug fell into disrepute.

In more recent years the extensive use of the cyanids of potassium, silver, etc., in the processes of photography, electroplating, and gilding has placed these active poisons at the easy disposal of many, has led to numerous cases of poisoning through carelessness and misadventure, and has brought potassium cyanid into prominent notice as one of the most frequently employed of poisons.

The statistics of poisoning in different countries afford somewhat contradictory information as to the degree of frequency of the use of the cyanic poisons. Tardieu gives a table of criminal poisonings in France from 1851 to 1863, including 617 cases, of which there is none by the cyanic poisons. The Reports of the Registrar-General of Great Britain for 1863–67 include 2,350 poisonings from all causes, of which 151 were caused by hydrocyanic acid and potassium cyanid, a number only exceeded in the cases of laudanum and the salts of lead. During the same period there were 6,696 suicides, of which 673 were by poison, and of these the cyanic poisons head the list with 121 cases. Of 1,263 murders 19 were by poison, and of these, 5 were by laudanum and 4 by the cyanic poisons. Lesser gives a table of 431 cases of poisoning occurring in Berlin, from 1876 to 1882, of which 74 were by potassium cyanid and 12 by hydrocyanic acid, while the only substance which caused a greater number of deaths than the former is carbonic oxid, 185. In our own country statistics of poisonings are exceedingly meagre, and such as exist are valueless by reason of insufficient and inaccurate data.

Murder by the cyanic poisons does not seem to be frequently attempted. By suicides hydrocyanic acid is often the agent selected, because, probably, of its rapid action, while the facility with which potassium cyanid can be obtained by any one is a reason of its frequent use for the same purpose. Accidental poisonings by the cyanic poisons are the result of carelessness or ignorance. A solution of potassium cyanid has been hastily drunk in mistake for water. The same substance in the solid form, bought to clean brass buttons, has been swallowed in mistake for another solid purchased at the same time. Numerous poisonings by oil of bitter almonds used for flavoring articles of food are recorded. Instances of death or serious poisoning caused by the medicinal administration of hydrocyanic acid are by no means as infrequent as they should be. In several cases the intent of the physician has been called in question, and a trial for murder or manslaughter has resulted.

EXPERIMENTS ON ANIMALS.—*Method of Action.*—As in the great majority of cases in which the human subject has succumbed to the action of the cyanic poisons, the clinical history has reached the last chapter before, or shortly after, the arrival of the physician, what knowledge we possess concerning their mode of action has been derived mainly from experimentation. Unfortunately the experimental method has, in the hands of different observers, led to widely varying opinions regarding the mode of action of these poisons.

The following is the usual train of appearances following the administration of a lethal, yet not overwhelming dose of hydrocyanic acid to a warm-blooded animal: There is dyspnœa, beginning with a few hurried respiratory movements, the animal staggers and falls in a powerful tetanic spasm, with opisthotonus, during which the diaphragm is fixed in contraction; the pupils are dilated; the tongue and eyeballs protruding, the latter glassy; there is involuntary evacuation of urine and fæces; the pulse rapidly diminishes in force and frequency, and, if the dose be large, the animal dies without any further symptoms. If the animal do not die at this point, the muscles relax; the condition of tetanus passes into one of general paralysis, with total loss of reflex irritability; respiration is resumed, the expiratory acts being quite long and the inspiratory very short, and the intervals between the movements being very long. The pulse is irregular, frequent, and barely perceptible. If the animal recover, the respiration and pulse gradually return to the normal; if it die, the intervals between the respirations increase in length, the pulse becomes imperceptible. No further convulsive movements are observed, except, immediately preceding death, a single convulsive expiratory effort attended by a piercing cry or shriek.

That hydrocyanic acid destroys life by the disorders of respiration which it produces may be regarded as certain; but concerning the underlying causes of these disorders no such certainty can at present be said to exist.

---

* The American Journal of Physiology, January 1st, 1902.

Preyer, from a number of carefully conducted experiments, has concluded that hydrocyanic acid causes death by irritation of the peripheral branches of the vagus in the lungs and heart. In his experiments doses otherwise certainly lethal did not kill animals in which the vagi had been previously divided; and when animals so prepared were killed by larger doses of the poison, they did not die from suffocation, as they otherwise would have done, but from the paralyzing action of the poison upon the heart. Preyer has further shown, not only in his earlier experiments, but in others, made subsequently to the publication of Böhm's views (see below), that while rabbits and guinea-pigs were invariably killed by 0.2 c.c. of a two-per-cent. solution of hydrocyanic acid, they did not die, but recovered after more or less severe symptoms of poisoning, if the same dose was administered to them shortly after they had received hypodermatically 0.5 c.c. of a one-per-cent. solution of sulphate of atropin. Atropin having been shown to produce paralysis of the peripheral branches of the vagus, an antagonism of the two drugs is explainable on the supposition that hydrocyanic acid possesses the power of irritating those nerves.

Böhm not only does not substantiate the views of Preyer, but reaches very different conclusions, which he thus summarizes: "1. The action of hydrocyanic acid is upon the central nervous system, whose functions are destroyed by larger quantities after a short period of stimulation. 2. The disturbances of respiration and circulation have their origin in analogous modifications in the activity of their centres in the medulla oblongata. 3. The vagus plays no part whatever in the action of hydrocyanic acid upon the respiration or upon the heart. 4. Atropin is no antidote to hydrocyanic acid. The only rational method of treatment of this form of poisoning is in the early use of artificial respiration."

It may be said in support of the views of Preyer, as against those of Böhm, that, while the experiments of the former were performed upon rabbits or guinea-pigs in a condition as near the normal as possible, and free from restraint, those of the latter were conducted upon cats, confined in the dorsal position, upon which tracheotomy had been performed, the jugular vein being in communication with a cardiograph, and which had been narcotized with varying quantities of chloral. Certainly the conditions of Preyer's experiments were the more likely to afford evidence of the normal action of the poison.

Amory differs from both Böhm and Preyer. He holds that artificial respiration neither prevents poisoning by hydrocyanic acid nor materially aids its elimination, although it may prevent the occurrence of convulsions or muscular spasm; that muscular irritability and nervous conduction are not impaired by hydrocyanic acid, if artificial respiration have been maintained, until after cessation of cardiac pulsations; that death from hydrocyanic acid is due to some other cause than asphyxia, "and it may be suggested that the fundamental cause is a state of blood-poisoning, due to some alteration either of the physical or the chemical condition of the blood."

The last sentence of Amory, quoted above, expresses a view which is conceded by Preyer, Böhm, and all other observers, that whatever may be the action upon any portion of the nervous system, a distinct change in the chemical composition of the blood occurs in poisoning by hydrocyanic acid. Upon this point much light has been shed by the observations of Preyer, Hoppe-Seyler, and Gaethgens. Cl. Bernard observed that under the influence of hydrocyanic acid the venous blood becomes red. According to the observations of Gaethgens, at the moment when the convulsive seizure marks the beginning of the action of the poison the venous blood assumes a bright red color, and a similar change in color from the usual venous tint to bright red is seen in the blood of the right heart. At a later stage, however, the venous blood in the cavæ, portal vein, and the right heart assumes a darker hue than that of normal venous blood; and this dark-colored blood is found in the veins of warm-blooded animals which have died from the action of the poison, even if the autopsy be made immediately after death. Quantitative analysis of the gases absorbed and exhaled by animals under the influence of hydrocyanic acid showed that in the beginning of the poisoning, while the venous blood is bright red, less carbon dioxid is produced than normally, and at the same time the expired air is richer in oxygen than usual—conditions which are the opposite to those observed in ordinary suffocation. In the later stages the elimination of carbonic acid is increased. Gaethgens also showed that prussic acid does not destroy the power of reduced hæmoglobin of taking up oxygen from the atmosphere; that fresh blood, saturated with oxygen, does not give up any of its oxygen by the action of hydrocyanic acid; that blood containing hydrocyanic acid does not give up carbonic acid to an atmosphere free from that gas; and that the separation of oxygen from fresh blood is impeded by the presence of hydrocyanic aid.

Preyer, and also Hoppe-Seyler, have obtained, by the action of hydrocyanic acid upon oxyhæmoglobin, a crystalline product, formed without separation of oxygen, which differs materially from oxyhæmoglobin and from reduced hæmoglobin in appearance and in properties, which has not the power of ozonizing oxygen, and which is not converted into oxyhæmoglobin by exposure to atmospheric air.

It seems clear, therefore, that hydrocyanic acid has the property of preventing the proper appropriation of oxygen by the tissues, as well as the formation, or at least the elimination of carbon dioxid, by entering into chemical composition with the blood pigment. It is probable also that this property is an important factor in the action of the poison upon the animal economy, although it can hardly be stated that this is its only method of action.

SYMPTOMS.—*Inhalation.*—Owing to the ready volatility of hydrocyanic acid, its absorption by the pulmonary surfaces is rapid. Coullon observed that "the odor of the acid caused one to fall unconscious and motionless." Ittner suffered from "constriction of the chest, interference with respiration, vertigo, lassitude, and shuddering," in consequence of having inhaled the vapor. Heller mentions a case in which severe tetanic spasms were produced by smelling a bottle containing a five-per-cent. solution. Dr. Letheby was rendered unconscious by smelling a bottle containing the concentrated acid. Taylor relates the case of a lady who "was immediately seized with dizziness, stupor, inability to stand, and faintness," from inhalation of the vapors produced by spilling a quantity of the five-per-cent. solution upon her dress. A student, engaged in preparing the acid in an apparatus whose joints permitted the escape of vapor, was found, after several hours, insensible, with closed eyelids, widely dilated pupils, cold limbs, and barely perceptible pulse. The muscles of the arms and legs were firmly contracted, the patient was in a condition of profound coma, but recovered after several hours (Regnauld). Coullon records a case in which inhalation of prussic acid vapor destroyed human life—that of a chemist who died in consequence of having spilled a quantity of the acid upon his naked arm. As but little, if any, absorption could have occurred through the skin, the fatal result was probably due to inhalation of the vapor.

Industrial poisoning by inhalation of prussic-acid vapor sometimes occurs in workshops devoted to electroplating and gilding, in which, by reason of imperfect ventilation, the vapors constantly emanating from the cyanid baths are allowed to accumulate. Persons exposed for a number of hours to such an atmosphere suffer from shooting pains in the forehead, pain in the region of the heart, palpitation, difficult respiration, a sense of constriction of the throat, and fits of weakness and somnolency.

By the Stomach.—The action of hydrocyanic acid, when taken by the mouth, varies with the magnitude of the dose, the degree of concentration having little, if any, influence. When taken in quantities above the medicinal dose, but still below that capable of causing death (♏ x. to xx. of the U. S. P. acid), it causes a sense of constriction of the chest, a feeling of impending suffocation, irritation of the throat, a sense of heat in the epigastrium, dizziness, impeded locomotion, a sense of constriction and heaviness of the head, and in some cases nausea or a craving for food. Salivation and ulceration of the mouth frequently occur.

When small poisonous doses are taken, the patient, in the act of swallowing, notices the hot, bitter taste of the acid, and almost immediately a sense of constriction of the throat. In the course of one or two minutes there are severe pain and sense of pressure in the head, increasing vertigo, progressive confusion of intellect, obscuration of vision, insensibility, with loss of muscular power. The face is pale and bloated, the eyes are prominent and glassy, the mouth is marked with froth. The patient is then seized with convulsions of a tetanic character, with the jaws firmly clenched. The pulse is quick, the respiration slow and stertorous, and mucous râles are heard over the chest. Vomiting is uncommon; if it occur, it is usually the beginning of recovery. The vomited matter, as well as the breath, has the odor of bitter almonds. If the case terminate in death there are usually strong tetanic convulsions, involuntary evacuation of urine and fæces, opisthotonus; then succeeds a condition of general paralysis, and death from asphyxia follows in a period varying from two hours to two days. When recovery occurs, it does so gradually, the respiration and circulation slowly returning to the normal condition without any further complications.

With large doses subjective symptoms are entirely absent. In less than a minute consciousness is suddenly lost and the patient falls if standing or sitting. Then usually follows a short convulsive seizure, during which there is in most cases involuntary evacuation of urine and fæces. After this the patient lies perfectly still, with prominent, glassy eyes, jaws firmly clenched, mouth covered with foam, face at first bloated, afterward pale and sunken, pupils dilated and insensible, surface cold and clammy, and muscles completely relaxed. The pulse, at first somewhat more frequent than normal, rapidly becomes weaker, until in the later stages it is imperceptible. The respiration is spasmodic, the inspirations are short, and immediately followed by a protracted expiration, after which succeeds a pause of considerable duration, increasing as the case progresses to a fatal termination. Death occurs during one of these pauses, the only apparent difference between the condition of the patient before and that after death being that no succeeding inspiration occurs.

Lethal Dose.—The determination of what is the minimum lethal dose of any poison is difficult, and more difficult in the case of hydrocyanic acid than in that of any other poison. This is chiefly because of the great variation in the strength of the medicinal acid, which, even if made of the proper degree of concentration originally, deteriorates rapidly by exposure to light or air.

Two cases are recorded in which the lives of adults were destroyed by ♏ xx. of Scheele's acid (= one grain or 0.065 gm. anhydrous acid, if the preparation was of the proper strength). It is probable, therefore, that one grain of anhydrous hydrocyanic acid (= ♏ xlv. U. S. P. acid) is the minimum lethal dose. It by no means follows that this amount is necessarily fatal. In a case in which so large a dose as 2.4 grains (0.156 gm.) of anhydrous acid was taken, the patient recovered under active and immediate treatment. Records of large doses, followed by recovery, are to be regarded, however, as of little value unless the true strength of the acid has been determined. Thus, in a French case, in which an adult male took ʒ ij. of Scheele's acid in two doses, without ill effects, and subsequently ʒ ij. of Vauquelin's acid (in all 10.2 grains = 0.66 gm. of the anhydrous acid), from which he suffered the usual symptoms, but finally recovered, the former preparation probably contained little, if any, hydrocyanic acid, and the latter was much deteriorated.

Treatment.—As a rule the patient will be found well under the influence of the poison, frequently apparently lifeless; yet treatment should not be neglected, however desperate the case may seem. The clothing should be instantly removed and cold water dashed upon the head and spine, which are then to be rubbed dry with, preferably warm, towels, and the cold affusion repeated; this should be done even if the patient is in convulsions. Any poison remaining in the stomach is to be removed by the use of the siphon, the stomach being subsequently washed out with warm water. Artificial respiration is strongly recommended by some authorities, by others considered to be useless. The constant current from twenty-five cells may be applied, one pole over the apex of the heart, the other over the pneumogastric in the neck, contact being made and broken coincidently with the inspirations. Friction with hot liniment is to be applied to the chest and abdomen. Ammonia and chlorin by inhalation have been frequently recommended. When used they should be much diluted with air; the former obtained by saturating a cloth with liq. ammon. dil., the latter by moistening chlorid of lime in a wide-mouth bottle with dilute vinegar. Ammonia and chlorin do not act as chemical antidotes, but as stimulants to the capillary circulation, an effect which is best attained by the injection of ammonia into a vein. Atropin hypodermically administered is regarded by Preyer as the physiological antidote of hydrocyanic acid, but, although Preyer's experiments have shown that animals already under the influence of atropin are more or less protected from the action of hydrocyanic acid, the use of atropin in cases of poisoning by hydrocyanic acid does not seem to be of much benefit. Although a mixture of persulphate and protosulphate of iron acts as a good chemical antidote to hydrocyanic acid, by converting it into the insoluble Prussian blue, its value is much diminished by the fact that it cannot usually be administered in time to prevent the absorption of the poison. It should be administered if possible; ʒ ij. of magnesia are first given to neutralize the acidity of the contents of the stomach, and immediately afterward a mixture composed of liq. ferr. tersulphat., ʒ ij., and ferri sulph. præcip., gr. xv., dissolved in water; afterward, in a few moments, the stomach should be washed out.

Post-Mortem Appearances.—Rigor mortis usually sets in early, and persists sometimes for days, particularly in the lower jaw. As in sudden death from any cause, putrefaction is rather more rapid than usual. The face is usually placid, sometimes bloated; the eyes are prominent and glassy, the pupils dilated; the mouth is more or less covered with foam. The veins everywhere are distended with dark, fluid blood. The brain tissue is normal, the cerebral vessels are full of dark, fluid blood. The left ventricle of the heart is usually firmly contracted and empty, the right heart full of dark, uncoagulated blood. But if death occur very rapidly, the blood may be bright red in color (see above). The larynx and trachea are filled with a bloody foam, and the lungs are highly congested. The stomach frequently presents no abnormal appearance, but usually it is red and inflamed, either over its entire extent or in patches. The most distinctive character noticeable is the odor of bitter almonds. This, in some cases, may be distinguished before any incision is made, sometimes only on opening the cranial cavity, the stomach, or the pericardium; while in some cases of undoubted poisoning by hydrocyanic acid the odor cannot be detected with certainty.

Detection after Death.—Owing to the great volatility and instability of hydrocyanic acid, the probability of its detection by analysis in the cadaver diminishes rapidly as time elapses, particularly if the conditions favoring putrefaction obtain. The analysis, therefore, if one be desirable, should be made as soon as may be after death. Nevertheless, instances are not wanting in which the presence of the poison has been demonstrated several weeks after death. Thus Brame detected hydrocyanic acid one month after burial in winter; Reichardt, two months after death, in a corpse undergoing putrefaction; and Tillner, four months after death.

Analysis.—The parts which should be first examined are the blood and the contents of the stomach. If death have been rapid the urine will not contain the poison. The material to be examined is subjected to distillation in order to separate the acid in such form that the distinguishing tests may be applied. If the indications do not point very decidedly to hydrocyanic acid the distillation should be combined with the search for phosphorus and other volatile poisons, the tests being applied to the first portions of the distillate. When hydrocyanic acid (or a cyanic poison) only is to be searched for, the apparatus is to be somewhat modified and no precautions with regard to light are necessary. If the material under examination be the contents of the stomach, certain sources of error are to be provided against. In the subsequent distillation in presence of an acid, hydrocyanic acid would be produced if a thiocyanate, usually a normal constituent of the saliva, or potassium ferrocyanid, or the pips of apples, pears, and other fruits were present. The last-named bodies are to be searched for, with the aid of a magnifier if necessary, in a portion of the contents, and, if found, are to be removed from the portion to be analyzed by filtration of the liquid, with the least possible exposure to air. Potassium ferrocyanid may have been taken as such, or it may be present as an impurity of potassium cyanid, and in the latter event, if not separated, would affect the quantitative result with a plus error. A portion of the filtered contents is dialysed, and the dialysate tested for ferrocyanid and thiocyanate by acidulation with hydrochloric acid and the addition of ferric chlorid. A blue precipitate indicates the presence of a ferrocyanid, and a red color in the liquid that of a thiocyanate.

In the absence of ferrocyanids and of thiocyanates the liquids to be examined—blood or contents of the stomach—are diluted, if necessary, with a known volume of water; 100 c.c. of the liquid are introduced into a 200 c.c. flask, connected with a Liebig's condenser, the lower end of which communicates by an air-tight joint with a small tubulated receiver, from the tubulus of which a tube, bent twice at right angles, is in air-tight communication with one limb of a bulbed **U**-tube. About 20 c.c. of a strong solution of silver nitrate are placed in the receiver and in the bend of the **U**-tube. The 200 c.c. flask is now disconnected from the condenser, enough aqueous solution of tartaric acid added to its contents to render them strongly acid, and the flask again connected with the condenser without loss of time. The flask is supported on a piece of asbestos board, and the distillation is slowly proceeded with until 10 to 15 c.c. of liquid have distilled over, or until the drops of distillate, as they fall into the silver solution, cease to produce any further precipitate. If the distilled liquid contain hydrocyanic acid, a white, caseous precipitate will be formed in the silver solution, the non-formation of which may be considered to be proof of the absence of cyanic poisons. If silver cyanid have formed, it is to be collected with the usual precautions upon a filter, whose dry weight has been determined, washed, dried at 100° C., and weighed. The weight so obtained, minus the weight of the filter, multiplied by 0.20194, gives the weight of hydrocyanic acid (CNH) in the amount of material distilled. The precipitate of silver cyanid is formed in solutions containing one part of CNH in 250,000; beyond that dilution the reaction fails (Link and Möckel).

The filter, with the adherent precipitate, is then placed in a flask, moistened with a few cubic centimetres of water, agitated, treated with 0.74 c.c. of a decinormal hydrochloric acid (3.64 HCl in 1,000) for every 0.01 gm. of silver cyanid found, again thoroughly agitated after corking, allowed to clear by subsidence, and decanted through a filter. The clear liquid so obtained is to be used for the application of the tests described below.

If the materials to be examined contain a ferrocyanid or a thiocyanate the operation is conducted as above directed, except that the material is rendered strongly alkaline with sodium carbonate, in place of acid with tartaric acid. Should the cyanic poison be mercuric cyanid its presence may not be revealed by either of the above methods.

TESTS.—1. *Thiocyanate Test* (Liebig, 1847).—Place a portion of the liquid in a porcelain capsule; add a few drops of a dilute solution of sodium hydroxid and a few drops of a yellow solution of ammonium sulphydrate; evaporate to dryness over the water-bath; add water; acidulate with hydrochloric acid, and then add two or three drops of solution of ferric chlorid. If the liquid contained hydrocyanic acid it will be converted by this treatment into sodium thiocyanate, which, with the ferric salt, gives a fine red color. Finally, add solution of mercuric chlorid, which discharges the red color formed by the thiocyanate, but does not affect a similar color formed by meconic acid.

This is the most delicate of the tests for hydrocyanic acid, a distinct reaction being obtained with a solution of 1 to 4,000,000 (Link and Möckel).

2. *Prussian Blue Test* (Ittner, 1809).—Render a portion of the liquid alkaline by the addition of dilute caustic potash solution, add a few drops of a solution of ferrous sulfate which has become yellow by exposure to air, agitate, and let stand ten minutes. A dirty greenish precipitate is formed. Now add hydrochloric acid in slight excess, warm slightly, and, if no blue or green color be immediately observed, examine again after several hours' standing. In the presence of small quantities of hydrocyanic acid the liquid is colored green, and deposits Prussian blue only after long standing; with larger quantities the liquid is colored blue, and, immediately or after a short time, deposits a flocculent dark-blue precipitate, while the color of the liquid gradually changes to yellow. This test fails (Link and Möckel) when the dilution exceeds 1 to 50,000.

3. *Guaiac Test* (Schönbein, 1868).—Moisten a strip of filter paper with a freshly prepared three-per-cent. alcoholic solution of guaiac, dry, moisten with a drop of 0.05 per cent. solution of cupric sulfate, and then with a drop or two of the suspected solution. In the presence of hydrocyanic acid the paper is colored a beautiful blue. With very concentrated solutions (one per cent.) the reaction is attained by simply bringing the moistened paper over the solution. With highly dilute solutions a larger quantity of the suspected liquid is to be brought upon the paper by slow dropping from a pipette.

A distinct reaction is obtained (Link and Möckel) with a solution of 1 to 3,000,000, or (Hermann) 1 to 120,000,000.

This reaction is of value only as confirmatory of others, or as a preliminary test, as the same appearances are produced by ammonia, volatile ammonium compounds, hydrochloric acid, tobacco smoke, ozone, etc.

4. *Nitroprussid Test* (Vortmann, 1887).—Add a few drops of a sodium nitrite solution, then two or three drops of ferric chlorid solution, and, finally, enough dilute sulfuric acid to cause the brown color to just change to light yellow, heat to boiling, cool, add ammonium hydroxid solution, filter, and add to the filtrate a drop or two of very dilute ammonium hydrosulfid solution. A fine violet color is produced, which passes into blue in a few minutes, then to green, and finally to yellow.

Other tests have been suggested: With starch and potassium iodid (Schönbein); with cupric sulfate alone (Lassaigne); with picric acid (Braun); with cobaltous chlorid (Braun); with mercuric oxid (Henry and Humbert), and with uranic nitrate (C. Lea). These are, however, all inferior to those given above, which are sufficient to characterize hydrocyanic acid with certainty.

CYANIC POISONS OTHER THAN HYDROCYANIC ACID.—What has been said above concerning hydrocyanic acid applies in the main to all substances owing their poisonous qualities to the presence of that acid. A few points, however, of variation or special interest require mention.

Potassium cyanid is at present far more frequently the cause of death than the acid itself, the potency of which is in no way diminished by its being in combination in a soluble salt. The symptoms are those of hydrocyanic acid poisoning, to which, if death do not occur with great rapidity, are added symptoms referable to the corrosive action of the potassium salt—burning pain in all parts with which the corrosive has come in contact. Vomiting is of much more frequent occurrence than in poisoning by hydrocyanic acid.

Potassium cyanid exerts a chemical action upon the skin, and is also readily absorbed through slight abrasions or excoriations. Serious poisonings, and even death, have in many instances resulted in this way in photographers, galvano-platers, or by the handling of plate-polishing powders containing potassium cyanid.

The post-mortem appearances differ markedly from those observed in cases of poisoning by hydrocyanic acid. While in the latter class of cases the autopsy may be said to reveal nothing of moment if the odor be absent, in cases of death from potassium cyanid the appearance of the stomach and intestines is highly characteristic if the poison have been taken in the solid form or in strong solution. Lesser ("Atlas d. gerichtl. Med.," Pl. ix., xiv.) has illustrated the appearances in a typical case. The mucous surface of the stomach is rugous, and of a light purple-red color, fading to a more brownish tint in the pyloric portion. The mucous membrane is more transparent than normal, and the red color is due more to an imbibition of the epithelium with blood pigment altered by the poison than to fulness of the vessels. If the autopsy have been long delayed, post-mortem corrosion may be extensive. In the duodenum, at the pylorus, is a narrow band of normal tissue; below this the mucous membrane is of an intense light-red color, and of greater transparency than normal. The remainder of the small intestine presents portions of normal tissue irregularly alternating with sections which are of the same light-red color as the duodenum, hyperæmic, and marked here and there with patches of extravasation varying in size up to the diameter of a quarter-dollar.

When pure, potassium cyanid contains forty per cent. of hydrocyanic acid. The commercial article usually contains carbonate, and sometimes potassium ferrocyanid, the former frequently in considerable quantity.

Other metallic cyanids, if capable of yielding hydrocyanic acid on contact with an acid in the cold, produce, when taken, the effects of the acid. Those which are decomposed by an acid only with the aid of heat are inert. *Mercuric cyanid* behaves more as a mercurial than as a cyanic poison, having produced effects very similar to those of corrosive sublimate in the few recorded cases. In a recent case in which it was administered, mixed with a powder capable of liberating free hydrobromic acid, it was decomposed and caused death in twenty minutes from cyanic poisoning. The *metallocyanids* are for the most part non-poisonous.

Potassium thiocyanate is possessed of poisonous properties which are, however, referable to the potassium rather than to the acid. *Mercuric thiocyanate* is the material of which the toys called Pharaoh's serpents are made. A few cases of irritant poisoning produced by swallowing these toys have been recorded.

Bitter almonds on contact with water at a slightly elevated temperature produce hydrocyanic acid by decomposition of the amygdalin which they contain. A few cases of poisoning by eating bitter almonds have been recorded. They do not differ from cases of poisoning by small doses of hydrocyanic acid.

Oil of bitter almonds, when insufficiently purified, contains as much as ten to fifteen per cent. of hydrocyanic acid, and, being in common use by confectioners and in the kitchen, is a prolific source of so-called accidental, as well as of suicidal poisoning. The symptoms are similar to those caused by potassium cyanid, and are usually comparatively slow in their development, although in some instances the action has been as rapid as that of hydrocyanic acid. From twenty to forty drops is the probable lethal dose for an adult.

Cherry-laurel water contains about 0.25 per cent. of hydrocyanic acid, and produces effects similar to those of the dilute acid. It is of historical interest, having been used in medical practice and, as a poison, as the precursor of hydrocyanic acid. It was the agent used by Donellan in the murder of Sir Theodosius Boughton, in 1781; and by Price, the last claimant to the discovery of the transmutation of baser metals into gold, to make away with himself, in 1784, when the falsity of his claim was about to be demonstrated.

MEDICO-LEGAL QUESTIONS.—The following points have arisen in trials for murder by prussic acid, and have proved to be the questions upon which the case mainly turned:

1. *Was death due to prussic acid, and not to apoplexy?* As, in the absence of a distinct and unmistakable odor of hydrocyanic acid, there exists no post-mortem appearance which is characteristic of this poison, and as the symptoms in some cases closely resemble those of an apoplectic seizure, it is highly desirable that in cases of suspected poisoning a distinct answer to the above question be had in unmistakable chemical evidence of the presence of the poison in the blood.

There are certain points of symptomatology and of morbid anatomy which are of great value in this connection if they exist. If a person poisoned with hydrocyanic acid do not die within a short time, there occur violent convulsions, with opisthotonus and rigidity of all the muscles. In apoplexy there may be rigidity of an extremity, but never of all the voluntary muscles. But if the poison cause death rapidly, the convulsions do not usually occur.

After death from hydrocyanic acid the meningeal vessels and the cerebral sinuses are found gorged with blood; but never, as in sanguineous apoplexy, is there extravasation of blood into the ventricles, the membranes, or the substance of the brain, nor are there clots.

In a classic French case, "l'affaire Héritier," tried at Cambèry, in 1841, the prisoner was sentenced, and would have been executed had not Orfila shown from the *facts* of the evidence that the death of the deceased, Praslin, was due to apoplexy, and that the *opinions* of the chemical and medical experts upon which the conviction was based were of the most flimsy character, even for that period.

2. *Are certain symptoms and appearances necessarily present?* The argument has been frequently advanced that death could not have been due to hydrocyanic acid because a certain supposed characteristic symptom, such as the shriek, convulsions, or involuntary evacuations, was not observed or could not have occurred.

When rabbits and other animals are poisoned with hydrocyanic acid they usually emit a loud cry or shriek. In some of the earlier trials for poisoning by this substance the defence was raised that death was due to other causes because this cry had not been heard. The records of numerous cases of undoubted death from prussic acid show that in the human subject the occurrence of this cry has not been observed.

Attempts have also been made to argue that death could not have been due to prussic acid because the deceased was found calmly disposed in bed, reposing upon and covered by clean and evenly folded bedclothing, and consequently neither convulsions nor involuntary evacuations could have occurred. Convulsions are not usually observed when large doses of the poison have been taken, and when they do occur they are frequently of a mild type. In the greater number of the many cases in which the body is found without any observation of symptoms having been had, the countenance bears a calm and placid expression, which would not indicate that convulsions had occurred.

Involuntary evacuations of fæces or urine, or both, have occurred in about one-half of the recorded cases.

The characteristic *odor* of hydrocyanic acid, which may be described as that of bitter almonds, does not belong to any other known substance, except the oil of bitter almonds (benzoic aldehyd) and nitrobenzol; the former, in its pure state, a substance only found in chemical laboratories, the latter an active poison.

In some instances of death from the cyanic poisons the odor is easily recognized and distinct. Sometimes it may be observed on entering the apartment in which is the corpse; sometimes, during life, in the expired air, or, after death, at the mouth; sometimes only after opening one of the cavities of the body, or the stomach, or on cutting into the lungs or liver.

When the odor has been *distinctly* recognized by more than one person, its existence is a factor of great moment in the evidence to prove the cause of death: but a failure to detect the odor is by no means of correspondingly great significance in the opposite direction. Several instances are recorded in which analysis has proved the presence of the poison, although the odor could not be distinguished either during life or after death.

3. *Was a person killed by hydrocyanic acid capable of certain voluntary acts?* Because hydrocyanic acid is capable, if taken in sufficient quantity, of destroying the power of voluntary motion almost instantaneously, within a few seconds after having been swallowed, it has been argued that death could not have been suicidal in a case in which the deceased was found in such a position as implied voluntary acts on his part after having taken the poison, or the presence of another person. Numerous cases are recorded, however, in which the person was capable of considerable voluntary effort after having voluntarily taken a dose of hydrocyanic acid sufficient to cause death.

4. *Was the hydrocyanic acid, detected in the body by analysis after death, introduced during life?* is a question which may arise upon a trial for murder by this poison. The defence may adopt either of the following methods of accounting for its presence:

(*a*) *It was introduced after death.*

(*b*) *It was given medicinally.* These claims, if false, are to be met in the same way whatever poison has been used, consequently they require no particular consideration in this place. It cannot be claimed that hydrocyanic acid was used for embalming.

(*c*) *Hydrocyanic acid is a normal constituent of the body.* The only cyanogen compound which has been shown to exist in the normal human body is the thiocyanate of the saliva and urine. If the precautions mentioned above have been taken, this substance cannot be mistaken for hydrocyanic acid.

(*d*) *Hydrocyanic acid is a morbid product of the economy.* Hydrocyanic acid has been, it is claimed, detected in the urine in dropsy (Brugnatelli), typhus, cholera, and hepatitis (Fourcroy, Osborn), and in the fluid of ascites (Goldefy-Dorhs). Although Buchner admits the possibility of the formation of hydrocyanic acid in certain pathological processes, Husemann very properly considers that, even if these somewhat doubtful observations be accepted, they have no forensic interest, as it is not in the urine or in pathological exudations that prussic acid is found in cases of poisoning.

(*e*) *Hydrocyanic acid is a product of putrefaction.* This argument was advanced by the defence in two English trials, cited by Taylor, and is based solely upon opinion. Several writers upon toxicology—Orfila, Buchner, Bonjean, Preyer—admit the *possibility* that hydrocyanic acid *may be* one of the numerous products of putrefaction, yet no writer has yet asserted that it *is* so produced, and numberless analyses of contents of stomach, blood, etc., in every stage of decomposition, have been made by many chemists without any evidence of its presence.

Rudolph A. Witthaus.

HYDROCYANIC ETHER.—This body, chemically *ethyl cyanide*, $C_2H_5.CN$, is a colorless ethereal fluid miscible with water, alcohol, and ether, and possessed of poisonous properties analogous to those of hydrocyanic acid. It is not used in medicine. *Edward Curtis.*

HYDROFLUORIC ACID.—Hydrofluoric acid is a pungent, corrosive gas, very soluble in water. The acid of commerce is an aqueous solution containing from thirty-six to thirty-eight per cent. of the anhydrous acid; it emits fumes which are extremely irritating. When applied to the skin it destroys the epithelium and underlying tissue, rendering the parts hard and structureless.

Hydrofluoric acid is an efficient bactericide and antiseptic, and for this purpose Dujardin-Beaumetz advocated its employment in the treatment of tuberculosis by inhalation. He vaporized one grain in an air-tight compartment of the capacity of 22 cubic metres. In this the patient is placed for an hour daily, the period being gradually prolonged. In some instances the results were very favorable, but in others it produced an irritation of the lungs and increased the pulmonary trouble. Inhalations have also been used in diphtheria and whooping-cough. In the latter much benefit is reported from the use of a tablespoonful in a quart of water, in an inhaler, every second day.

Internally, hydrofluoric acid is a marked depressant, acting upon the vaso-motors and lowering the force and frequency of the pulse. In excessive doses it causes death by profound collapse and failure of respiration.

As a vaso-motor dilator its employment has been suggested in chronic rheumatism, epilepsy, and goitre. In the latter condition it was thought to be of especial value by Woakes, of London, but it has not proved to be of much service.

The alkaline fluorides are selected for internal administration. The fluoride of sodium or of potassium in doses of one grain are quite unirritating, and may be used for a prolonged period.

Locally, solutions of the strength of one part in three thousand may be used for ordinary antiseptic purposes. Under the title of *fluorol*, sodium fluoride has been used in a two-per-cent. solution to replace perchloride of mercury. The solutions are unirritating and free from any toxic action. A half-per-cent. solution may be used for the eye. *Beaumont Small.*

HYDROGEN DIOXIDE.—Hydrogen dioxide, H_2O_2, commonly called *peroxide of hydrogen*, is formed by reaction between barium dioxide and mineral acids in the cold. Obtained in concentrated condition, this body appears as a colorless, transparent, heavy, oily fluid, of specific gravity 1.452, neutral to test paper, remaining fluid at temperatures far below the freezing point of water, but rapidly and even explosively suffering decomposition into water and gaseous oxygen upon even a slight elevation of temperature, or upon contact with charcoal and certain metals and oxides. Even at ordinary temperatures the same decomposition occurs spontaneously to a greater or less extent.

Hydrogen dioxide mixes in all proportions with water and dissolves also in ether. As a medicine, it is used in solution in one or other of those fluids, the aqueous solution being commonly known as *oxygenated water*, and the ethereal as *ozonic* or *ozonized ether*. The *aqueous* solution in common use contains three per cent. of hydrogen dioxide by weight, a strength representing a charge of ten volumes of oxygen to one of the water of the solution. Such a solution is official in the United States Pharmacopœia under the title *Aqua Hydrogenii Dioxidi*, Solution of Hydrogen Dioxide. It contains a little sulphuric acid, purposely allowed to remain, as a preservative, from the charge of acid used to clarify the solution. This solution is a sparkling, clear, colorless aqueous fluid, odorless, but having an acidulous and disagreeable chlorinous taste, and producing a curious sensation and a soapy froth in the mouth, through evolution of oxygen. Its specific gravity ranges from 1.006 to 1.012 at ordinary temperatures. It tends to decompose spontaneously into water and oxygen, and accordingly will deteriorate by age, especially if exposed to light or to warmth. If subjected to evaporation at a temperature not exceeding 140° F. the solution will gain in strength through loss of water, but if heated rapidly it is liable to decompose at once and with explosive violence. Because of these various properties, the solution should be kept in dark amber-colored bottles, *loosely* stoppered and in a cool place. A tight stopper may be blown violently from the bottle, or the bottle itself may be burst, if the stopper be immovably seated. Furthermore, since deterioration by keeping is inevitable, a freshly made sample should be procured always, when possible, for use. Old specimens will certainly be under standard in strength, and even may be wholly spoiled and inert.

Solution of hydrogen dioxide is neither corrosive nor poisonous, and is irritant only to especially sensitive parts, such as the eyes, the urethra, or raw surfaces. Its use in medicine is because of its ready decomposition, with yield of free oxygen. Such decomposition is determined by mere contact of the solution with many things, among which are the organic matters found in blood, mucus, pus, and other morbid discharges, diphtheritic membrane, the bodies of pathogenic micro-organisms, and decaying organic substances generally. It coagulates albumen powerfully. By virtue of the yield of oxygen the solution destroys, by oxidation, the morbific quality of animal secretions and excretions. When added to pus, brisk effervescence ensues and the pus corpuscles are quickly disintegrated. Similarly, when washed over a secreting surface, frothing occurs, crusts of dried secretion are loosened, and foul odors disappear. The foaming will continue till all adhering pus or mucopus is destroyed, when, after washing, the surface will be found to be perfectly cleansed and of healthy appearance. Solution of hydrogen dioxide is thus powerfully detergent and disinfectant to all styles of morbid surface conditions, whether of skin, mucous or serous membrane, or wounds or ulcers. The action, however, is evanescent and does not seem to include any intrinsic healing virtue, such as is shown by silver nitrate. For ordinary purposes, the pharmacopœial ten-volume solution may be used in full strength, but for application to sensitive surfaces such as the eye, the upper nasal passages, or the urethra, it should be diluted with from one to four or more parts of water. It may be applied by swabbing, by injection, or by spraying, but only instruments or utensils of hard rubber, glass, or porcelain should be allowed contact with the solution. To affect the surfaces of the stomach or intestines the solution may be given, without fear, by swallowing or by enema. From one to two or three teaspoonfuls may be given at a dose by the mouth. This dose should be well diluted with water and taken from a vessel of porcelain or glass. Other medicines should not be combined with the solution.

Attempts have been made to utilize the solution of hydrogen dioxide as an oxidizing agent within the system for the cure of disease. But when given by swallowing, a dose of the solution is almost wholly decomposed in the stomach, and, when administered hypodermatically, similar decomposition takes place at once in the juices of the part receiving the charge. In either case, therefore, but little of the solution can enter the blood unchanged, so that there is at best but small chance for a constitutional effect of any moment. If injected into the veins, the solution is instantly decomposed by the blood, and, in cases in which this procedure has been tried upon animals, it has often been followed quickly by death from embolism, due to coagulation of the blood by the disengaged oxygen.

Aqueous solutions of hydrogen dioxide stronger than that of the Pharmacopœia are to be found in the market (so-called "hydrozone"), and also solutions with glycerin as the basis (so-called "glycozone"), and solutions in ether ("ozonic ether": "pyrozone"). The ethereal solution is, naturally, highly inflammable.

Solutions of hydrogen dioxide *bleach* powerfully, and are much used for such purpose. *Edward Curtis.*

HYDROPERICARDIUM: DROPSY OF THE PERICARDIUM.—By hydropericardium is meant a collection of non-inflammatory fluid in the pericardial sac. It is distinctly a transudate and not an exudate. Some authorities include all collections of fluid in the pericardium, inflammatory and non-inflammatory, under this one term. By general consent, however, hydropericardium and hydrothorax are understood to mean transudates. A few cubic centimetres of fluid are practically always found in the pericardial sac after death. The fact that the amount varies with the lapse of time before the autopsy,—the longer the wait, the larger the amount of fluid,—suggests that most of this fluid is a post-mortem transudate. It may amount to even two or three ounces. Not until the fluid exceeds 100 c.c. (about three ounces) is the condition spoken of as hydropericardium.

Anatomic Alterations.—Like transudates in other parts of the body, this fluid is light yellow, or slightly greenish-yellow in color, usually clear, of low specific gravity, and containing few formed elements. There may be some floccules of coagulated albumin. It may contain urea or bile, especially in renal and hepatic diseases. The percentage of albumin, according to Reuss, is less than in pleural transudates, and greater than in peritoneal transudates. The quantity of fluid varies very much, depending on many circumstances. It may reach from 500 to 750 c.c. Corvisart has reported the enormous quantity of eight pounds—about 4,000 c.c.

The pericardial sac is distended according to the amount of fluid; in the large collections the lungs are compressed and the diaphragm is forced downward. The pericardium proper is thinned, or if the case is of long duration may be thickened. In chronic cases, the subserous fat about the heart disappears, the subserous cellular tissue appears œdematous, and the endothelia are relaxed, swollen, and of granular opacity. The muscular substance of the heart is pale and flabby.

Scientific opinion is as yet divided in the explanation of the presence of transudates. By many transudation is considered a process of filtration; others hold that the capillary walls are to be regarded as living organs, with a capacity for secretion, under the stimulating influence of irritating substances in the blood.

Etiology.—Hydropericardium is never a primary disease, but always secondary to some other disease. In comparison with the frequency of similar collections of fluid in the pleural and abdominal cavities, and the subcutaneous tissues, it is a rare condition. The explanation of this fact probably lies in the incessant activity of the heart. It occurs occasionally as a very rapid collection of fluid in some cases of acute nephritis, as in scarlatinal nephritis. Most commonly it is a part of a chronic dropsy associated with diseases of the heart and kidneys. Less commonly it is found in the various cachexias which produce an anæmic condition of the blood, such as tuberculosis, cancer, scurvy, and the severe anæmias. In these diseases the pericardial dropsy almost always follows transudation into the pleural cavity. Very rarely the dropsy has a predilection for the pericardial sac, rather than for its usual locations. Probably some local alterations in the pericardium would explain this. It may occur as a result of some local interference with the circulation, which hinders the return flow in the pericardial or cardiac veins. Atheroma of the coronary arteries, aneurism, disease of the lungs, pleura, or the heart itself, tumors and inflammations of the mediastinum, all may impede the circulation in these veins. In rare cases the sudden development of a pneumothorax is followed by hydropericardium.

Symptoms.—These are very indefinite, and can scarcely be separated from those of the associated disease. The condition comes on insidiously and would not be recognized were it not for careful physical examination. A familiarity with the possible complications of chronic heart and kidney disease puts the physician on his guard. The dyspnœa and cardiac distress rarely may be chiefly dependent upon the hydropericardium. There is never any acute præcordial pain, as in inflammation of the pericardium. Pericardial friction sounds are never present. If the fluid is large in amount compression of the lungs may add to the dyspnœa.

Physical Signs.—The reader is referred to the article on *Pericarditis* for a discussion of these, as they are the same except for the fact referred to above—viz., that pericardial friction sounds are never present in hydropericardium, either before the collection or after the absorption of the fluid. The transudate is said to move more quickly with change of body position than the inflammatory exudate.

PROGNOSIS.—It is always grave because of the fundamental disease. The fluid in the pericardium adds an extra impediment to the already weak heart and thus hastens the fatal issue. In rare cases, as in the effusions associated with acute nephritis, there may be recovery.

TREATMENT.—This consists, in the majority of cases, in the treatment of the primary disease, with cardiac tonics and diuretics. Usually paracentesis only delays the fatal issue a short time. However, in rare cases it may be distinctly useful—*e.g.*, when the patient seems to be dying as a result of great local obstruction in the pericardium, which is overwhelming the heart. The operation is not difficult, but must never be undertaken, unless the diagnosis be certain. For a description of the operation see the article on *Pericarditis.*

James Rae Arneill.

HYDROQUINONE.—Hydroquinone, or *hydrochinon,* as it is called by German authors, is chemically *paradioxybenzene,* $C_6H_4(OH)_2$, one of a trio of isomeric diatomic phenols, of which resorcin and pyrocatechin are the other two members. Hydroquinone appears in transparent, colorless, rhombic plates or prisms, fusible at 169° C. (336.2° F.), and subliming without decomposition. The crystals dissolve readily in alcohol, ether, and hot water, but in not less than seventeen parts of cold water. The reaction is neutral and the taste slightly bitter.

Hydroquinone has been proposed as an antipyretic. It is capable of producing convulsions and other derangements in the lower animals, but in therapeutic doses, in man, operates as a speedy, but transient, antipyretic in fever. In such operation the medicine is remarkably well borne, even so large a dose as forty grains producing no derangement worse than a very transient feeling of fulness in the head and slight giddiness, and ordinary doses being free from even this effect. The fall of temperature begins, as a rule, within half an hour after administration of a single dose, reaches its maximum in from two to two and a half hours, and the ensuing rise attains the original temperature in from one to two hours additional. For a transient impression such as described, a dose of from 1.00 to 1.33 gm. (from fifteen to twenty grains) suffices, while for a continuous one, three or four such doses should be given during the twenty-four hours. During continuous medication with hydroquinone the urine may appear of a dark-brown color, due to the presence of products of decomposition of the medicine.

Edward Curtis.

HYDROTHERAPY.—In the present enlightened era of medicine the chief aim of the physician is to aid the inherent powers of the human organism to eliminate morbific agents and reinstate the disturbed equilibrium of the economy, by all means which enhance the patient's capacity to resist the inroads of disease. In the accomplishment of the latter water plays an important part The simplicity of this remedial agent and the neglect of precision in its application have been the chief obstacles in the way of its more universal acceptance. The fact that water is one of the few remedies which has survived since the day of Hippocrates and has been advocated and used by the most eminent physicians of every time, was the writer's incentive to its investigation twenty-five years ago. The clinical results obtained by him have won his highest esteem, especially since he discovered that its action is based upon recognized physiological principles. The latter must be clearly understood before the real value of hydrotherapy can be appreciated.

The action of water upon the human organism is derived from its physical and mechanical effects.

The physical qualities of water are utilized in hydrotherapy because it is an excellent vehicle for conveying the thermic and mechanical effects aimed at. Water absorbs and gives up heat readily; it may be used in solid, liquid, or gaseous form; it may be applied to any limited part of the body or to its entire surface. Hence its physical property alone makes it a most flexible therapeutic agent.

Thermic agents affect living tissues in the most pronounced manner. Smooth muscular fibre contracts under cold and expands under heat, and its contractility may be entirely destroyed by an excess of either. By the conveyance of cold or heat by means of water we are, therefore, enabled to produce striking effects upon vital processes which depend upon muscular activity. As cold and heat are irritants, their reflex effects conveyed through the nervous system also become valuable therapeutically. Applying these axiomatic principles, we find that circulation, respiration, tissue change, and heat production may be positively influenced by the application of water as a medium of conveyance of cold and heat, and that abnormal conditions of the functions may be remedied and their healthy equilibrium restored. That such effects are really produced, laboratory experiment as well as observation at the bedside has again and again demonstrated.

In my book on hydrotherapy * many experiments are detailed showing the influence of hydriatic procedures upon the calibre of blood-vessels, the action of the heart, and even upon the composition of the blood, the respiration, and the secretions. All applications of cold involving the entire surface of the body, or a considerable part thereof, result in an increase of the number of blood cells; the percentage of hæmoglobin and the specific gravity of the blood are also increased when reaction, manifested by cutaneous hyperæmia, ensues. When reaction fails, the erythrocytes, and often the leucocytes also, are diminished.

That these effects may be utilized to explain the rationale of cold applications in disease has been often demonstrated. For instance, Thayer, of Johns Hopkins University, observed that the blood drawn from the lobe of the ear of a typhoid-fever patient after a Brand bath, contained three times the number of leucocytes, ascertained by actual count to be present previous to the bath. This has been confirmed by Winternitz, Breitenbach, myself, and others, in chronic cases and in healthy persons. Since this enormous increase could not be the result of new production during the fifteen-minute bath, the conclusion is inevitable that the increased activity of the circulation, induced by the changing anæmia and hyperæmia of the cutaneous surface resulting from the cold bath and friction, has driven these cells from their hiding-places on the outskirts of the blood stream and elsewhere, and has brought them into active service.

Cold improves the muscular tone of the vessels, *i.e.*, it increases tension; warmth relaxes, causing passive dilatation and loss of tone. Although both produce a hyperæmia, one is the result of reaction and is tonic, while the other is the result of relaxation and is atonic. This trite fact is sadly disregarded in practice. Its more general recognition will do much to neutralize and remove the fear of shock from cold applications in atonic conditions.

The reflex effect of cold and heat conveyed from the skin to the central and sympathetic system, thence to organs and tissues, is an important therapeutic factor, and demonstrates that the thermic action of water upon the human organism is capable of influencing its every part and function in the most pronounced manner.

By guiding and directing these well-ascertained effects of cold and heat, as conveyed by water to the skin, we may evoke changes in the circulation, remove stasis in one and fill another vascular area, deplete others, and thus aid powerfully in removing pathological states.

Water may be applied with accurate dosage by varying the temperature, duration, and pressure. A very high or a very low temperature produces destruction of tissue, while cold and moderately hot water produce a rubefacient effect. Water driven under high pressure destroys tissues, and under moderate pressure causes rubefacient or stimulating effects.

There are also various modifications in hydriatric technique which must be clearly understood before we employ hydrotherapy in disease.

---

* "The Principles and Practice of Hydrotherapy," William Wood & Co.

Technique.—It is the aim of this article to simplify hydrotherapy and render it accessible to the general practitioner. Minute attention to details is the first essential for the successful application of all hydriatric procedures; without this, failure is sure to ensue. The following procedures are best adapted for the application of water in disease: Ablution, affusion, sheet bath, drip sheet, compresses, wet pack, tub bath, douche. Their application in various diseases will be shown.

Ablution consists of the application of water by the hand, or with a wash cloth, over successive parts of the body. The method and the temperature of the water vary with the object in view. In febrile conditions the chest, the back, the abdomen, and the lower extremities as far down as the knees are successively bathed every two or three hours, beginning at 75° and reducing the temperature by one degree at each application until 60° F. is reached. It is important to avoid chilling and to bear in mind that reaction is aimed at.

In chronic affections the ablution is a useful preliminary to the more active hydriatric procedures. The patient is first warmed by being snugly wrapped nude, in two long-haired woollen blankets, like a mummy, for one hour. The face is bathed in water of 60° F.; the blankets are successively opened over his chest, abdomen, back, lower extremities to the knees, and these are bathed with the hand, each part being immediately dried and replaced under cover. A general dry rubbing with a woollen cloth, or the hand, follows.

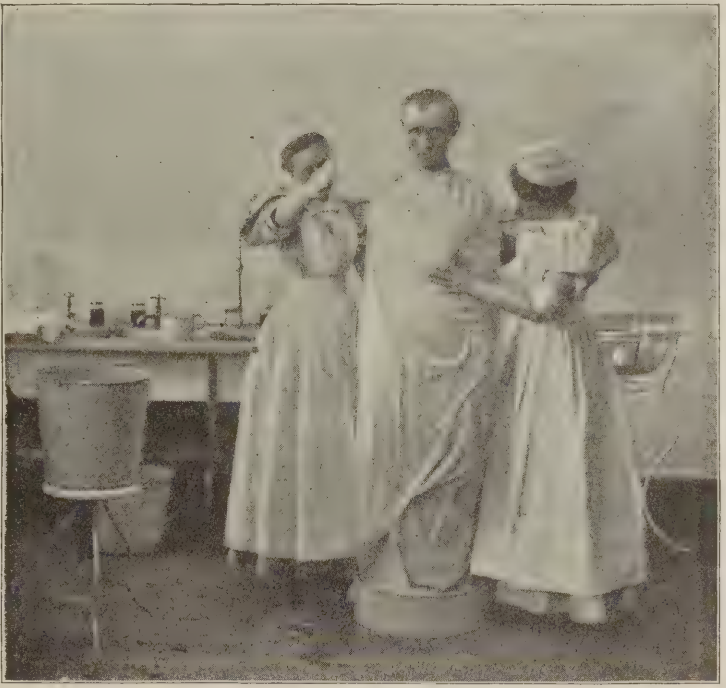

FIG. 2756.—Drip Sheet Mode of Friction.

For the General Ablution the patient stands in twelve inches of water at 95° to 100° F., and is rapidly washed down with the hands, while water—of a temperature of 80° F. at first, but on each succeeding day of a little lower temperature until 60° F. is reached—is poured upon him with the hand or from a vessel. Afterward he should be subjected to gentle friction. Reaction must always be produced.

The *rationale* of the action of ablutions may be found in the gentle shock and reactive stimulus, which is refreshing. The superficial capillaries are dilated, as evidenced by the rosy hue of the skin following ablution with friction, the inspiration is deepened, and cardiac action is bettered.

Affusion.—Having a wet cloth around the head, the patient, sitting or standing in a tub containing twelve inches of water at 100° F., receives a broad stream of water poured with force from a basin, bucket, or pitcher. According to the height from which the water is poured and the lowness of the temperature will be the stimulating effect. The affusion is useful in coma and in stuporous delirium, indicating adynamia and nerve prostration. By this method Currie made his remarkable cures in typhus fever, using chiefly sea water, the patients lying on the deck. In *scarlatina,* when the system is overwhelmed by the poison, the circulation embarrassed, the skin pale or marbled or cyanotic, the respiration shallow, temperature high, pulse rapid and feeble, truly marvellous results may be obtained by the judicious use of brief affusions. Reaction occurs rapidly, and with it come an improved peripheral and general circulation, deepened inspiration, bright countenance, and roseate skin. Rapid affusions of water at a temperature of from 70° to 60° F., have, in my experience, saved lives in these desperate cases.

Sheet Bath.—A rubber sheet covered by a blanket is laid upon one-half of the bed. A linen sheet is now dipped into water having a temperature of from 60° to 70° F., according to the effect desired, and, *without being wrung out,* is laid upon the blanket; the patient, whose face has been bathed with ice-water, and upon whose head a wet cloth is placed, is moved over to the wet sheet, which is wrapped snugly around him. The first impression will be a surprise—called shock—to the cutaneous nerves. Reaction ensues from the patient's own temperature, and its establishment is aided by the manipulations of the nurse, who, with out-stretched hands, gently but firmly sweeps over the wet sheet, omitting the legs and forearms. So soon as one part of the body becomes thoroughly warmed, water from 50° to 60° is poured from a cup or squeezed from a sponge over it, until it again cools. These passes, or frictions, are alternated with the pouring on of small quantities of cold water, until the entire body feels cooled or the patient shivers. Rigor must always be avoided, because it is an evidence of contraction of the vessels. As the friction prevents this objectionable feature of all cold baths we have in the sheet bath an admirable roborant antipyretic, the effect of which may be greatly enhanced by allowing the patient to remain in it, after wrapping him in the blanket, for half an hour. Its mildness as compared with the full cold baths, for which it is an excellent substitute, renders it more acceptable to the patient and his friends, and it may thus be utilized as a valuable initiatory antipyretic measure. It is applicable in all acute diseases in which an elevated temperature is a leading manifestation.

Drip Sheet (Fig. 2756).—In chronic cases the sheet bath is a useful adjunct, and in many cases an important element of the treatment—as, for example, in phthisis, in neurasthenia, and in chlorosis. Here it is called a drip sheet, and is applied while the patient stands in water of 100° F.

The flexibility and simplicity of the method commend it especially. By wringing the sheet well out (cold rub), or by using a coarser sheet, or a lower temperature, for a short time, or by slapping with the wet sheet, instead of simply rubbing the hand over it, the local excitation of the cutaneous nerves and vessels may be enhanced. By saturating it with more water, the antipyretic effect is increased, and this may be still more intensified by a more prolonged application.

The compress is made by cutting four folds of old linen to fit the part. The cloth is more or less wrung out of water at or a little above 60° F. and secured by a flannel bandage wider than the cloth. For tonsillitis it is very useful if applied, not around the neck but from ear to ear and secured by a flannel bandage pinned on top of the head. For articular rheumatism a compress snugly secured by a thin flannel bandage of one layer hastens recovery. In pneumonia the compress, surrounding the thorax like a vest and secured over the shoulder and around the chest by pins, is of paramount value. The abdominal compress is useful in all fevers, as is the trunk compress, enveloping the entire trunk. Compresses are usually renewed every hour in acute cases, and always covered by one layer of flannel to permit evaporation—never covered by oiled silk, which would convert them into a poultice.

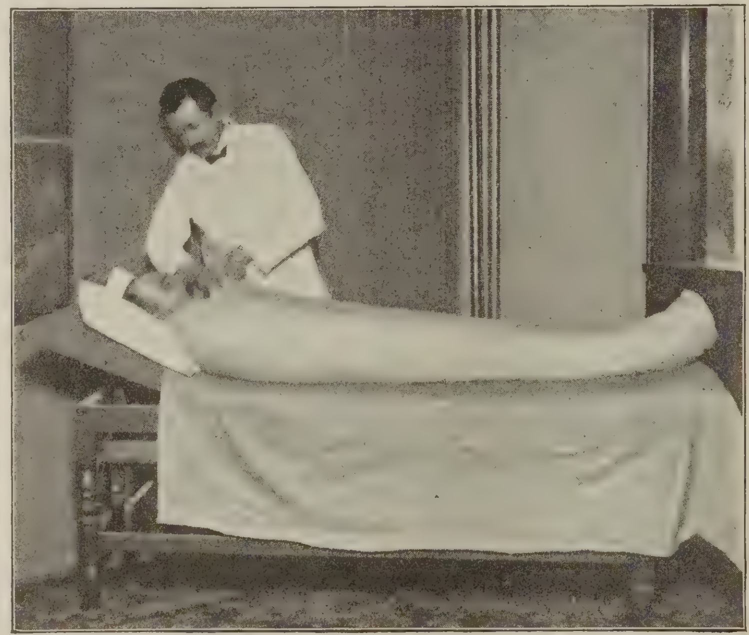

Fig. 2757.—Wet Pack, Showing Method of Tightening Blanket Around Neck.

The Ice Bag may here be referred to. This should always be covered with flannel and never allowed to remain continuously for a longer time than forty-five minutes. It should be replaced at the end of fifteen minutes. Its utility in internal hemorrhages is fallacious, because the blood is driven from the surface into the collateral circulation beneath. Its beneficial effect as an antipyretic for parts situated deeply is fallacious, as proved by the experiments of W. Gilman Thompson and others. The same remark holds true for the ice coil. As an application in feeble and irregular heart action the ice bag is invaluable, if reaction is permitted. The ice coil is a fallacious procedure in fevers, because it cools only the parts beneath it, making them cyanotic, and therefore retards the circulation.

Wet Pack.—A large woollen blanket is spread upon a mattress. Upon this is spread smoothly a linen sheet, *wrung out* of water of a temperature of from 50° to 70° F., according to the nature of the case; the blanket should be long enough to extend from the nucha to a foot or more beyond the patient's extremities. The patient, with a wet cap upon his head, places himself upon the sheet, with his arms raised from the body. One-half of the sheet is now rapidly folded around his body and pressed between the arms. It is snugly secured around the neck and beyond the feet. The blanket is now drawn firmly from the left and tucked under the right side of the body, the right border of the blanket being drawn over to the left in the same manner; then, finally, it should be secured firmly under the body and around the neck, and should be folded over the feet (Fig. 2757). *Success depends upon exclusion of the air by the blanket cover.* If the latter has been skilfully applied, the patient will resemble a mummy, and will get warm in an hour or less.

The wet pack must be followed by some hydriatric method which restores tone to the cutaneous vessels which have been relaxed by it. A sheet bath or a cold affusion will serve this purpose.

The cold sheet produces irritation of the cutaneous nerves, and contraction of the peripheral vessels, and the latter state persists until reaction ensues. Inasmuch as no mechanical aid is given by the attendants, the reaction must depend entirely upon the vital powers of the patient. As soon as the first shock is over—which lasts from five to twenty minutes, and sometimes produces shivering—the cutaneous vessels begin to dilate, and the temperatures of the skin and of the sheet approach equality. This equalization of the two temperatures occurs quickly in fever patients, and slowly in persons having a normal temperature. The sheet bath is, therefore, superior to the wet pack as an antithermic procedure. Many failures are due to the use of the wet pack in fever; it is far more useful in chronic cases.

In chronic diseases the patient is wrapped in a sheet wrung out of water at from 60° to 70° F. as indicated; the higher temperature being employed at first and this being gradually reduced by one or two degrees at each succeeding treatment. Lying for an hour in this pack the patient's body is enveloped in a vapor of its own creation. The reactive labor thus involved is a great benefit to the circulation, and it has been demonstrated to aid in enhancing tissue metamorphosis. The patient often falls asleep. The calming effect of an hour's sleep in the wet pack is valuable in functional neuroses, hysteria, and some heart troubles. It is superior to the hot pack in insomnia and excited mental states.

The therapeutic application of the wet pack is extensive, the procedure being valuable in all chronic cases in which defective tissue metamorphosis is a prominent element, as in *diabetes, rheumatism, gout, anæmia, chlorosis*, and some disorders of the digestive apparatus.

The Full Bath.—A tin tub six feet long, and filled to three-fourths of its depth with water at a temperature of from 80° to 65° F., is placed near the patient's bed in acute cases and shut out from view by a screen. A double blanket covered by a linen sheet is spread upon the side of the bed to be occupied by the patient after the bath, the pillow being covered by a towel. The patient now receives a cup of hot black coffee. He is undressed and a light napkin is applied over the sexual organs. His face is bathed with ice-water, and, if too feeble to step into the bath, he is lifted into it by two assistants, preferably on a small hammock, from which the sticks have been removed. With the greatest gentleness and least fuss he is lowered into the water. He gasps and shudders a moment, or perhaps cries out. But gentle reassurance by word and deed, a calm demeanor, devoid of haste, and the absence of all actual force or argument will quiet him. Friends or relatives must be kept out of the room. An air cushion suspended at the head of the tub will make a head rest, and a large water cushion ring makes a comfortable support for his nates. Two nurses must constantly practise good friction or chafing over *successive* parts of the body. These frictions are of *supreme importance* in preventing chilling, collapse, cyanosis, and heart failure. The effect of the continuous gentle chafing is a suffused redness, which demonstrates that the calibre of the cutaneous vessels is considerably enlarged. As this is being done in successive parts of the body, we really manage to maintain a constant contraction and dilatation of the peripheral vessels, the former being accomplished by the contact with the cold water in motion, the latter by the friction and its attendant reaction. Complaints of chilliness must not be regarded as an indication for removal of the patient from the bath, unless they be accompanied by decided chattering of the teeth, or the face becomes cyanotic. Several times during the bath, which usually lasts fifteen minutes, a basin of water at 50° F. is gently poured over the patient's head and shoulders. If the patient is somnolent or delirious, several basins of cold water are poured over head and shoulders. The bath being finished, the patient is gently lifted out, the napkin covering the sexual organs rapidly dropped, and he is placed upon the previously prepared linen sheet, so that the upper edge extends above his shoulders to the nucha. He is now carefully wrapped in the sheet, a fold being pressed in between the arms and the body and between the lower extremities. The blanket is now wrapped around the patient. If the body temperature has been high, above 103° F., in the rectum, the patient is allowed to lie in the sheet for five or ten minutes; if the temperature is lower he should be at once dried with the sheet and afterward with soft towels. In either case hot bottles are to be placed against the feet. Usually the patient will fall asleep.

When a bath having a temperature of from 70° to 65° F. is given every three hours in the case of a patient who has a rectal temperature of 103° F., this may be looked upon as the ideal bath designed by Ernest Brand, of Stettin, for the treatment of typhoid fever.

In the case of the graduated bath, devised by von Ziemssen, the preparation for bathing and drying the patient is the same as in the Brand bath. The tub is filled with water at 90° F. Colder water is added for half an hour until the water temperature reaches 68° F. *Chafing is here also an all-important element of the bath.* The patient is wrapped in a prepared sheet and blanket without being dried, for a quarter of an hour, and then he is dried and his clothing replaced.

The rationale of the cold baths, which have been chiefly applied in typhoid and other infectious fevers, is so exact and scientific that it must lend firmness born of conviction to the attendant who applies them with a clear understanding of their aims and capabilities. The nervous system is overwhelmed by toxæmia. An indefinable malaise is followed by ataxia, general lassitude, somnolence, and other adynamic manifestations, which culminate in severe cases in stupor, delirium and coma, subsultus, tremor, etc. The heart, being called upon to do extra duty, threatens to fail, and often does fail, not owing to the elevated temperature only, but to a paretic condition of the capillary circulation, induced by the infective process, which embarrasses the propulsive action of the cutaneous arterioles.

The depreciated condition of the nerve centres, which in typhoid and similar fevers is the leading point of attack, must be the leading point of defence. From it originates a condition of the circulation which, by its effect upon the peripheral vessels, not only disturbs heat radiation, and thus develops temperature elevation, tympanites, etc., but later gives rise to other most perilous conditions, such as failure of the heart, local hypostases, bed-sores, etc. The stimulating, refreshing effect of cold water and friction upon the terminal fibrillæ of the sensory cutaneous nerves is conveyed to the central nervous system; the gasp emitted by the patient is evidence of a reflex effect. The cutaneous arterioles are stimulated and dilated in reaction, filling with cooled blood, and thus the heart, laboring ineffectively to overcome these paretic conditions, is afforded some relief. Elastic resistance at the periphery being thus increased, the ventricular contraction becomes more complete, and the blood courses with increased vigor through the entire organism. Excretion is enhanced, and the vitality of the patient rises. The patient's condition is the best evidence that these effects are salutary. He who has witnessed the dull eye of a typhoid patient glisten after a cold friction bath, who has felt the dicrotic pulse rebound, who has seen the apathetic countenance brighten, the urine increase, and slumber ensue, must be convinced of the value of cold procedures in infectious fevers. Reaction must always be induced by friction during the bath.

In Typhoid Fever, the Brand bath, above described, is of the greatest value, as clearly shown by the only absolutely reliable medical statistics extant. Dr. Vogl, medical director of the Bavarian army, has published the records of a period of forty years, covering all types of epidemics of typhoid fever and all kinds of treatment; and according to these statistics, based upon 8,500 cases of the disease occurring in soldiers, the mortality has been reduced, by the Brand bath, from twenty-two per cent. down to three per cent. The subjects being all of the same sex, occupation, age, and environment, and the inquiry covering large numbers and a long period, these statistics are unique and absolutely reliable.

The writer's method of procedure is as follows: When he suspects that he is dealing with a case of typhoid fever he proceeds at once to use ablutions every two or three hours, applies an abdominal compress between the ablutions, and then orders a sheet bath of from 80° to 70° F. On the fourth day he orders a friction bath at 90° for fifteen minutes, as above described, to be succeeded in four hours by others at 85°, 80°, 75°, and 70° F. These may be taken in the bath-room. When the diagnosis becomes positive the baths must be administered in a six-foot tin tub, placed alongside of the bed, eighteen inches from the floor. The temperature of the bath should never be less than 65° F., but cold enough to produce good reaction —70° to 75° F. being the average. Active friction must be continued for fifteen minutes, and affusions given as above described. This is the Brand bath given every four hours as long as the rectal temperature registers 103° F. Abdominal compresses at 60° F. are always applied between the baths. When this bath cannot for any reason be obtained, the *sheet bath* is an excellent substitute, because it furnishes the thermic excitation and the reaction is furthered by friction over the sheet. A *towel bath* is also useful when the sheet bath is positively inapplicable. This consists of a towel smoothed, dripping, over the back and successively over the glutei and the front of the body, and friction with a block of ice held in gauze, until each part is cooled. The patient is dried and left to rest. This may be repeated every two or three hours. All cold baths must be given with friction, and chattering of the teeth and cyanosis must be avoided.

In Scarlet Fever and Measles the tub bath of 90° F. gradually reduced to 85° F. without friction, continued for from eight to twelve minutes, and repeated every four hours, is soothing and antithermic.

Pneumonia.—Happily, the day of fighting pneumonia as a disease is passing away. The enlightened practitioner prepares the pneumonia patient by providing him with a comfortable bed, pure air, easily assimilated food and drink, and good nursing. He no longer relies upon aconite, veratrum, quinine, repeated antipyretics, morphine, stimulants, and stuffing, because he recognizes these to be impedimenta, when the patient should be stripped for the fight. They embarrass the eliminating function, impair the appetite, and cripple his resources. The application of cold water, on the contrary, meets all the indications for which these powerful remedies were formerly applied—and it accomplishes it without their depreciating effects. What affords more comfort to a child suffering from pneumonia than a tub bath with good friction in water of 95°, reduced during five to eight minutes to 85° or 80° F.? A few baths of this kind repeated every four to six hours, without fuss or confusion, at the bedside (not in a bath-room), calm the respiration, reduce temperature, promote sleep, slow and strengthen the pulse, and refresh the oppressed nervous system. In the interval between the baths I am in the habit, if the temperature and pulse are high, of wrapping around the upper half of the trunk a compress made of three folds of old linen and wrung out of water at 65° F. and always covered by a wider bandage of one layer of thin flannel (without oiled silk), snugly secured over the compress.

By renewing this compress every hour the good effects of the bath are maintained and their frequent repetition is rendered unnecessary.

In the adult patient the tub bath is not so useful, because it involves more trouble to, and disturbance of, the patient, especially if pleurisy be present. Here the wet compress around the chest, not too firmly wrung out of water at 60° F., usually fills all therapeutic indications. It becomes hot, and when removed the re-application causes a deep inspiration, a betterment of pulse quality, and an increase of urine. The latter is also enhanced by draughts of from four to six ounces of water at 45° F., administered regularly every two hours.

No claim is made that cold water cures the disease. The object of these mild cold procedures is to fortify the patient's resisting powers and thus to aid him in maintaining a successful defence against the disease until its natural limitations are reached. The frequency of application, the temperature of the water, the extent of the saturation of the compress, the duration of the bath, the selection of the procedure, are matters for judgment in each individual case. That we can utilize all these, and thus adapt them to conditions as they arise in each individual case, gives this remedial agent a positive advantage over all others and entitles it to more extensive trial and study than it has received. Large clinical observation is the basis of these views.

The Douche is a procedure by which water is driven upon the patient's body from the nozzle of a hose the internal diameter of which varies from one-eighth to one-half inch. The ordinary shower bath and the needle bath are multiform douches. The water is usually supplied from a reservoir placed at a height of from thirty to seventy feet, and giving a pressure, at the nozzle, of from fifteen to thirty-five pounds to the square inch. A douche table has been devised by the author (1894) by which the temperature, duration, and pressure are regulated before the patient receives the water. This apparatus is useful only in institutions. It has been adopted in the United States (St. Elizabeth) Hospital in Washington and in many other lunatic asylums. It is adapted only to hospitals treating chronic cases in large numbers.*

CHRONIC DISEASES.—Chronic diseases furnish such a favorite field for hydrotherapy that no internal disease should be yielded up as hopeless until this mode of treatment has been systematically tried, in connection with all those hygienic agencies which are usually of more avail than medicinal agents, viz., exercise or rest, diet, drink, clothing, climate, etc.

The general ablution, drip sheet, wet pack, and douche are useful if they are employed in a properly graded manner. Beginning with the general ablution and gradually lowering the temperature, and doing the same with the drip sheet, always producing reaction, and then, if need be, going on to the wet pack, we have a variety of modes and measures which afford great latitude in energizing the system, enhancing its vital capacity so as to throw off the materies morbi or re-establish the equilibrium of the circulation and nerve centres. (See above for technique.)

A case of anæmia, for instance, which has resisted iron, strychnine, malt, digestives, etc., often assumes a different aspect when the neuro-vascular discipline produced by this treatment is secured. The effect of increased oxygenation may be greatly aided by following daily treatment with exercise in the open air. The pallid lips assume a ruddier hue, the languid eye brightens, the step becomes lighter. Appetite and assimilation are improved because of the enhanced hæmatosis and improved circulatory conditions in the gastro-intestinal mucous lining. (For rationale see above.)

Neurasthenia.—A type of cases which I see quite often is that trying class of neurasthenics who wander from one doctor's office to another, and sooner or later become the prey of charlatans. These patients present every phase of depreciated vascular and nerve condition; some are the prey of morbid fears and become the despair of family, friends, and physician. If such a case be subjected to a methodical course of hydrotherapy the result will often prove a revelation, provided there be no organic basis for the malady. If mild procedures do not meet the indications, douches adapted with regard to temperature, duration, and pressure to each individual case, play the most important rôle here. These are capable of arousing the dormant neurons, enhancing vascular activity, and improving general and local nutrition. The cortical centres, which are the chief points of failure in these depressed neurasthenics, feel the impulse of a better circulation and nutrition. The morbid ideas and illusions vanish. The hypochondriacal introspection ceases, and the patient slowly but surely regains his neuro-vascular equilibrium. The results of hydrotherapy in such cases are, in my experience, far more enduring than those following other methods of treatment.

Insomnia is markedly affected by hydriatric measures.

Rheumatism, Sciatica, Gout, Neuritis.—Another set of cases which are greatly benefited by hydrotherapy are those unsatisfactory rheumatic, gouty, and lithæmic conditions which are the bane of the doctor's life and which we are often so glad to rid ourselves of by sending them to the hot springs. These may be very satisfactorily treated at home.

My personal experience with hydrotherapy in chronic diseases extends over a period of ten years and embraces a very large number of cases of the most varied pathological conditions. The application of this method of treatment to such varied diseased conditions is rendered possible by its flexible nature, which enables the physician to adapt it, by modifications of temperature, pressure and duration, and numerous technical details, to the most varied pathological manifestations, provided he has mastered the rationale of its mode of action, and provided the carrying out of the details is not left entirely to the judgment of bath-nurses It would be much better to consult some work on hydrotherapy than trust the latter.

When douches are needed, only institutions under the supervision and direction of a trained physician should be resorted to, for in no other way shall we be likely to avoid the dangers of the empirical application of the procedure, which has so often brought disaster to both and discredit to this remedial agent. *Simon Baruch.*

HYDROXYLAMINE.—This compound base is very unstable and exists only in solution. It is ammonia in which one atom is replaced by the hydroxyl group. The formula is NH_2OH. *Hydroxylamine hydrochloride* forms in colorless crystals resembling ammonium hydrochloride; it is hygroscopic and very soluble in water, alcohol, and glycerin. It possesses active reducing properties, in consequence of which it has been proposed as a substitute for chrysarobin and other reducing agents in the treatment of skin diseases, such as psoriasis, parasitic affections, and in lupus. The disadvantage attending its use is the toxic symptoms that may arise from absorption. These ill effects are due to its reducing action on the hæmoglobin of the blood. It may also prove very irritating to the skin. For ordinary use, a strength of one part in a thousand should be commenced with and increased to one in a hundred, if no local irritation is produced. The application may be made twice or three times a day. *Beaumont Small.*

* See author's treatise mentioned on p. 788.

HYÈRES AND COSTEBELLE.—Hyères, situated in the department of the Var, is the most southern of all the winter stations along the French Riviera. It is fifty-five miles southeast of Marseilles and seventy-two and a half miles west of Cannes. Unlike the other Mediterranean resorts, it is three miles from the sea, lying at the foot of a steep hill having an elevation of about seven hundred feet. It is sheltered by the mountains from the north and northeast winds, but exposed to the northwest and west winds; hence it suffers, like the other resorts on the coast, from the disagreeable "Mistral," which is especially frequent in February and March. It is less affected by the sea breezes, not only on account of its distance from the sea, but also on account of the protection afforded by the islands lying off the coast—the Isles d'Hyères.

Costebelle, a suburb of Hyères, consisting of a few houses and several hotels surrounded by pine woods, is almost on the coast, so that patients can easily have the change from the more sedative air of Hyères to the more bracing and stimulating atmosphere of the seaside.

The town of Hyères itself contains 17,700 inhabitants, and consists of the old and the new town, the latter being the resort of invalids and visitors,—a place where there are villas, hotels, fine avenues, and public gardens.

The winter climate is mild, dry, and sunny, but, as has been said, there exists the one great disadvantage of the cold northwest wind (mistral). "Favorable as I believe this station to be," says Cazalis, quoted by Burney Yeo, "up to the time that the mistral begins to blow, equally dangerous do I believe it to be from that moment." "It is a most searching wind," says Cormack ("The French Riviera—Hyères as a Health Resort," *The Climatologist*, January 15th, 1892), "and very trying to invalids and those of a nervous temperament. Patients, as a general rule, are much better at home than out of doors while it lasts."

Climatic Data of Hyères. (From Biden and Cormack.)

	November.	December.	January.	February.	March.	April.	Mean of six months.

* At midday and 8 A.M.

In looking over the climatic table of Hyères arranged from data of Drs. Biden and Cormack, it will be observed that the mean average temperature for the months from November to April inclusive, does not vary very much from month to month. Neither do the extremes appear to be very great. The average daily range is large, owing to the rapid fall of the thermometer after sunset, which frequently amounts to as much as seven or eight degrees.

Between the hours of 8 A.M. and 4 P.M., however, says Cormack, the winter temperature may be said to vary between 50° and 59° F. in the shade, and from 75° to 85° F. in the sun. Occasionally the freezing point is reached. The air is moderately dry, as indicated by the relative humidity, and there are no mists. The rainfall is small, and for the six months rain falls on an average only on 39 days.

There is a very large amount of sunshine, an average of 135 days out of a possible 181 days, or three-fourths. There is an average of 22 days of light winds and 22 of strong ones. If the winds, especially the mistral, could only be eliminated, this resort, as indeed the others of the Riviera, which in like manner suffer, would be most delightful; but the health resort is yet to be discovered in which every climatic factor is favorable. As has been referred to in the article upon *Cannes*, the climate of the Riviera, in the writer's opinion, is far inferior to that of southern California, with which it is comparable, especially in temperature, dryness, the amount of sunshine, and, more than all, in regard to the winds. Southern California is free from high, cold winds like the mistral. In Southern California we have, moreover, that degree of equability which is nowhere found on the Riviera.

In like manner comparing the Riviera with southern Florida, we find that the climate of the latter possesses that measure of warmth and equability which is not found in the former, and is free from cold winds, though on the other hand, Florida is considerably moister than the Riviera. Speaking in general of the winter climatic characteristics of Hyères, we may say that they are mildness, purity of air, abundant sunshine, and moderate dryness. On the other hand, the chief feature of an unfavorable nature is the "fearful" mistral. "It rakes the valley from end to end, with no obstacle to stop it or turn it; it blows sometimes for six or seven days together, and nights too!" (Cazalis, quoted by Burney Yeo.) Although cold, this mistral is a very dry wind, and a wind which generally brings fine, clear weather. The air loses its humidity and becomes dry, cold, penetrating, and irritating. As has been before noted, it is not frequent until February or March.

The invalid's day, as given by Cormack (*op. cit.*), is comprised between the hours of 10 A.M. and 3 P.M. for the warmest months, and between 11 A.M. and 3 P.M. when the days are colder. At sunset there is a rapid fall of temperature which renders it dangerous for delicate persons to go out after that time. There is also a marked difference between the sun and shade temperatures, so that it is always wise to be provided with a wrap. The vegetation is luxuriant and varied. "The mountains and hills are covered with trees as green in the winter as in the summer." The orange, olive, and palm trees are seen on every hand. Roses, violets, anemones, hyacinths, etc., are sent in great quantities during the winter to the European markets, and early fruit and vegetables are cultivated for the Paris market. There are many charming and picturesque promenades, and in this respect, says Burney Yeo, Hyères is much better off than most other resorts on the Riviera. The outdoor diversions are many and varied; botanizing, butterfly catching, antiquarian research, boating, fishing,, golf, tennis, etc., are some of them. The valley in which Costebelle is situated is better sheltered from the mistral, and is "enbosomed in pine woods, broken here and there by vineyards and olive orchards. . . . Near the shore there are large groves of olive trees, which are finer than at Hyères itself, and indicate a warmer climate" (Sparks, "The Riviera"). The water supply of Hyères is said to be good and the sanitary condition satisfactory, except in the old portions of the town. The accommodations are good and abundant.

As to the class of invalids for which the climate of Hyères is beneficial, the testimony is conflicting. Cormack says it is "admirably suited for cases of phthisis," while Drs. Sparks, Weber, and Yeo, says Richards, are rather non-committal. In the writer's opinion, the value of this climate for phthisis is very slight, and while there are so many other resorts of approved value for this disease, he would never think of sending a phthisis patient there, for the reason that the cure cannot be a continuous one on account of the heat in summer, and, secondly, on account of the winds, especially the mistral.

Of other diseases said to receive benefit here, there are mentioned various bronchial affections, liver complaints, Bright's disease, diabetes, asthma, heart disease, rheumatism, gout, and the feeble condition of delicate children. This resort is also suitable for that large class of the feeble from age or other cause who sustain life with less effort in any mild, sunny climate like this; and, finally, for that class who temporarily are worn out with all the demands of city life, who desire a change, *per se*, and who prefer a place where they can lead a simple life out of doors under sunny skies and in pure air, and devote themselves to rest, and freedom from exacting business or social duties. *Edward O. Otis.*

HYGROMA.—The term "hygroma" has been applied to a variety of conditions involving cyst-like spaces filled with fluid. Thus, widely different processes have been classified under the same head. It seems desirable to abandon the use of the word and to apply to the various conditions names more suggestive of their pathology. An increase in the amount of fluid in a tendon sheath leads to the formation of a cyst sometimes called hygroma. The term has been applied also to synovial bursæ distended with fluid.

Hygroma Congenitum Colli.—This term has been applied to a form of lymphangioma of the neck. The admirable description by König ("Lehrbuch d. speciellen Chirurgie," i., 528, 1893) has been largely drawn upon in the following account.

The tumor is present at birth. The surface is irregular and the tumor itself is lobulated. The lobules sometimes fluctuate, and at other times are very tense. The location is almost always in the submaxillary region. It may grow very rapidly and become very large. In this case it involves the entire anterior surface of the neck, extends to the face, and hangs over the clavicle and sternum upon the thoracic wall. Cystic lymphangiomata may also occur over the clavicle and on the dorsal surface of the neck. The ventral tumors may penetrate toward the pharynx, larynx, and œsophagus, and disturb the functions of these organs. The skin over the tumors is usually thin and may be even translucent. The growth is very prominent, and the portions lying directly over the great vessels may pulsate.

The functional disturbances in many cases are not marked; in others pressure upon the organs of the neck leads to dysphagia and dyspnœa and congestion of the vessels of the head. The patients may succumb to these symptoms, but this is not the rule. The prognosis is unfavorable, as the majority of the cases soon become cachectic and die. Operation usually hastens the fatal result.

The tumors occupy the subcutaneous and deep connective tissues, extending close to the vertebral column. They displace and may infiltrate organs, as do the malignant tumors. They are multilocular and consist of relatively thin connective-tissue walls which may be lined by endothelium. They are filled with a clear or yellowish liquid, which as a result of hemorrhage may become thick and chocolate-colored. The larger cysts are usually superficial; the smaller ones lie more deeply in the tissues, even at the base of the skull, in the mediastinum, and about the trachea and œsophagus.

In the tumors there occur spaces in the connective tissue of various forms which are not separated from the connective tissue by any special membrane. The larger spaces are rounded in form, or are divided into pockets by septa springing from the wall. They communicate with each other by larger or smaller openings.

It is probable that the spaces arise secondarily, because the smaller they are the more clearly defined are the communications. The smallest spaces consist of a system of vessels constricted at irregular intervals, or of a cavernous tissue whose lumina present an anastomosing system of channels. In either case the condition is continuous with a system of small anastomosing vessels, whose lumina are cylindrical or cleft-like, and have the characteristic distribution of lymph vessels. The spaces and channels are lined by endothelium.

The cystic spaces, then, consist of enlarged and distended lymph vessels. According to König this view is supported by Köster, von Winiwarter, Wegner, and others. It was formerly held by Rokitansky, Virchow, and Arnold that they originate from the connective tissue.

Perhaps most of the forms observed in adults originate in the same way. In these rare cases the tumor usually contains only a few cyst-like spaces and occurs near the trachea or in the region of the clavicle. It is possible that some of them originate from aberrant thyroids.

It seems desirable to abandon the name "hygroma" for this condition, and to use instead, "lymphangioma," a term more suggestive of its pathology.

H. S. Steensland.

HYGROPHILA.—The herb, also the seeds, of *H. spinosa* T. And. (fam. *Acanthaceæ*), an annual or biennial plant of India, very largely used medicinally by the natives. The herb contains a crystallizable body which is probably alkaloidal; the seeds; considerable gum; and much fixed oil, with indications of an alkaloid (*Hooper*). The drug acts as a diuretic and has been sparingly used as such in British practice. It has also been marketed as an adulterant of chiretta. *Henry H. Rusby.*

HYOID BONE, FRACTURES AND DISLOCATIONS OF.—Of the few cases on record of fracture of the hyoid bone, three were produced by hanging; three by the throat having been seized between the thumb and fingers; three by direct blows or falls upon the front of the neck; and one by muscular action alone.

In those cases in which the injury was produced by hanging, the body of the bone was broken. In all of the other examples the fracture involved one of the great cornua, or occurred at the junction of the cornua with the body. Crepitus is generally absent. In two of the recorded instances the adjacent mucous membrane of the pharynx was ruptured.

The symptoms observed have been a sudden sensation as if a bone had been broken; in a few instances a profuse bleeding from the fauces; difficulty in opening the mouth; in some cases dysphagia and aphonia; pain in movements of the tongue, with, usually, more or less swelling about the neck, and ecchymosis; later, cough, expectoration, and hoarseness. The circumstances which indicate with certainty the nature of the accident are unnatural mobility of the fragments, with or without crepitus, and an angular inward projection, which may generally be felt in a careful examination of the pharynx. The accident can be regarded as dangerous only in view of its complications. Of three cases in which it resulted from a direct blow only one survived, while of three resulting from lateral pressure upon the cornua all recovered.

The amount of difficulty in replacing the fragments of the bone will depend largely upon the extent of displacement and the consequent laceration of the neighboring tissues. An attempt should be made to accomplish replacement by introducing one finger into the mouth, while, with the opposite hand, the fragments are supported from without. From the nature of the parts, any attempt at the application of a splint or support will be useless.

Rest to the parts, together with general measures to allay inflammation, will generally constitute the available treatment.

Luxation of the hyoid bone is a very rare accident. The principal symptoms noted have been pain at the seat of injury and difficulty in swallowing. In a case observed by Daly (*Archives of Laryngology*, vol. i., p. 162) luxation of the left cornu had been of frequent occurrence, caused usually by laughing or yawning. A laryngoscopic examination showed no internal lesion. Reduction was effected by grasping the throat firmly with the thumb and index finger of one hand, steadying the head with the other hand, and then directing the patient to swallow vigorously, while at the same moment the parts were compressed between the thumb and finger, and then quickly released again. After the third effort the patient suddenly declared that he was relieved, and, in proof of this, he moved his head rapidly in all directions with ease and comfort, and drank successfully a glass of water.

D. Bryson Delavan.

HYOSCINE, SCOPOLAMINE.—($C_{17}H_{21}NO_4$.) An alkaloid obtained from henbane and scopola, and existing in other Solanaceæ. It occurs as a thick, colorless syrup, soluble in alcohol, only slightly in water, but all its salts form in large, white, prismatic crystals, freely soluble in water, insoluble in alcohol and ether. The salts also resemble each other in therapeutic as well as physical properties. The hydrobromate, hydrochlorate, sulphate, and hydriodate are prepared, and the first-named is official.

As a mydriatic, it is rapid, energetic, and brief, but its action is readily maintained. During the administration of the drug its effect on the pupil is an early symptom. Dilatation is said to be more marked with a one-fourth to one-half-per-cent. solution than with a one-per-cent. solution of atropine; it has to be used with caution on account of the readiness with which the system is affected. In this direction, therefore, it is to be classed with atropine. For its effects upon the peripheral nervous system, and upon the secretions, the action of atropine may also be consulted. Centrally, however, its action is very different. The stimulant action so characteristic of atropine is here present, if at all, only as a very brief primary stage, and is followed by sedation, or depression, which constitutes the characteristic action of the drug. In very sensitive subjects the period of excitement may be prolonged, but usually it constitutes the slightest preliminary stage, and is followed by drowsiness, and if the dose be full, by a natural sleep. The spinal centres are similarly depressed, especially the reflexes. Depression of the sensory centres is very mild and does not materially affect painful conditions. Circulation and respiration are both reduced, though the pulse rate is increased.

Its toxic action is shown by the dilated pupil, rapid pulse, relaxed arteries and redness of the surface, dry, hot skin, rapid breathing, and coma and convulsions. Therapeutically, hyoscine has come into prominence as a sedative and hypnotic. It has largely supplanted morphine in the treatment of acute mania and delirium tremens, in restlessness, in the violent manifestations observed in all forms of mental disorders, and in hysteria and epilepsy. Its sedative action is very rapidly produced, and in the majority of cases a calm and refreshing sleep ensues. From this sleep the subject can be readily and completely roused. When pain is the cause of insomnia, the remedy is not of much service. Its action is purely calmative and sedative on the brain, and it should not be administered as a powerful or decided hypnotic. In insomnia it is applicable only in cases in which this arises from central or nervous excitement. In mania, and when there is much excitement, it should be given in full doses of gr. $\frac{1}{60}$ by the mouth, or gr. $\frac{1}{120}$ to $\frac{1}{100}$ hypodermically; a small dose is generally sufficient. When the symptoms are less acute, smaller doses should be given.

Hyoscine has also proved itself very efficient in the treatment of chronic mania and all nervous affections accompanied by mental restlessness; also in nervous diseases characterized by debility and tremors, as in paralysis agitans, disseminated sclerosis, and chronic alcoholism. In these cases the stimulating action of small doses is taken advantage of, and gr. $\frac{1}{200}$ daily or twice a day is a sufficient dose. Its antispasmodic action is also secured with the same small dose, and it may be used, and with benefit, in chorea, asthma, and other spasmodic troubles of a nervous origin. The system readily becomes accustomed to it, and calls for increasing doses. When cardiac disease is present the use of hyoscine should be avoided or it should be given with great caution, on account of its depressing action on the heart and circulation.

The early physiological effects of the drug are manifested far in advance of dangerous symptoms, but in some cases very severe toxic symptoms have been produced by doses of gr. $\frac{1}{20}$ and $\frac{1}{10}$. Pilocarpine and morphine are physiological antidotes. The former has proved very serviceable and may be administered freely, as much as two grains having been required in a case of delirium tremens in which a comatose condition followed frequent doses of hyoscine.

Henry H. Rusby.

HYOSCYAMINE, HYOSCYAMINA. — ($C_{17}H_{23}NO_3$.) An alkaloid obtained from henbane and also existing in other species of *Hyoscyamus*, and in belladonna, stramonium, and other *Solanaceæ*. Professor Ladenburg demonstrated that atropine, daturine, and duboisine are identical with hyoscyamine, both in chemical constitution and in physiological action. Any difference is to be found in the molecular arrangement of the constituents, and not in any fundamental change. The terms "atropine" and "hyoscyamine" have been applied to the heavy and light mydriatic alkaloids obtained from the belladonna and henbane plants, the former being the heavy and the latter the light alkaloid. It is now known that both the heavy and the light alkaloids may be obtained from either plant, according to the process of manufacture. The light may be converted into the heavy by melting under reduced pressure, by the addition of caustic soda to its alcoholic solution, and in other ways.

Hyoscyamine occurs in light, silky, snow-white crystals, without odor, soluble in one hundred and twenty parts of water, freely soluble in alcohol, and in acidulated water. There is also an uncrystallized or amorphous hyoscyamine, of a dark-brown extract-like mass, with a strong disagreeable odor. This appears to be a mixture of the various alkaloids and extractive matters. A sulphate, hydrochlorate, hydrobromate, and hydriodate of hyoscyamine are prepared, the first and third of which are official; they are alike in degree of strength and character, forming white, fine crystals very soluble in water. A sulphate and hydrobromate prepared from the amorphous alkaloid are amorphous, deliquescent salts, and less active and certain in their effects.

The therapeutic properties of hyoscyamine are very uncertain. At times it exactly resembles atropine, at others quite closely hyoscine. The cause of this variation is not determined, but it appears probable that it is due to the presence respectively of atropine and hyoscine in the commercial article, as such is the effect when these impurities are known to exist. The degree of activity is equally variable. It is normally weaker than both atropine and hyoscine, and is often so weak as to require doses which would be dangerous in the case of either of those alkaloids. On the other hand, alarmingly poisonous symptoms sometimes follow the ordinary dosage, which is larger than that of the others. The presence of the amorphous salts in the market is the source of much of the uncertainty of its action, and the cause of many of the toxic symptoms. The dose of these salts is usually much larger, being from gr. $\frac{1}{8}$ to i., but they should never be employed. Even the "pure" alkaloid of Merck is given in one-quarter-grain doses, while his "chemically pure" alkaloid must not be given in excess of gr. $\frac{1}{50}$.

The mydriatic action of hyoscyamine is rapid and powerful, but not so manageable as that of atropine. Cases are reported in which it produced spasms of the ciliary muscle and intense pain and distress; the solution used was gr. $\frac{1}{4}$ to the drachm, and relief was obtained by placing in the eye a stronger solution of the same alkaloid. The toxic effects produced are the same as those of hyoscine, viz., dryness of the throat and mouth, and of the skin, accelerated pulse, dilated vessels, and excitement followed by convulsions and coma.

This alkaloid is employed as an hypnotic, nerve sedative, and antispasmodic, in mania, restlessness, delirium, insomnia, and all conditions accompanied by mental excitement; also in asthma, chorea, epilepsy, etc.

Henry H. Rusby.

HYOSCYAMUS. See *Henbane.*

HYPERIDROSIS is a functional disorder of the sweat apparatus accompanied by a more or less excessive increase of the normal amount of sweat excreted. This increase may be local or general. Local forms are symmetrically confined to certain regions such as the palms of the hands, soles of the feet, axillæ, or genital regions. Cases of unilateral excessive sweating, confined to one side of the body wholly, have been observed, but they are rare; of more frequent occurrence, although still not common, are the cases of unilateral sweating limited to one side of the head or to one limb. Usually intermittent, the sweating in some cases may be continuous and is aggravated by hot weather, emotion, depression of general health, etc.; and the disturbance may be temporary or permanent, depending upon its exciting cause. Subjects of the disorder are nearly always in a lowered state of health, sometimes hysterical and often nervous. The direct causes which lead to local hyperidrosis are quite undetermined. Examinations of sections from the palms of the hand fail to show any abnormal features of either the glands or the epithelium. The disorder is to be regarded as purely functional, connected with a disturbance of the vaso-motor control, no doubt, but as yet the exact links of the chain have not been definitely placed.

In the *treatment* of hyperidrosis, whether local or general, the condition of the patient's general health is of prime importance; the various ferruginous tonics, mineral acids, arsenic, strychnine, and quinine, are all of value. Belladonna and atropine, though but of temporary benefit, are of service at the outset of treatment in most cases. Cold baths for general toning of the circulation are strongly recommended. External treatment must be resorted to and is often very efficacious. In the local form that attacks the hands much benefit will be derived from immersing the palms for a few moments only in water as hot as can be borne, dabbing dry with a soft cloth, and then dusting on boric acid powder. The same treatment for the soles of the feet may be employed. A saturated alcoholic solution of boric acid dabbed on the palms during the day will control very well the excessive sweating of the hands that is so annoying to those who do much writing. Hebra's treatment for hyperidrosis of the feet consists of enveloping the feet, the toes separately, after thorough washing and drying, in strips of cotton cloth, over which is spread, to the thickness of a knife blade, his Unguentum diachyli. The parts are well bandaged and the patient may subsequently either remain at rest or pursue his vocation, wearing shoes and stockings that have not been previously used. In twenty-four hours the feet are redressed without washing, after dry rubbing and a dusting powder. This process is repeated daily for from ten to twenty days, after which a dusting powder, preferably boric acid, may be substituted for the local dressing. There occurs a parchment-like desquamation of the skin in thick, yellowish-brown flakes, beneath which is formed a new and at first tender, but apparently normal, epidermis. When the latter has lost its tenderness, the feet are for the first time washed with water. The process is to be repeated in case of failure.

Prognosis in any case of hyperidrosis is uncertain. At times treatment may meet with brilliant success; again, it is followed by complete failure. The disorder may disappear spontaneously, only to recur and prove obstinate to all measures. *Charles Townshend Dade.*

HYPERMETROPIA—H—(from ὑπέρμετρος, overmeasure, and ὤψ, eye—less correctly hyperopia; *Uebersichtigkeit*, Ruete, 1853; incorrectly *hyperpresbyopia*, Stellwag, 1855) is the name given by Donders (1860) to the abnormal refractive condition of the eye in which its principal focus—*i.e.*, its focus for parallel or practically parallel rays, such as are received from a distant object—lies at some point beyond the actual position of the retina. In H the antero-posterior axis of the eyeball is too short relatively to the focal length of the eye as determined by the radii of curvature of its three refracting surfaces, namely, the anterior surface of the cornea and the anterior and posterior surfaces of the crystalline lens, and in typical H the axis is actually shorter than in the normal or emmetropic eye. H is ordinarily an inherited condition, and may then be regarded as a result of incomplete development of the great posterior segment of the eyeball, in consequence of which the axis remains shorter than in the normal eye.*

The essential points of difference between the emmetropic and the hypermetropic eye are shown in Fig. 2758, in which the dotted outline represents in section the normal or emmetropic eye, and the continuous outline a hypermetropic eye. It is a property of the emmetropic eye, when in a state of accommodative rest (see *Accommodation and Refraction*), that the sum of the refractions at the surface of the cornea and at the two surfaces of the crystalline lens is just sufficient to unite all the rays of a parallel pencil, *A, E, B,* in a focus upon the retina at *E.* When the retina is so misplaced as to lie within the principal focus of the dioptric media, the pencil is cut by the retina before its rays have come together, and the image of a distant point upon which the eye is directed is formed at *H* as a circular spot of appreciable diameter (circle of confusion). What is true of a pencil of rays emanating from one point of the distant object is true of pencils emanating from other points of the same object; the inverted retinal image is, therefore, more or less confused, and all the finer details of the object are lost. This confusion of distant vision is experienced by every hypermetrope whenever his accommodation is fully relaxed, and it may be evoked artificially, in any case of H, by paralyzing the accommodation by instilling a drop or two of a mydriatic solution, such as atropine, into the conjunctival sac.

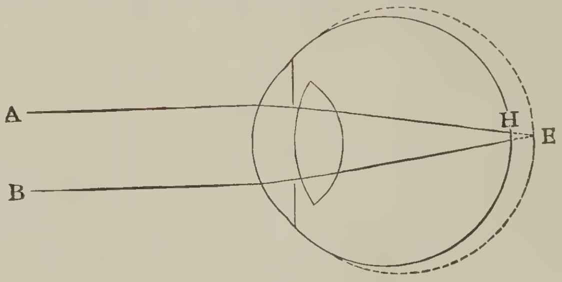

FIG. 2758.

As the emmetropic eye, when in a state of complete accommodative relaxation, is adjusted for the focussing of parallel rays upon its retina, so the hypermetropic eye is adapted for the focussing of rays of some definite degree of convergence. Fig. 2759 shows a convergent pencil, *A′, H, B′*, focussed upon the retina of the hypermetropic eye at *H*, and also a pencil, *A, H, B*, of rays originally parallel, but rendered convergent by passing

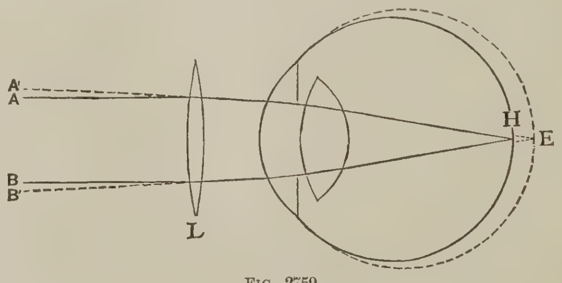

FIG. 2759.

---

* H is, in fact, the normal condition in the Quadrumana, and in the higher Mammalia generally.

through a convex lens, *L*. The hypermetropic eye receiving and focussing such a convergent pencil becomes practically equivalent to an emmetropic eye receiving and focussing a pencil of parallel rays, and as any required degree of convergence may be given to an originally parallel pencil by allowing it to traverse a convex lens of suitable power, so the vision of a hypermetrope may always be perfectly corrected for distance by wearing properly chosen (neutralizing) convex glasses.

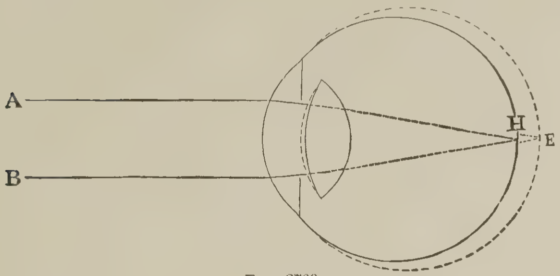

FIG. 2760.

H does not ordinarily give rise to defective vision at a distance so long as the range of accommodation (A) remains unimpaired, as in the case of young persons. The reason of this will appear from an inspection of Fig. 2760, which shows a hypermetropic eye adjusted for the focussing of a pencil of parallel rays, *A*, *H*, *B*, through the increase in the convexity of its crystalline lens incident to the act of accommodation. The focussing of the several pencils of rays which form the retinal image is here as perfect as in the case shown in Fig. 2759, but with the difference that some part of the accommodation is expended in advancing the focus from its normal position at *E* to the actual position of the retina at *H*, so that only the unexpended part is available for the further adjustment of the eye to meet the requirements of near vision.

Fig. 2761 shows a hypermetropic eye, in its condition of fullest accommodative adjustment, focussing a divergent pencil, *A*, *H*, *B*, emanating from an object situated at its nearest point of distinct vision. Fig. 2762 similarly shows an emmetropic eye focussing a more divergent pencil, *A*, *E*, *B*, emanating from a nearer object situated at its nearest point of distinct vision. Comparing these two figures, it will be seen that the near-point of distinct vision for the hypermetropic eye lies farther from the eye than the near-point of distinct vision for the emmetropic eye, so that the hypermetropic eye, as compared with the emmetropic eye, is limited in its region of adjustment for near vision (region of accommodation), and the higher the grade of H the greater the limitation.

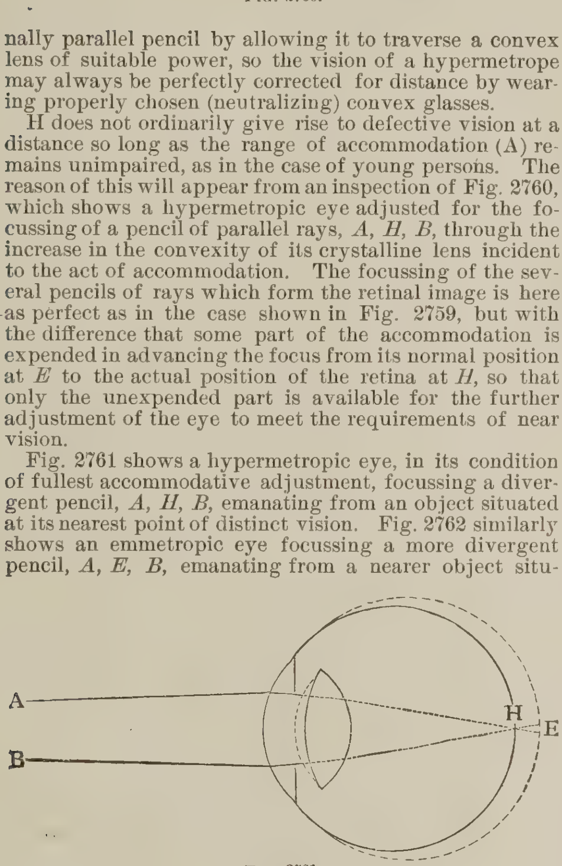

FIG. 2761.

In very high grades of H the absolute range of accommodation (A) may be insufficient, even in young persons, for the perfect focussing of parallel rays upon the retina, in which case H is said to be absolute (H *absoluta*). This condition is shown in Fig. 2763, in which the focus of the parallel pencil, *A*, *H*, *B*, which, without aid from the accommodation, would lie at *E*, is, through the full exercise of the accommodation, advanced to *H*, which, however, still lies behind the actual position of the retina at *Ha*. A point in the distant object, which in the emmetropic eye would be depicted as a point at *E*, is, therefore, actually depicted as a circular spot (circle of confusion) at *Ha*. Even under the full exercise of the accommodation this circle of confusion still remains a spot of appreciable diameter; the retinal image of the distant object is therefore made up of circles of confusion instead of points, and, although it may be improved in definition through the exercise of the accommodation, the picture remains confused in its details.

This distinction, in young persons, between H *absoluta* (H > A) and the lesser grades of H (H < A) is important. In H < A the hypermetrope is able to see at a distance by using only a part of his accommodation, and he has still a residual accommodative power sufficient to meet, in some measure, the requirements of near vision. He therefore forms the habit of using some part of his accommodation in every act of vision, and by a strong exercise of the same faculty he may even be able to read, although necessarily at the cost of excessive effort, and generally for a limited time only. Hence a hypermetropic child is apt to be judged harshly by parents or teachers, who, recognizing the fact that he is able to apply himself effectively to his books for a short time, are slow to comprehend that he becomes quickly wearied and is incapable of sustained application (see *Asthenopia*). In certain cases, however, impelled by the strong desire to see distinctly, the child learns to force his accommodation by concentrating an abnormally powerful impulse upon the two correlated functions of accommodation and convergence, and thus acquires the power of sustained application by sacrificing binocular vision and laying the foundation of a convergent squint. (See *Asthenopia* and *Strabismus*, also later in this article.) In H > A (H *absoluta*), on the other hand, distinct vision is impossible even at a distance, and, although the definition of objects may be considerably improved by a strong accommodative effort, it nevertheless falls so far short of perfect vision as not to offer a sufficient motive for continuous or prolonged exertion. In H *absoluta*, therefore, the case is apt to be regarded as one of defective vision, and glasses are perhaps tried at random until a pair of convex spectacles is found, which renders the use of the eyes comparatively easy. But even here prejudice may come in to deter a parent from permitting the child to

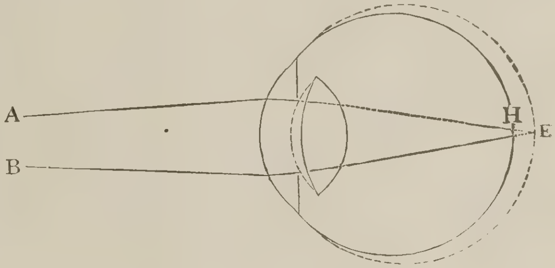

FIG. 2762.

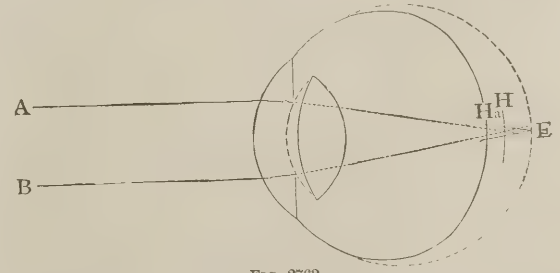

FIG. 2763.

wear spectacles "old enough for its grandfather," and efficient aid from glasses may be withheld.

H *absoluta* is but rarely met with in the first years of childhood, for the reason that at this early age the normal range of accommodation is very large; but often in youth, and still more in adult life, the progressive limitation of the range of accommodation comes into play to increase the disability of the hypermetrope, and, with advancing years, to render it complete. Thus all cases of $H < A$ pass sooner or later through the stage $H = A$ to $H > A$ (H *absoluta*), and the hypermetrope suffers in turn from disabilities incident to successive stages of his refractive anomaly, to find rest and distinct vision, perhaps after the lapse of many years, in convex glasses of which he should have had the benefit in childhood.

As the emmetrope at about the age of forty-five years has generally lost so much of his power of accommodation as to require aid from convex glasses to enable him to see distinctly at the usual reading distance of about one-third of a metre (twelve to fourteen inches), so the hypermetrope finds his near-point receding beyond this limit of distance at an earlier age dependent on the grade of H. Hence he will need convex glasses for reading, comparatively early in life, and will be compelled to change them from time to time for other glasses, which must always be of greater power than those which would suffice for an emmetrope of the same age. For the emmetrope the limit of power of the convex glasses required in old age for reading does not much exceed 5 dioptries; the hypermetrope, however, requires in old age reading-glasses of a power equal to $H + 5$ dioptries, which in an extreme case may amount to as much as $10 + 5 = 15$ dioptries, or even a little more, although generally much less than this. It will be observed that the limit of aid required by the hypermetrope is expressed by the sum of two quantities which are themselves limited, thus meeting the objection not infrequently urged by venders of spectacles, that a time will come when no glasses can be found of sufficient strength to admit of reading. In fact, the power of the convex glass which fully corrects the refractive deficiency in childhood will never require to be increased by more than four or, at most, six or eight dioptries to meet the further disability incident to loss of accommodation, to the diminution of the refractive power of the crystalline lens in old age, and to senile deterioration of the acuteness of vision. (See *Presbyopia;* also H *acquisita,* later in this article.)

We have seen (*vid.* Fig. 2760) that a hypermetrope who sees distinctly at a distance necessarily makes use of some part of his accommodation, and that he is compelled to accommodate in excess of the normal degree in order to see nearer objects distinctly. He thus forms the habit of associating some degree of accommodation with the act of directing the eyes upon any distant object, and he generally continues to accommodate to some extent even when he is made to look through neutralizing convex glasses. Hence it may happen that a hypermetrope will reject as incompatible with distinct distant vision not only such convex glasses as completely correct his refractive defect but even notably weaker convex glasses, and, in exceptional cases, this habitual tension of accommodation may be so great as even to simulate myopia. In such a case the grave mistake may be made of having recourse to concave glasses to correct a supposed but non-existent myopia, and so materially aggravating the actual disability.

We have, therefore, to recognize a hidden or latent H (H *latens*—Hl), which eludes discovery by the ordinary subjective tests made with convex glasses, and also a manifest H (H *manifesta*—Hm), which is readily detected and measured by this mode of examination. Thus we may have to do with a case of apparent emmetropia, or possibly even of apparent myopia, which, on thoroughly paralyzing the accommodation by atropine, turns out to be really a case of H; and in every case of H in a young person with normal accommodation we obtain, by tests with convex glasses alone, a measurement which falls notably short of the total refractive defect (H *totalis*—Ht) as measured by means of convex glasses after artificial paralysis of the accommodation.

Hl is then the expression of the degree of accommodative tension which persists during the fixation of a distant object, and the ratio which it bears to Hm is dependent upon the extent of the range of accommodation. Hence it is greatest in childhood, and it diminishes year by year throughout youth and adult life until, at the age of sixty, or perhaps somewhat earlier, it becomes wholly merged in Hm, which then becomes equal to Ht. $Hm = Ht$ is also realized as a pathological condition as a result of paralysis of the third (motor communis) nerve, or of its terminal branches, and it is produced artificially by the instillation of atropine or other sufficiently powerful mydriatic drug. It is also generally true that the hypermetrope relaxes his accommodation almost completely when the eyes are not in use, so that it is practicable, in a large proportion of cases, to measure Ht objectively by means of the ophthalmoscope, either by the direct method of examination or by employing the shadow test (see *Shadow Test*). More frequently, however, we first measure Hm subjectively, by successive trials with convex glasses, until we have fixed upon the strongest glass through which a test-object, such as the appropriate selection from the test-letters of Snellen, is seen distinctly at a distance of five or six metres, and then measure Ht by the use of the same test-letters at the same distance, after having fully paralyzed the accommodation by means of atropine or of hyoscyamine; we then calculate Hl by means of the equation, $Hl = Ht - Hm$.*

We have thus far considered H in its relations to A mainly as if it were a question of vision with a single eye; as a fact, however, we see with the two eyes at one and the same time, so that every act of binocular vision involves two simultaneous adjustments—namely, accommodation for some particular distance, and convergence of the axes of the two eyes upon the object for which they are severally accommodated. In emmetropia these two adjustments go hand-in-hand, so that parallelism of the visual axes is associated with complete relaxation of the accommodation, and convergence upon any near object is associated with accommodation for the same distance; or, taking as units of measurement the degree of accommodation required for distinct vision at the distance of one metre (1 dioptrie), and the degree of convergence necessary for single vision at the same distance of one metre (1 metre-angle), we find in emmetropia n units of accommodation (n dioptries) always associated with n units of convergence (n metre-angles). In ametropia this harmony of relation is essentially disturbed, for with convergence equal to n metre-angles the corresponding accommodation of n dioptries is either too great (in M) or too little (in H) for distinct vision at the distance of the point of intersection of the visual axes. Confining our attention to the conditions as they exist in H, we find that with convergence of n metre-angles the accommodation necessary for distinct vision amounts to $n + H$ dioptries; or, inverting the form of the statement, with accommodation of n dioptries, the convergence necessary for single vision is only $n - H$ metre-angles; in other words, any given degree of convergence calls for a relatively strong effort at accommodation to meet the requirements of distinct vision, and, *vice versa,* the degree of accommodation required for distinct vision must be associated with a relatively weak effort at convergence in order to admit of single vision with the two eyes.

The maximum of accommodation (*absolute* A) is attained only when the convergence is simultaneously exerted to the utmost, and even in emmetropia this involves a very strong crossing of one of the eyes. In H, however, excessive convergence is the rule in every act of accommodation whenever the conditions are such as not to admit of binocular vision, and *absolute* A is attained only in conjunction with even stronger crossing than in emmetropia.

---

* As a rule, Hl is less than Ht, and the latter is the arithmetical sum of Hl and Hm, but in the exceptional cases in which H simulates emmetropia $Hm = 0$: in the still rarer cases in which an apparent myopia gives place to H after artificial paralysis of the accommodation, Hm appears as a negative quantity, and Hl is greater than Ht.

H *absoluta* includes, therefore, only those cases in which, even under the condition of extreme crossing of one of the eyes, the accommodation is insufficient for distinct vision at a distance.

In convergence for any given distance the associated accommodation is found by experiment to be always less than when the convergence is for some shorter distance; in other words, every act of convergence not only compels an approximately proportional exercise of the accommodation, but inhibits, within certain limits, its greater exercise. Hence, in binocular vision, the *relative* A (A_1, *i.e.*, the range of accommodation as related to the convergence) is always less than the *absolute* A; we have, therefore, to recognize a type of H in which the *absolute* A is sufficient for distinct uniocular vision at an infinite or at some finite distance, but in which the *relative* A is insufficient for perfect binocular vision at any distance (H *relativa*).

In H *relativa* perfect uniocular vision is possible, not only for distant, but in most cases also for near objects, but only on the condition of crossing the non-participating eye.

It has been stated elsewhere that the link by which the accommodation and the convergence are tied together is not an absolutely rigid one. This is proved by the fact that, as a rule, perfect binocular vision is still possible when moderately strong concave or convex glasses, or convergent or divergent prisms, are placed before the two eyes. In the former case the convergence remains unchanged notwithstanding the altered accommodation, and in the latter case the accommodation remains unchanged notwithstanding the altered convergence; but to these adjustments of the convergence to varying states of the accommodation, and of the accommodation to varying states of the convergence, there is a limit well defined in each case, but differing in different cases. This binocular range of accommodation (A_2) may undergo considerable modification, according as it is habitually exercised in a negative or in a positive sense, and the ability to relax the binocular accommodation in M, or to force it in H, is usually considerably greater than in emmetropia, thus conserving in a measure the harmony of the two adjustments. Confining our attention to the conditions as they exist in H, we find that in moderate grades of H, with ample range of accommodation, it is often perfectly easy to accommodate accurately for a distance without convergence of the visual axes, and in many cases, at least in childhood and youth, also to accommodate and converge correctly for the ordinary reading distance, without conscious fatigue.

This type of H, in which binocular vision is perfect for a distance, and in which it may be also possible to read easily with the two eyes, is called H *facultativa.*[*]

As the power of convergence remains practically constant throughout life, while the range of accommodation diminishes progressively through the periods of youth and maturity until it is reduced to zero in old age, it follows that H *facultativa* is but an early, and often a quickly passing stage in the life-history of most hypermetropes, changing sooner or later to H *relativa*, and ultimately to H *absoluta;* nevertheless, the duration of each of these earlier stages is not infrequently measured by years, and may then afford abundant time to develop the characteristic disabilities and to work out the special tendencies to mischief incident to each type.

These disabilities and tendencies must now be considered in detail.

(*a*) In H *facultativa* binocular vision is perfect at a distance without glasses, and also with convex glasses of any power up to that which measures the manifest hypermetropia. In the case of many young hypermetropes, convergence for some short distance is also associated with good accommodation for the same distance, so that it may be possible to use the eyes easily in near work. In other words, the sphere of the habitual exercise of the accommodation (region of accommodation) has become so adjusted to the abnormal condition of refraction as to allow the two correlated functions of convergence and accommodation to work harmoniously together. This compensatory displacement of the region of accommodation is sometimes so perfect, in childhood and youth, that, even with Ht = 3 or 4 dioptries, the prolonged use of the eyes in reading or other close work may be unattended with fatigue, and in many other cases the available binocular accommodation proves equal to all ordinary demands upon it. A young hypermetrope may thus remain for years in complete unconsciousness of his defect, but sooner or later, as a consequence of the progressive physiological limitation of A, or perhaps of a temporary impairment of this function incident to some transient illness, or in connection with the change to a new vocation which calls for an unwonted exercise of the accommodation, he finds that his eyes are no longer equal to the demands made upon them. The inability to use the eyes continuously in near work may be first discovered in connection with the increased requirements of the higher grades in school, or the assiduous employment of the eyes in fine sewing. In other cases the disability manifests itself in early childhood, as when the eyes are first exercised in the more delicate tasks of the kindergarten, or in beginning the study of geography from maps crowded with names engraved in minute letters. Small near objects are, perhaps, still seen clearly for a little while, and apparently without great effort, but the accommodation soon becomes fatigued, and fine print then appears blurred, or may become altogether illegible. Under the strong stimulus of emulation, or dread of censure, the child may perhaps persevere in his efforts, though at the cost of physical and mental strain and with increasing sense of fatigue, until at length he is compelled to desist. After a short rest he may be able to resume his work, but only for a shorter time than before, and he soon finds himself unable to read at all. Thus the familiar picture of accommodative asthenopia is developed, to give place, sooner or later, to inability to see distinctly at the distance of the point of intersection of the visual axes (see *Asthenopia*).

(*b*) H *relativa*, by its definition, implies a state of conflict between the convergence and the accommodation at all distances. Either the two eyes are habitually directed upon the object, in which case the lagging accommodation is insufficient for the perfect focussing of the retinal images, or the accommodation asserts itself in a strong effort to see clearly with a single eye, and the axis of the fellow-eye assumes a crossed direction. The conflicting impulses on the one hand to focus perfectly for the distance of the object, in order to see it distinctly, and on the other hand to direct the two eyes accurately upon it, in order to avoid seeing it doubled, thus contend for the mastery until at length one of two alternative conditions is established—namely, distinct vision with a single eye, the other eye assuming a crossed direction (periodic or confirmed convergent strabismus), or single vision with the two eyes, but with insufficient accommodation and consequent imperfect recognition of the finer details of the object.

Any condition which detracts from the perfection of binocular vision may predispose to the development of convergent strabismus in the presence of H. Prominent among such conditions is an original or acquired imperfection of one of the eyes. Thus an imperfect eye is easily thrown out of use whenever the vision of the fellow-eye may be materially improved by so doing. In fact, we find that in by far the greater number of cases of strabismus the crossed eye is decidedly inferior to its fellow in visual acuteness, even though no structural defect is to be detected. Again, any pathological condition of one eye, attended with temporary or permanent impairment of its visual acuteness, may so detract from the importance of the part which it plays in binocular vision as to allow it to be easily excluded from participation in the act of vision. Under this category fall cases of strabismus, dating from the appearance of a corneal phlyctenula, or following the formation of a corneal scar. Again, it would appear that the faculty of perfectly controlling the convergence to meet the requirements of binocular vision is often more tardily acquired than that of perfect accommodation, so that a hypermetropic child with normal acuteness of vision in both eyes may acquire the habit of crossing one eye in order to see clearly with the other before he has become confirmed in the habit of using the two eyes together. In such cases the crossing is apt to alternate between the two eyes (strabismus alternans), and this alternation may either persist for years or may give place to the more common condition of habitual crossing of one and the same eye. A difference in the grade of H in the two eyes is often sufficient to determine the crossing of the more hypermetropic eye, and this in some cases even when this eye is in other respects somewhat the better eye.

---

[*] Donders, who made the first thorough study of hypermetropia, writing for English readers ("Anomalies of Accommodation and Refraction of the Eye," London, 1864), gave the name *facultative* H to this condition. In its French and Italian forms this word has a well-recognized meaning, and from these languages it has been adopted in German. In English it can hardly be said to be fully naturalized. Its meaning, as given in the "Dictionnaire de l'Académie," is "Qui laisse la faculté de faire ou de ne pas faire une chose; dont on peut, à son gré, faire ou ne pas faire usage." The writer of this article ventured, in the first edition of this HANDBOOK, to adopt a Latinized form of the word, with a view to more perfect uniformity of notation.

(c) H *absoluta*, the ultimate stage to which every case of H necessarily tends, has been already defined as a condition in which distinct vision is impossible, even under a maximum exercise of the accommodation conjoined with the strongest convergence. With the development of this absolute disability, the hypermetrope learns to desist from unavailing efforts at accommodation, and so finds relief from his asthenopia in enforced amblyopic vision. If in the previous stage of H *relativa* the excessive convergence has been limited to the times of actual exercise of the accommodation (periodic strabismus), now that no effort suffices for distinct vision, he learns, with the cessation of all attempts at accommodation, to abandon also the habit of crossing the eyes. Very pronounced strabismus may thus become decidedly less pronounced, or may possibly even disappear.

Paresis of accommodation, from impairment of the function of the ciliary nerves, is attended, even in emmetropia, by many of the characteristic symptoms of H; and when it occurs in a hypermetropic subject it may develop special conditions, which may be temporary or permanent according to the nature of the cause which underlies the paresis. Thus, in connection with the temporary paresis of accommodation not infrequently observed as a sequel of diphtheria, H *facultativa* is converted, at least for the time being, into H *relativa* or H *absoluta*, and H *relativa* into a higher grade of the same or into H *absoluta*. If the change is limited to the state of H *relativa*, vision becomes indistinct, or, more rarely, a true convergent strabismus appears, which may even develop later into permanent squint. Complete paralysis of accommodation, or paresis occurring in connection with a very high grade of H, develops, on the other hand, the condition of H *absoluta* with attendant indistinctness of vision at all distances and immunity from all tendency to crossing of the eyes.

Artificial paresis or paralysis of accommodation, evoked by the instillation of a mydriatic solution into the conjunctival sac, may play an important part, in the presence of H, by transforming H *facultativa* into H *relativa* or H *absoluta*, or H *relativa* into H *absoluta*, thus promoting in some cases and suppressing in other cases a preexisting tendency to strabismus. As a rule, incomplete mydriasis, when limited in its effect to the production and maintenance of the condition of H *relativa*, favors the development of strabismus, and may even evoke it in a case of H *facultativa* which might otherwise have passed gradually through the stage of H *relativa* to H *absoluta* without other symptoms than those of accommodative asthenopia with ultimate inability to see distinctly except by the aid of convex glasses. On the other hand, a condition of complete mydriasis, if long enough maintained, may, by rendering all efforts at accommodation unavailing, lead also to the abandonment of excessive exercise of the convergence, and so permit binocular vision to reassert itself even in a case of already developed crossing.

Myotics work a change in the relation of the accommodation to the convergence exactly the opposite of that produced by mydriatics. Under the influence of eserine, or of pilocarpine, H *absoluta* may be transformed, for the time being, into H *relativa*, or H *relativa* into H *facultativa*, or even into temporary emmetropia or myopia. Unfortunately, however, for the general applicability of this method to the amelioration of the condition of young hypermetropes, the known myotics are essentially transient in their effect, so that it is always difficult, and often practically impossible, to maintain a uniform degree of myosis for any lengthened period. In low grades of H in young persons the systematic instillation of very small doses of pilocarpine is often of use by assisting the accommodation for a time, and may thus be a valuable adjuvant to other measures, such as carefully regulated daily exercise of the eyes, in dealing with asthenopia when dependent in part upon temporary weakening of the accommodation. In the higher grades of H, and especially in middle and advanced life, the sphere of usefulness of myotics is extremely limited.

It has been already stated that H is ordinarily an inherited defect, the result of incomplete development of the posterior segment of the eyeball. Myopia, on the other hand, is generally an acquired condition, resulting from a pathological distention of the eyeball. It follows that a similar pathological distention, when it occurs in the hypermetropic eye, must necessarily be attended with a corresponding lessening of the grade of H. At a certain stage in this progressive distention H may thus pass into the condition of emmetropia, though with a thinned and weakened eyeball especially prone to further yielding of its coats under the continued action of the distending force. That a change from H, through emmetropia, to myopia, is of not infrequent occurrence is proved by the fact that individual cases of H in young persons, when examined at intervals of several years, often show a progressive diminution in the grade of H, or even a transformation into emmetropia or myopia. The statistics of the refractive condition of the eyes of large numbers of school children, showing a progressive decrease in the proportion of cases of H and a corresponding increase in the proportion of cases of myopia in the higher as compared with the lower classes, also the occasional occurrence in hypermetropic, emmetropic, or slightly myopic eyes of pathological changes in the fundus, such as are ordinarily found in the higher grades of myopia, point unmistakably in the same direction. The disappearance of H through its transformation into a pathological emmetropia or myopia must, therefore, be recognized as a possible, though, in most cases, an undesirable, event, and this possibility should always be kept in mind in weighing the indications for and against operative intervention in the treatment of strabismus in young children.

A form of H dependent on a physiological increase in the focal length of the crystalline lens (H *acquisita*) is a frequent incident in advanced presbyopia. In old age the myopic eye becomes, from this cause, somewhat less myopic, low grades of myopia pass into emmetropia or through emmetropia into low grades of H, emmetropia is transformed into H, and H becomes appreciably increased in grade. Inasmuch as A has now become reduced to a comparatively unimportant quantity, acquired H is nearly always absolute, and so reveals itself as a true *hyperpresbyopia*, necessitating the use of convex reading glasses of a focal length somewhat shorter than the actual reading distance, and of weaker (neutralizing) convex glasses for perfect vision at a distance.

H *acquisita* may also occur as a result of flattening of the cornea from disease, in which case it is generally complicated by irregular, or sometimes by approximately regular astigmatism (H + Ah). In such cases the damaged eye not infrequently goes out of use, and, in the presence of H of the other eye, may become crossed. If, however, this eye happens to be the better eye, the very strong accommodative effort required for tolerably distinct vision may give rise to crossing of its fellow.

A pathological shortening of the focus of the crystalline lens is not infrequently observed in the incipient stage of cataract in old persons. H may thus pass into emmetropia, or through emmetropia into myopia, and emmetropia may be transformed into a grade of myopia sufficient to admit of reading without the aid of glasses. This seeming improvement, often called second sight, is however, only temporary, and is lost sooner or later in the progressive failure of vision incident to increasing loss of transparency of the crystalline lens.

The diagnosis of H turns on the fact that the hypermetropic eye, when in a state of accommodative rest, is able to focus only convergent rays upon its retina at or near the fovea centralis, and, conversely, that a pencil of rays given off by any point in the fundus at or near the fovea centralis must necessarily emerge from the eye as a divergent pencil (see Fig. 2764). The methods employed for the detection and measurement of H are either subjective, based upon the recognition by the patient of the strongest convex lens through which distant objects are seen with undiminished distinctness, or objective, based upon the recognition by the examiner of the degree of divergence of the efferent pencils emanating from the fundus. The subjective method is generally the more accurate, and is to be preferred whenever the patient has approximately normal acuteness of vision, together with sufficient intelligence and training to enable him accurately to define his perceptions. Objective methods are, on the other hand, invaluable in the case of young children, and also in the case of exceptionally stupid or illiterate persons of riper years. By the subjective method we first measure Hm by preliminary tests made without the use of a mydriatic and we may subsequently determine Ht by repeating the tests after having thoroughly paralyzed the accommodation by instillations of atropine or of hyoscyamine. By objective methods we obtain, in most cases, a pretty accurate measurement of Ht without having recourse to full artificial mydriasis, although it is often desirable, or even necessary, to dilate the pupil in order to secure a satisfactory view of the central portions of the fundus. Inasmuch as it is not ordinarily necessary to paralyze the accommodation, we may, with great advantage, avail ourselves of the rapid but transient mydriatic action of cocaine, which, besides sufficiently dilating the pupil for purposes of observation, has the additional effect, in many cases, of measurably controlling any existing nystagmus. A mixture of cocaine hydrochlorate with euphthalmin hydrochlorate, in a solution containing one per cent. of each, may also be used for obtaining transient dilatation of the pupil.

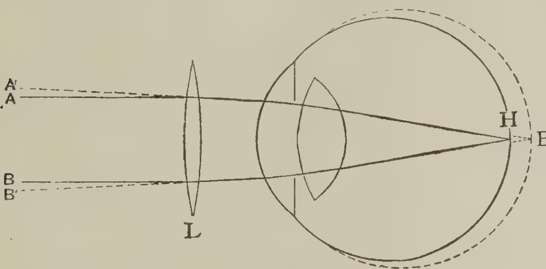

FIG. 2764.

In applying the subjective method we make use of a suitable test-object placed at the greatest convenient distance from the eye, usually the test-letters of Snellen hung upon the opposite wall of the room at a distance of say 5 metres, and direct the patient to read, with eyes well open, as many of the letters as he can. If vision is shown by this test to be of normal acuteness ($\frac{5}{5}$, or perhaps $\frac{5}{4}$), H *absoluta* and also myopia of any degree higher than 0.2 dioptrie are excluded; also any notable grade of astigmatism. H *facultativa*, or, under the condition of crossing of the visual axes, H *relativa*, may, however, be present. We next place a pair of weak convex trial glasses before the eyes, and again direct the patient to read as many of the test-letters as he can, using preferably another test-card with different letters. If through these glasses the acuteness of vision is still equal to $\frac{5}{5}$, we change the convex trial glasses for others of greater power, until we have hit upon the strongest convex glass through which the patient enjoys his maximum of visual acuteness. The value of this glass is the measure of Hm.* Having measured Hm, it is often possible to make a sufficiently accurate estimate of Ht by taking into account the degree of Hm and the age of the patient, but in other cases it is important to measure it directly. To this end we repeat the examination after having paralyzed the accommodation by the instillation of atropine or of hyoscyamine. Of these two agents the latter is the more powerful, and one or two instillations of a one-per-cent. solution are generally sufficient to produce full paralysis of accommodation in the course of an hour; if atropine is used it is generally advisable to repeat the instillation two or three times at intervals of half an hour, and to defer the examination for an hour or so longer. In many cases of H the accommodation yields more slowly to the relaxing influence of mydriatic agents, so that the full measure of Ht is obtained only after repeated instillations continued for at least twenty-four hours. Under the effective use of either of these mydriatics Hm and Hl become merged for the time in Ht, H *facultativa* and H *relativa* give place to H *absoluta*, certain cases of apparent emmetropia turn out to be actually cases of H *facultativa* in which H has been concealed by habitual tension of the accommodation, and a few cases of apparent myopia are shown to be really cases of emmetropia or of H, but simulating myopia through persistent accommodative tension.

The objective measurement of H is made with the aid of the ophthalmoscope by the direct method, using as points of observation the finest visible details of the fundus in the neighborhood of the fovea centralis. The best objects for this purpose are the smaller retinal vessels, which serve also for measuring any difference of refraction in the different ocular meridians (see *Astigmatism*), and the general texture of the fundus, which is usually distinctly granular. Under ophthalmoscopic examination, in a well-darkened room, the accommodation is generally found to be so far relaxed that the ophthalmoscopic measurement may be accepted as a very close approximation to Ht; the measure of Ht is then the strongest convex lens, placed behind the hole in the mirror, through which the details of the fundus are distinctly visible. This measure must, however, be corrected for the distance of the lens from the eye, and also for any ametropia which may be present in the eye of the observer.

Under full mydriasis an abnormally large area, both of the cornea and of the crystalline lens, is uncovered and brought into action in the formation of the retinal image, and it is not infrequently the case that, owing to a lower refractive power in the uncovered marginal zone, measurements obtained under atropine show a slight excess over Ht as it exists when the pupils are of normal diameter. It is therefore generally advisable, when glasses are to be given to correct the total hypermetropia, to prescribe them of a somewhat lower power than that indicated by tests made with dilated pupils.

The shadow test (retinoscopy, so-called; see *Shadow Test*) affords very accurate measurements. In common with the ophthalmoscopic observation of the fundus in the erect image, its results are wholly independent of the degree of vision which the patient may enjoy, and of the accuracy of his statements regarding his recognition of test-letters.

---

* In strictness, 0.2 dioptrie should be subtracted from this measure, to allow for the finite distance of 5 metres at which the test-card is hung; and in the case of glasses of short focus a further correction must be made for the distance at which the lens is placed in front of the cornea, which is ordinarily about 15 mm. As most measurements of the refraction are made for the purpose of selecting glasses, this latter correction is generally superfluous.

For a description of additional devices which may be employed for the detection and measurement of hypermetropia, see *Optometry.*

The discovery of H is oftenest made through the recognition, by the patient, of an inability to use his eyes freely in near work, and if he happen further to discover that the reading glasses of some elderly person are of assistance to him, he may perhaps select for himself a pair of convex glasses sufficient for his present needs; and, having once experienced the aid afforded by these glasses in reading, he will be very likely, in replacing them, to choose glasses of greater power, until at length he arrives at an approximate correction of his Ht. In this self-treatment he will, however, be very likely to encounter opposition from the spectacle venders, owing to a still somewhat prevalent notion that convex glasses are injurious to the eyes of young persons, and that the stronger the glass the greater the injury. He is liable, therefore, either to be deterred from using glasses of the necessary strength, or to procure and wear such glasses as enable him to read with comfort, though under protest and in the dread of "wearing out his sight" through having recklessly forestalled the aid which he is told should be reserved exclusively for old age.

In early childhood H is seldom discovered except by the oculist, who is generally first consulted in consequence of some peculiarity in the manner of using the eyes, or because of the discovery of a tendency to strabismus. The child is noticed to scowl when looking intently at distant or near objects, or he is observed, in reading, to contract the opening of the eyelids, so as partially to cover the pupils, and at the same time to hold his book quite near to the eyes, in order to increase the size and intensity of the retinal images. In other cases he complains that he cannot distinguish the letters in his reading-book, or he miscalls certain words through imperfect recognition of individual letters. Possibly he tries on his mother's or grandmother's glasses, and, seeing much better through them, asks for them to aid him in his lessons, which he then learns more easily and with unwonted correctness. Not infrequently he learns to see distinctly with one eye by crossing the other whenever he is compelled to fix his attention closely upon any small object (periodic strabismus), and the family physician is perhaps consulted because the child is becoming cross-eyed. Of this suggestion he too often makes light, and puts off the parent by saying that "the eyes will probably come right of themselves," or that "the child is too young to be treated for cross-eye," or that "there is no help for cross-eye until it has become fully established, and then only by a surgical operation"; and so he advises waiting "until the child is old enough to decide for himself." "Teething," "indigestion," "worms," "mimicry" of a cross-eyed companion or nurse, "looking at the tip of the nose" or "at a lock of hair," and many other imaginary or, at most, only secondary causes are often invoked, with the result of encouraging mischievous delay through the neglect of the primary and essential factor in the case, namely, the hypermetropic conformation of the eyes. Unfortunately for the child, there is just enough of plausibility in some of these suggestions to lead a physician to give the worst possible advice in a matter which he does not understand, and to encourage a parent to accept bad advice when given by his trusted medical adviser.

The treatment of H is by supplementing the deficient refraction (*i.e.*, deficient relatively to the length of the axis of the eyeball) by means of neutralizing convex glasses, the effect of which is to advance the position of the principal focus of the eye to the actual position of the retina. The hypermetropic eye with its correcting glass forms a compound dioptric system, whose nodal point is farther from the retina than is the case when the same eye is focussed for distance by the exercise of its accommodation; the retinal image is, therefore, somewhat enlarged by the glass, and when the correcting glass is placed, as is usually the case in wearing spectacles, at or very near the anterior focus of the eye (about 15 mm. in front of the cornea) the size of the retinal image is found by calculation to be the same as in the emmetropic eye. With the exact correction of Ht the hypermetropic eye becomes, therefore, practically emmetropic, with normal region of accommodation; no part of the accommodation is expended in focussing parallel rays in distant vision, and A is rendered available in its entirety to meet the requirements of near vision. H *absoluta*, H *relativa*, and H *facultativa* being alike reduced to emmetropia, the conflict between accommodation and convergence ceases, and the patient is relieved of his asthenopia and of any pre-existing tendency to crossing of the eyes in the act of accommodation for distant or for near objects. The neutralizing convex glass required for the exact correction of Ht is that which, under complete relaxation of the accommodation, gives the maximum acuteness of vision at a distance.

The accurate correction of Ht is, therefore, the end to be kept constantly in mind in giving convex glasses to a hypermetrope; nevertheless, it is often better to reach this full correction by successive stages. Thus a young hypermetrope with large Hl may find it impossible to relax his accommodation fully on first using convex glasses, and may, therefore, reject neutralizing glasses as impairing distant vision and compelling him to read or work at an inconveniently or uncomfortably short distance. On the other hand, he will probably take very great satisfaction in somewhat weaker glasses which correct, or perhaps slightly overcorrect, his Hm. After wearing such partially correcting glasses for a few days or weeks a larger fraction of Ht will have been rendered manifest, and the glasses may then be changed for others of shorter focus, and these again for others, until the full correction of Ht is reached. Proceeding in this way, we may give the patient from the start all the help which he can receive from glasses, and at the same time spare him the inconvenience and possible disqualification for work attendant upon the production of complete artificial paralysis of the accommodation. If the previous condition of the patient has been that of H *absoluta*, the glasses first given will fully correct the manifest hypermetropia, and will enable him to see distinctly at a distance, and also to read unless he is also presbyopic; if of H *relativa*, they will relieve the accommodation both in distant vision and in reading, and will in a great measure do away with the necessity for excessive convergence in order to see distinctly; if of H *facultativa*, they will make it possible to use the eyes for finer work and for a longer time without fatigue. In proportion as Hl becomes merged in Hm, through the wearing of the weaker glasses, the change to stronger convex glasses renews the good effect of the former, until at length the full correction of Ht is accepted.

When, through uncorrected H *relativa*, accommodative insufficiency or periodic convergent squint has been developed, these symptomatic conditions usually disappear with the wearing of neutralizing glasses, and the eyes recover the power of working easily and harmoniously together in binocular vision. As the glasses afford needed aid to the accommodation, as well in distant as in near vision, they should, as a rule, be worn constantly; and to this end they should be mounted as spectacles rather than as a *pince nez*, and should be fitted with elastic bows curved behind the ears (see *Spectacles*).

If convergent strabismus has become already established, the effect of convex glasses is first of all to do away with the causes which incite to further development of the squint, and thus to arrest it in its actual stage. Secondly, they tend to diminish the existing grade of deviation, and in some cases, especially of recent squint, they may even suffice to bring back the optic axes almost immediately to their normal direction, and thus re-establish binocular vision. In other cases the full effect of the glasses requires a much longer time for its complete realization, which may be attained only after the lapse of many months or even of several years. Hence we should not hastily despair of finally curing even a pretty high grade of strabismus, when associated with a high grade of H, by glasses, even though the immediate effect be conspicuously inadequate; in such a case the use of strong convex glasses will sooner or later become imperative, on account of the visual disabilities incident to a high grade of H, and if worn only after a full correction of the squint by tenotomy, they may easily determine divergence of the previously crossing eye. In the presence of a high grade of H resort should ordinarily be had to surgical procedures only after the complete correction of Ht, and after the lapse of sufficient time to develop the full effect of the optical correction.

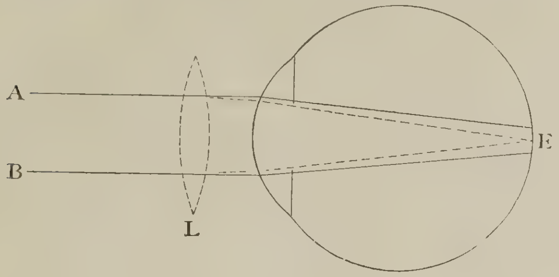

FIG. 2765.

The prompt correction of H by convex glasses is generally indicated on the first appearance of one or more of its characteristic symptoms (asthenopia, incipient strabismus convergens, or impaired distinctness of vision). They should, as a rule, be worn constantly during the waking hours, and it should be made clear to the patient, or in the case of a child to the parents, that they will probably be needed throughout life, in order to make it possible to use the two eyes easily and effectively in near work. Only in low grades of H, in which the rest afforded by weak convex glasses is not infrequently followed by a very marked amelioration of asthenopic symptoms, is it occasionally found practicable to lay them aside after this result has been attained (see also vol. i., pp. 583, 584, under *Asthenopia*).

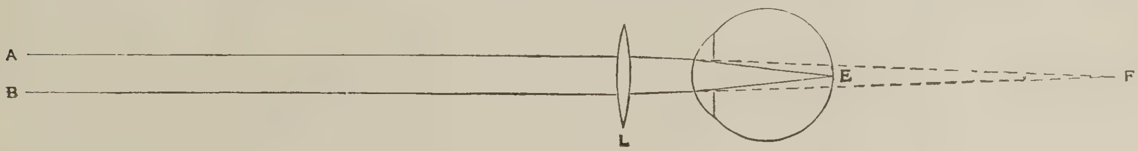

FIG. 2767.

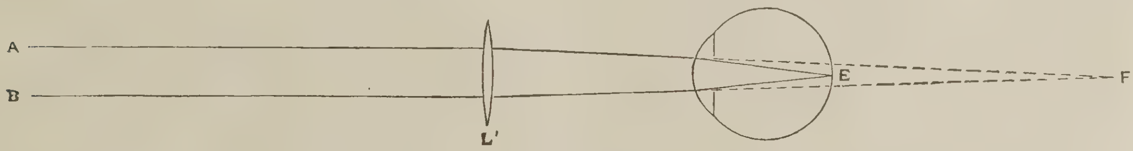

FIG. 2768.

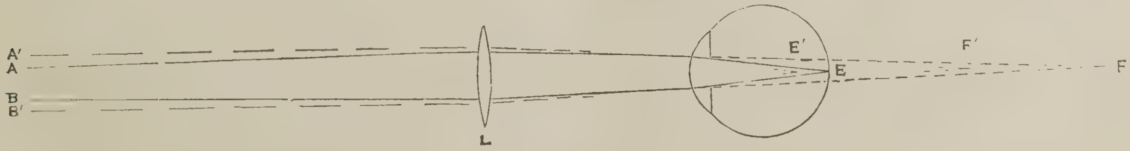

FIG. 2769.

APHAKIA.—Absence of the crystalline lens as a part of the dioptric system of the eye has been already noticed in this HANDBOOK (vol. i., p. 58). The deficiency in refractive power, as observed after the operation for cataract in an originally emmetropic eye, is so great as to necessitate the wearing of a convex glass of about 11 dioptries in order to raise vision to its maximum of acuteness at a distance, and a glass of 14 or 15 dioptries for reading. In the case of an eye previously myopic, a lens of less power than 11 dioptries suffices for distance, and for an eye previously hypermetropic a stronger lens is required. It follows that an eye with a pre-existing myopia of very high grade may, after the loss of its crystalline lens, be found to be nearly or quite emmetropic, and cases are occasionally observed in which, after an operation for cataract, no glass is required to bring out the maximum of visual acuteness for distance, and in which a convex glass of only 3 or 4 dioptries is required for reading. On the other hand, a glass of as high power as 20 dioptries may be needed for distance in a case in which there has been a pre-existing H of high grade, and a still stronger glass, of 23 or 24 dioptries, will then be required for reading.

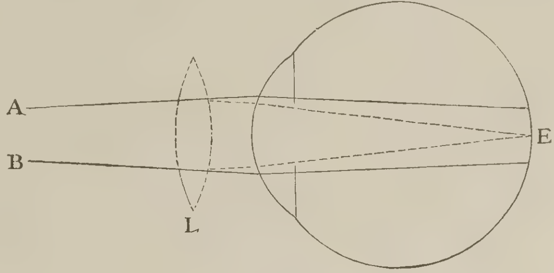

FIG. 2766.

As a consequence of the very great diminution in refractive power due to the loss of its crystalline lens, the unaided aphakial eye is unfitted for the performance of its proper function as a camera obscura. Fig. 2765 illustrates the insufficiency of the refraction at the cornea, in the absence of the crystalline lens, to focus the pencil of parallel rays, *A*, *E*, *B*, except as it is first converted into a convergent pencil by means of the convex lens *L*. Fig. 2766 similarly shows a divergent pencil, such as reaches the eye from a near object, rendered convergent by a stronger convex lens, to be focussed upon the retina at *E*.

Besides the diminished refractive power in the aphakial eye, there is also entire loss of accommodation. Hence the necessity for a stronger glass for near than for distant vision. The distance of the correcting-glass from the eye is, however, a matter of very considerable importance. Fig. 2767 represents an aphakial eye corrected, by the strong convex lens *L*, for focussing the pencil of parallel rays, *A*, *E*, *B*, upon the retina at *E*; the parallel pencil is converted by the lens *L* into a convergent pencil having its focus at a certain point, *F*, behind the retina, from which point the refractive power of the aqueous and vitreous humors, as determined by the convexity of the cornea, is just sufficient to advance the focus to *E*.

Fig. 2768 shows the same aphakial eye, with parallel rays focussed at *E* by the help of a weaker convex lens, L′, placed at a greater distance from the eye. In Fig. 2769 the lens *L*, which is of the same power as in Fig. 2767, is shown removed about an inch farther from the eye, and with its focus for parallel rays advanced, by the same distance, to *F′*, from which position the refractive power of the eye would advance it still farther to *E′*, which lies within the distance of the retina. A pencil, *A*, *E*, *B*, diverging from the conjugate focus of the lens *L* is, however, focussed by the lens at the distance of *F*, and, through the further refraction at the cornea, at *E*. By thus removing the correcting glass farther from the eye, we increase the refractive power of the combined dioptric system, made up of the lens *L* and the aphakial eye, and so may provide, in some sort, a substitute for the lost accommodation.

The position of the (single) nodal point of the aphakial eye (at the centre of curvature of the anterior surface of the cornea) coincides very nearly with that of the (second) nodal point in the perfect eye when in a state of complete accommodative relaxation. The effect of the convex glass worn in front of the aphakial eye (Figs. 2765, 2767, and 2768) is to form (with the eye) a compound dioptric system whose (second) nodal point falls farther forward (farther from the retina) than in the original (perfect) condition of the same eye. The retinal image formed by the help of the strong convex spectacle lens is, therefore, notably larger than the image of the same object in a normal eye of the same dimensions and corneal curvature. In the case of an aphakial eye wearing a convex lens of 13 dioptries 15 mm. in front of the vertex of the cornea, the ratio of the size of the retinal image to that of the image in the perfect eye is about 1.32 : 1. In the case of a convex lens of half the strength (6.5 dioptries), mounted 105 mm. in front of the cornea, the ratio is about 2.64 : 1, which is nearly equal to the magnifying power of an ordinary opera-glass.

Owing to the entire absence of accommodation in aphakia, Hl = 0, and Hm = Ht; hence all distinctions of Hm and Ht, and of H *facultativa*, H *relativa*, and H *absoluta* disappear, and the aphakial eye either sees distinctly, when it is perfectly corrected for the distance of the object, or indistinctly, when it is left uncorrected or is imperfectly corrected. The conflict between accommodation and convergence, which in H gives rise to asthenopia or to strabismus, has therefore no existence, and if either of these symptomatic conditions is developed in a case of uniocular aphakia, the causes must be sought elsewhere than in the aphakial eye.

Notwithstanding its great refractive deficiency, and the consequent imperfect definition of its retinal image, an aphakial eye, though uncorrected, may continue to take part with its fellow in binocular vision, and may thus render valuable service, not only by conserving the binocular field of vision in its normal extension, but also by aiding, to a useful extent, in the recognition of differences in distance (stereoscopic vision). Very often, however, binocular vision is not fully regained after the removal of an opaque lens, and the aphakial eye is then especially prone to acquire a false direction. In the presence of H in the fellow-eye, an aphakial or otherwise materially defective eye may become crossed; on the other hand, the co-ordination of function of the recti interni muscles of the two eyes with each other, and with the accommodation in the eye which still retains this faculty, may become impaired, and the aphakial eye may then gradually assume a divergent direction, notwithstanding the presence of such a grade of H in the fellow-eye as would ordinarily give rise to marked convergence. In acquired binocular aphakia, following a double operation for senile cataract, the convergence ordinarily remains fully under control, and, in the absence of pre-existing deviation of the axis of one of the eyes, binocular vision is generally retained.

In the otherwise perfect aphakial eye a properly selected convex glass restores nearly or quite normal acuteness of vision at the particular distance for which the correction is given, and, by reason of the considerable magnifying effect of the glass, vision may occasionally be raised even above the accepted normal standard of $\frac{5}{5}$. A moderate excess or deficiency of power in the correcting glass for distance is of no other importance than that vision is left somewhat deficient in acuteness, but reading glasses of excessive power may, in binocular aphakia, give rise to undue strain upon the recti interni muscles by bringing the reading distance too near to the eyes.

In uniocular aphakia, so long as the fellow-eye retains normal or nearly normal acuteness of vision and is without notable refractive defect, it is a frequent practice to leave the aphakial eye uncorrected. In cases in which the condition of the other eye is such as to call for the wearing of a correcting glass, it is generally practicable, and often desirable, to prescribe also the proper correction for distance for the aphakial eye. A tendency to divergence of an aphakial eye, in a young person, may often be arrested by wearing for a time a concave glass, of from 1 dioptrie to 3 dioptries, before the emmetropic fellow-eye, at the same time correcting the aphakial eye as accurately as possible for distance.

The first adequate description of H is by the English surgeon James Ware, in the Philosophical Transactions for 1813. Ware recognized the condition as "occurring in young persons"; as dependent on refractive insufficiency due to "a disproportionate convexity of the cornea or crystalline lens, or of both, to the distance of those parts from the retina"; as not involving "the power by which the eyes are adapted to see at distances variously remote" (*i.e.*, the accommodation); as "requiring a glass of considerable convexity to enable [the person] to see distinctly, not only near objects, but also those that are distant"; as of such a nature that "the same glass will enable many such persons to see both near and distant objects"; and as differing from the condition existing after the loss of the crystalline lens, the subjects of which "always require a glass, to enable them to discern distant objects, different from that which they use to see those that are near." In short, the description of the visual conditions in H *absoluta* and in most cases of H *relativa* is complete, and Ware is justly accredited by Donders with the discovery of H—a discovery which was, however, destined to remain almost fruitless for nearly half a century.

Ruete (1853) proposed the very appropriate name *Uebersichtigkeit* for this condition, but his description falls short of that of Ware in clearness and accuracy.

Stellwag (1855) described H correctly, as a condition in which the principal focal length of the eye is greater than the actual distance of the retina; but, in proposing for it the name *hyperpresbyopia*, he failed to emphasize its independence of accommodative insufficiency.

Donders (1859–60) first studied H exhaustively in its relation to different conditions of the accommodation, and gave to it its now universally accepted name. The present article is little more than a *résumé* of the principal facts established by that admirable physiologist, as embodied in his great work on the "Anomalies of Accommodation and Refraction of the Eye," New Sydenham Society, London, 1864.

John Green.

[For the convenience of the reader the following list of abbreviations used in this article is appended, following Donders, but with a few changes in form necessitated by the adoption of the modern metric notation.

H = Hypermetropia; Hm = H *manifesta*; Hl = H *latens*; Ht = H *totalis*; M = Myopia; A = Absolute range of accommodation; A_1 = Relative range of accommodation; A_2 = Binocular range of accommodation.]

HYPERNEPHROMA is a term suggested originally by Birch-Hirschfeld, and since adopted by other writers, to designate tumors that result from proliferation of adrenal tissue—it being immaterial whether the tumors arise in the adrenal itself or in regions where aberrant or misplaced (heterotopic) portions of adrenal tissue are known to occur. Though the terminology that suggests hypernephroma is not scientific, it finds justification in the peculiarities of structure of adrenal tumors and in the fact that the precise histogenetic position of the adrenal has not yet been determined. Lubarsch speaks of these tumors as hypernephroid tumors or tumors after the type of the adrenal with or without destructive characteristics.

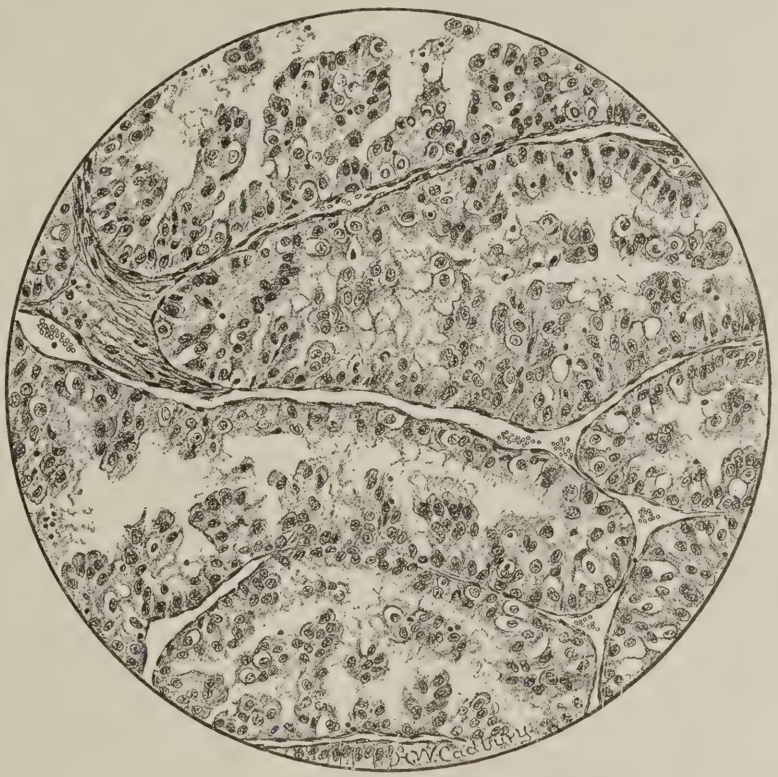

FIG. 2770.—Section of a Hypernephroma. Hæmatoxylin-eosin preparation. Zeiss apochrom, 8 mm., compens. oc. No. 4. For the most part the stroma consists of naked and intact capillaries that contain some blood corpuscles and that in some places are considerably dilated (more dilated than is usual). For the most part also the cells are attached directly to the endothelium of the capillaries, and they show marked fatty infiltration. In the section depicted the tumor presents large alveoli-like formations with central necrosis. In the upper right-hand region there are a number of high columnar cells.

During recent years considerable attention has been directed to the occurrence of *accessory adrenals* and to the great variety of displacements, in whole or in part, to which the adrenals are subject. Thus one or both adrenals may be absent; and the adrenal, if present, may be intimately adherent to the kidney and portions of its tissue may be displaced within the kidney. Accessory adrenals or portions of adrenal tissue have been found in the immediate vicinity of the normal situation of the adrenal, in the adjacent retroperitoneal connective tissue, in the kidney (usually directly beneath the capsule), about the renal blood-vessels, in the spermatic cord, between the testicle and the epididymis, in the inguinal canal, in the broad ligament (Marchand's adrenal), in the solar plexus, in the cœliac ganglion, in the liver, in the pancreas, etc. These accessory adrenals usually occur singly, though there may be more than one. They are yellowish in color, rather firm in consistence, and they vary in size. Usually they are about 2 to 3 mm. in diameter, but they may be so small as to be detected only by microscopical examination, and when the seat of hyperplasia or of tumor formation they may reach the size of a man's head. As a rule, they consist of one, two, or all three layers of the cortical substance; rarely medullary substance also is found. Schmorl states that they may be found in ninety-two per cent. of all bodies—a statement that has not found concurrence on the part of other observers. Presumably tumor formations may result from proliferation of any accessory adrenal; especial interest, however, attaches to the occurrence of adrenal tumors or hypernephromas in the kidney and in the broad ligament.

In the kidney adrenal rests are found usually at the upper pole of the organ, in the cortex, and directly beneath the capsule. Sometimes they are themselves entirely encapsulated, being separated from the subjacent kidney tissue by a band of well-developed fibrous connective tissue. In some cases through openings in this connective-tissue capsule portions of adrenal tissue invade the kidney, and in other cases no connective tissue whatever separates one tissue from the other. The kidney tissue adjacent to the misplaced adrenal tissue may present no deviations from the normal, but what is of especial interest and importance is that in some cases cysts, evidently dilated uriniferous tubules, are present at the junction of the two tissues, and that in other cases (as illustrated by one of my own cases) areas of kidney tissue are entirely or almost entirely included within these misplaced adrenal rests.

It is scarcely pertinent in this connection to discuss the different tumors of the adrenal that in a strict sense may be included within the scope of the designation hypernephroma. It will suffice to describe that class of tumors variously designated lipomas, adenomas, carcinomas, sarcomas, adenosarcomas, angiosarcomas, endotheliomas, and peritheliomas of the kidney—tumors the true nature of which was first recognized, in 1883, by Grawitz, who referred them to proliferation of aberrant adrenal rests. The opinions of Grawitz have been abundantly confirmed by Wiefel, Hollen, Ambrosius, Chiari, Strübing, Löwenhardt, Beneke, Horn, Marchand, Ulrich, Lubarsch, Askanazy, McWeeney, Manasse, Gatti, Ricker, Warthin, Pick, myself, and others.

Hypernephromas of the kidney (as well as hypernephromas of the broad ligament and of other structures) may be small and benign or large and malignant. The small tumors usually are situated in the cortex of the kidney; they are well circumscribed, generally encapsulated, nodular, yellowish or yellowish-white, and moderately firm. The larger tumors, which may attain a great size, replace more or less the kidney structure, though even in the largest tumors a narrow layer of compressed and distorted kidney tissue usually limits the tumor below. Usually, though not always, the tumor is separated from the remaining kidney structure by a more or less complete and intact connective-tissue capsule. In many cases, however, the capsule has become invaded and penetrated by the growth, and careful search is necessary to detect even remnants of it. It is nevertheless one of the characteristic features of hypernephromas. The tumor consists of spheroid or ovoid nodes that vary in size and are separated from one another by bands of connective tissue. Each node in turn is made up of smaller nodules into which as a rule but very little connective tissue penetrates. On section the growth is whitish (like brain medulla), or grayish-white or yellowish-white, sometimes reddish-white or brownish-white in color, opaque though sometimes glistening, and moderately firm in consistence in the well-preserved areas. The tumor exhibits a marked tendency to different retrograde changes, necroses, fatty metamorphoses, hemorrhage, etc., in consequence of which softening and pseudocystic formations may develop. True cystic formations are not uncommon, and in rare instances calcification may occur. The tumor may invade and finally penetrate the pelvis of the kidney. Invasion and penetration of the renal veins also is quite common, and in this way—that is, by way of the blood-vessels—if not exclusively, at least in the vast majority of cases, metastases may occur. These have been observed in almost all the tissues of the body.

On microscopic examination, the smaller hypernephromas reveal as a rule a well-formed connective-tissue capsule that recalls the capsule possessed by adrenal rests in the kidney; it may be complete, surrounding the tumor on all sides, or it may cover the tumor only on the surface. Even the larger and malignant hypernephromas sometimes are well encapsulated, and, even in those cases in which the capsule has become penetrated, remains of the capsule are often evident—a feature, as already pointed out, that constitutes one of the characteristics of this variety of tumor.

Histologically a hypernephroma is a tumor that consists of a stroma made up of a rather close network of capillaries, and of cells intimately associated with the capillaries and arranged in rows, columns, or masses within the meshes of the vascular network. The cells are epithelial in appearance and contain fat and usually glycogen. The tumor in cell-forms, cell-arrangement, and cell-contents reproduces or resembles the adrenal and certain tumors derived from the adrenal, and differs entirely in structural peculiarities from tumors derived from the uriniferous tubules.

The small and benign hypernephromas reproduce exceedingly well the structure of the adrenal and of certain tumors—so-called strumas or adenomas—that develop from the cortex of that organ. The larger and typical hypernephromas consist of nodules that vary somewhat in size and that are separated from one another by more or less delicate trabeculæ of connective tissue. As already pointed out, the stroma consists of a rather close network of capillaries. Frequently these are collapsed and scarcely apparent—whence in some cases on superficial examination, the tumor presents an appearance suggesting an adenoma for which it has frequently been mistaken. In many areas, however, the capillaries are quite apparent, and in certain areas sometimes they are much distended and more or less filled with blood. They may be demonstrated readily by injection procedures. The single layer of endothelium of which the capillaries consist is usually well preserved, though sometimes it may be the seat of some proliferation. In some cases the capillary stroma here and there is reinforced by a slight amount of connective tissue that proceeds as delicate trabeculæ from the connective tissue limiting the nodule. This is found especially in those tumors that present large alveolar-like formations and that are likely to be mistaken for carcinomas or alveolar sarcomas. In rare instances the connective tissue may exhibit some fatty infiltration.

The arrangement of the tumor cells within the capillary network recalls the zona fasciculata of the adrenal cortex, that is, the cells are arranged in rows or double rows, or in columns or cords. The tumor cells are attached directly to the walls of the capillaries—to the endothelium. This association of the capillaries with the tumor cells is one of the distinctive characteristics of hypernephromas and is absent only in those regions where a small amount of connective tissue reinforces the capillaries. The tumor cells vary somewhat in shape; for the most part they are polygonal, but they may be columnar, cubical, roundish, or irregular. The cell protoplasm is sometimes faintly granular, sometimes homogeneous, and exhibits usually rather large vacuoles—residua of extracted fat. The cells are epithelial in appearance and they contain one, sometimes two nuclei each, that are large, round, or ovoid; these stain well and reveal distinct nucleoli that are often metachromatic.

The arrangement of the cells into solid cords, though present in many tumors, is not so common as is their arrangement into rows and double rows with an intervening free space—an appearance extremely suggestive of adenoma formation (on superficial examination only, since the presence of the capillary network and the intimate association of the tumor cells with the capillaries immediately excludes all thought of adenoma formation). In these cases on cross section of the capillaries the cells appear attached to them as radii; on longitudinal section of the capillaries the cells appear arranged along the walls of the vessel in rows—palisades, as it were. On transverse section of the vessels that reveal the radial attachment of the cells, the attached ends of the cells frequently appear narrow and slender, their free ends swollen, rounded, and club-shaped. In these cells the nuclei are usually situated at the club-shaped extremity, though they may be situated at different heights, so that an appearance suggestive of a double layer of epithelium is produced. The free ends of a row of cells attached to one capillary in many areas are in contact with the free ends of a row of cells attached to an adjoining capillary. In many places between two adjoining rows of cells there is a space filled in part with cells similar in appearance to those attached to the capillary, and in part with cell detritus. These are especially common in those tumors that reveal rather large intercapillary spaces—tumors that morphologically resemble a carcinoma or an alveolar sarcoma. Into some of these spaces papillary excrescences appear to project a short distance.

The fat contents of the cells, though not uniform in all parts of the tumor, constitute a characteristic feature of hypernephromas. It is distinctly a fatty infiltration. In sections that have been prepared by the use of alcohol and ether the fatty infiltration is represented by vacuoles, that usually are large though they may be small. In some cases the fatty infiltration is so marked and the vacuoles are so large that only the nuclei and the outlines of the cells are to be detected.

Glycogen is a common constituent of these tumors. It is present in almost all cases, in all the tissues, and in different forms, generally as granules of varying size. In the differential diagnosis of kidney tumors, Lubarsch attaches considerable importance to the presence of glycogen, a substance that he believes is present in hypernephromas but not in true kidney tumors. This opinion is not shared by some other observers, and I have myself found glycogen in a primary cylindrical cell carcinoma of the kidney, as well as in tumors of other organs. Importance, however, it does possess.

Diagnostic importance attaches also to the presence in hypernephromas of intense black pigment granules, pigment granules similar to the pigment normally present in the adrenal cortex. In addition, considerable blood pigment, that gives the iron reaction, is usually found.

Lecithin, a substance to which Lubarsch, following Alexander, directed attention, and which Gatti found in a hypernephroma, may possess some diagnostic importance. This substance is found in the normal adrenal, in greater amount in the medulla than in the cortex. Gatti by chemical investigation found it in his tumor in amount approximating that of the normal adrenal cortex. As, however, we possess no microchemic reaction for its detection, it loses considerable of its otherwise possible differential diagnostic importance.

Variability in the histologic structure of hypernephromas has been repeatedly noted; they have been described as presenting an alveolar, a tubular, and a trabecular appearance. In some cases marked atypical proliferation may occur. Thus there may occur large alveolar-like formations in which only the cells directly in contact with the capillaries are well preserved, and these cells may be attached to the endothelium not regularly as palisades, but irregularly. The nuclei are frequently hyperchromatic and irregular; in some cases they exhibit karyokinetic figures. In some hypernephromas, generally large and malignant growths, giant cells, containing three, four, or more nuclei, may occur. Not infrequently the small veins are totally occluded by the tumor cells, and in this manner, that is, by way of the blood-vessels, metastasis occurs. The metastatic nodules reproduce the structure of the primary growth. As already pointed out, hypernephromas exhibit a marked tendency to the occurrence of hemorrhage and different retrograde metamorphoses. These are particularly manifest upon microscopic examination.

Especial interest attaches to the occurrence of cysts in hypernephromas. It suffices to mention that many so-called cysts may be merely dilated capillaries or lymph vessels. Other so-called cysts are doubtless but enlarged spaces between adjoining rows of cells of which mention has already been made—spaces more or less filled with degenerating cells and cell detritus. But other cystic spaces lined with well-formed cylindrical epithelium are evidently true cysts. Some time ago Ricker drew attention to the association of cyst formation and misplaced adrenal rests. He supposed that new growths of the adrenals may originate from misplaced kidney rests, and that certain tumors of more than ordinarily irregular formation—generally containing true cysts and therefore atypical hypernephromas—may develop from adrenal tissue that has either enclosed or is otherwise intimately associated with renal rests, commonly in the form of small cysts. My own investigations bear out the probable correctness of this opinion. I have already referred to the occurrence of cysts, evidently dilated uriniferous tubules, at the junction of adrenal and kidney tissue in some cases of misplaced adrenal rests, and to the partial or complete enclosure of kidney tissue within misplaced adrenal rests. It is warrantable to assume that, in the event of proliferation of the adrenal rests, the enclosed kidney tissue proliferates also, and gives rise to certain well-formed cysts with cylindrical epithelium.

As an additional proof of the adrenal origin of these tumors of the kidney, it is of interest to mention the similarity that they bear to tumors that develop in the adrenal itself and do not implicate the kidney.

The small and benign hypernephromas rarely give rise to clinical manifestations; commonly they are accidental findings at the necropsy. The larger and malignant hypernephromas give rise to symptoms that scarcely permit of their clinical differentiation from other tumors of the kidney. Hypernephromas occur at any age, even in new-born infants, though they are more common in adult life; they appear to occur more frequently in women than in men; they involve either kidney indiscriminately; they vary in duration from several months (apparently) to a number of years; and they vary in size from that of the smallest adrenal rest to that of a man's head. It has been pointed out by a number of observers that hypernephromas are characterized clinically by the fact that they pursue a long benign course entirely devoid of symptoms (though it is difficult to conceive how this can be recognized clinically), and that then suddenly they take on malignant characteristics, proliferate rapidly, give rise to metastases, cachexia, and the death of the patient, unless they be removed by surgical procedures. It has been said also that a hypernephroma may be inferred from the detecting of a murmur upon auscultating a tumor of the kidney. Perhaps hypernephromas may be diagnosed clinically when it becomes more generally recognized that primary carcinoma of the kidney (developing from true kidney structures) is uncommon, and that most of the so-called primary carcinomas and alveolar sarcomas of the kidney are in reality hypernephromas.*

Aloysius O. J. Kelly.

HYPERTRICHOSIS.—(Synonyms: Hirsuties, Polytrichia, and Superfluous Hair.) By hypertrichosis is meant either an abnormal amount of hair growing in a location where hair normally is found; or the appearance of sexual hair at an unusual age upon a part which later normally is covered with hair; or the growth of coarse hair on a part usually covered only with lanugo hair.

Instances of the first variety are occasionally seen. Thus Leonard reports the case of a man whose beard measured six feet six and a half inches in length. There is said to have been a man in Eidam, Holland, whose beard was nine feet long; and the Burgermeister of Braunau rejoiced in a beard that reached to the ground. Women have been known to have hair that trailed behind them on the ground.

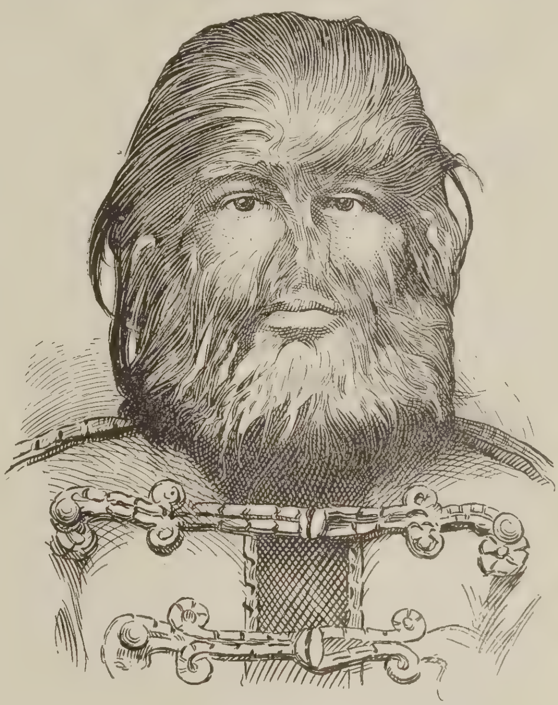

FIG. 2771.—The Russian Dog-face Boy.

Precocious development of hair is technically called *heterochronie.* This variety includes cases of a beard growing on the face of a young boy; and of well-developed pubic hair in children of tender years. Such cases are rare.

Most cases of hypertrichosis belong to the third variety, that is, the growth of coarse hair in places usually supplied only with lanugo hair. Of such are the growth of coarse hair in the nostril and ears in people past middle life; of hair on the back of the nose, and about the nipples and on the chest of women. The two chief forms of this variety of hypertrichosis are the universal form and the growth of the hair on the face of a woman.

The subjects of *universal hypertrichosis* are technically called Homines pilosi. This is a very rare form, and is both congenital and hereditary. The whole body is covered with long hair except in those locations upon which hair never grows, namely: the palms of the hands, the soles of the feet, the backs of the last phalanges of the fingers and toes, the inside of the labia majora, the prepuce and glans penis. The hair of the trunk is somewhat softer than that of the pubic region and scalp. Both sexes are affected in much the same way. The hair grows away from certain well-defined centres. On the forehead it grows to the right and left from a line down the middle of the forehead; on the back downward and outward from the spinal column; and the common centres of distribution are preserved upon the limbs and scalp. With the excessive growth of hair there is a deficiency in the development of the teeth, and the subjects of this deformity are usually of small size.

---

* For references consult Kelly, A. O. J.: "Ueber Hypernephrome der Niere." Ziegler's Beiträge zur pathologischen Anatomie und zur allgemeinen Pathologie, xxviii., 280, 1898; and "On Hypernephromas of the Kidney." Philadelphia Medical Journal, ii., 223, 283, 1898.

Reports have been published of several families of hairy people. Perhaps the best known is the Kostroma father and son, both of whom have been exhibited before the public. The son was for some years in a circus combination in this country under the name of "The Russian Dog-faced Boy." The writer saw him in 1886 when he was sixteen years old. He seemed to be a well-developed boy, though short in stature, muscular, active, energetic, and intelligent. He was said to be in good health and good-tempered. The accompanying picture shows the growth of the hair on his face. The hair was fine, glossy, blond, and about four inches long. The trunk was covered with hair that was specially well-marked down the spinal column, where it stood out like the mane of a horse. The body hair was very fine and more fluffy than that on the face. He had a cast in one eye and was near-sighted. He had only five teeth, two upper canine, and two lateral and one middle incisor, and these were misshapen and discolored.

Partial Congenital Hypertrichosis is of more frequent occurrence than is the universal form.

Many of the so-called cases are instances of nævus. True cases are most often associated with spina bifida, a growth of long hair being found on the lumbar region. Ornstein (*Berlin. Gesellschaft f. Anthropol.*, 1876, 1877, and 1885) says that sacral hypertrichosis is very common among the Greeks, and reports two cases of tails in Greek soldiers. One was one quarter of an inch long and cone-shaped; the other was not so long and was stumpy.

Bearded Women.—This is the form of hypertrichosis that is of most interest. Hair appears on the face of a woman at two distinct periods of life, namely, at puberty, and at middle life in connection with the menopause. The most difficult cases to manage, because the amount of the hair is the greatest, is the form that begins in early life. As in a man the hair continues thickening in amount until twenty-five or thirty years of age. At first the growth is fluffy, fine, lanugo-like. If left alone it may remain so for many years. If attempts are made to destroy it by pulling, shaving, or using depilating powders, it grows more rapidly coarse. Even if left to itself it will grow coarser in time. While all the regions spoken of as the bearded portions of the face are affected in pronounced cases in women, the growth is usually most marked on the upper lip and chin. In a few cases the beard is as coarse and full as that of the average man, though commonly there is but little hair on the lower lip. Such a growth on the face of a young woman may have a bad effect on her mind. She is apt to become abnormally sensitive about even a very moderate growth, attempts in many ways to destroy it, and only makes matters worse; in some instances she may become insane.

When the hair does not begin to grow coarse until the menopause it rarely grows to any great extent. Commonly there are only a few stiff hairs scattered about the chin and on the upper lip.

Transitory Hypertrichosis is met with. Such are growths of hair on a limb which has been for some time confined in a fracture box; that which comes after injury to certain nerves; that which follows prolonged irritation of a part by blisters. In such cases the exciting cause being removed the hair falls from the part. In some women the hair will grow on the face during pregnancy or amenorrhœa, the hair disappearing after delivery or the relief of the amenorrhœa.

Etiology.—Many theories have been formed to account for general hypertrichosis. Unna's theory is probably correct, which is that it is due to the persistence of the fœtal or primitive hair, the change in type from the fœtal to the permanent hair for some reason not taking place. It is known that at a certain time in its intra-uterine life the fœtus is covered with fine hair. Before birth this hair is all shed. Some children do not complete the change in type until a short time after birth. In the general hypertrichosis cases no change in type occurs. The occurrence of subsequent cases in the same family is doubtless due to heredity.

The cause of hirsuties on women's faces is heredity in the great majority of cases. Reversion to the male type, the woman bearing a markedly strong resemblance to her father, may account for some cases, and perhaps for the first case in a family that afterward shows this trait in many of its women. That there is some relation between proper functioning of the organs of reproduction and the hair on the face, as shown by absence of the one and the presence of the other, is evident; still in the great majority of patients no such relationship can be traced. Such influence is most constant and most pronounced at the time of the menopause. Few of my patients have shown masculine traits, and many of them have been mothers of several children.

Local partial acquired hypertrichosis is due to an increased blood supply to the part from the application of blisters and the like. Certain forms of insanity are attended with hypertrichosis.

Treatment.—For universal hypertrichosis there is practically nothing to be done, not because the hair could not be destroyed, as in the partial cases, but because the work would be endless.

For partial cases due to local causes nothing need be done, because the hair falls of itself when the local stimulant ceases to act. It is in hirsuties in women that our aid is chiefly called for, and the treatment effective in that form is equally effective in all forms of partial acquired or congenital hypertrichosis. The only means at our command that is at all reliable is electrolysis, and that is absolutely effective. We owe this operation primarily to Dr. Michel, of St. Louis, who invented it for the destruction of ingrowing eyelashes, he being an ophthalmic surgeon. Dr. W. A. Hardaway, of the same city, first used it for the cure of hirsuties and introduced it to the notice of the medical profession.

The requisites for the operation are a constant-current galvanic battery, a sponge electrode, a needle-holder electrode, needles, a pair of epilating forceps with easy spring, good eyes, and a steady hand. A reclining chair that can be raised or lowered is a convenience. I always use a dentist's chair. If the operator's eyes are not good it will be necessary for him to wear glasses. A needle-holder electrode with a lens attached is on the market.

The patient must be placed in front of a window, preferably one with northerly exposure so as to avoid the glare of the sun. She is given the sponge electrode, moistened with a solution of baking soda, and attached to the positive pole of the battery. Some prefer that the positive pole should be immersed in a bowl of water, and that the patient place her fingers in this. The needle, which is either a steel jeweller's broach, No. 5, 7, or 8, or one of platinum, is placed in the needle electrode attached to the negative pole of the battery. The operator takes hold of the hair with the forceps, puts it slightly on the stretch, and passes the needle into the hair follicle alongside of the hair, and to a depth of about an eighth of an inch. If the needle is properly passed no resistance will be felt. If not, one feels the tissues give way under the pressure of the needle. The needle being in place, the patient is told to place her hand on the sponge or into the water, as the case may be, and thus the current is caused to run. The patient experiences a burning sensation somewhat like the sting of a bee, a little frothing takes place about the needle, and in a few seconds the hair will leave the follicle on slight traction. The hair is always to be removed by the operator. As soon as the hair is out the patient removes her hand from the sponge and the operator then withdraws the needle. It is important always to follow this exact order of inserting the needle before having the hand placed on the sponge, and removing it after the hand is taken off from the sponge so as to avoid the slight shock that otherwise would be felt.

The amount of current to be used varies with the patient's ability to endure pain, and with the place upon which it is necessary to work. A milliampèremeter is a comfort in working, and a current strength of 1 to 2 milliampères is adequate for the work. If one has not the metre the current strength may be roughly said to be that from six to eight freshly charged cells. Most pain is felt on the upper lip and the nearer to the nose we go the greater is the pain. From forty-five to seventy hairs can be removed in an hour. The coarser the hair the fewer can be removed in the time. There is no scarring in the majority of cases, excepting on the upper lip, where it is difficult to avoid slight pitting of the skin. Some skins will show the marks of the work in the form of pitting, just as some skins will develop keloidal scars after slight wounds. A certain number of hairs will come back, because it is not possible for any one exactly to hit the hair papilla every time. The returns will vary from fifteen to twenty-five per cent., and more if the operator is not skilled. This necessitates going over the face a second or third time. Care must be had not to take the hairs out in too close proximity, at least one hair being left between every two extracted. If this precaution is had the danger of scarring will be greatly reduced.

Attempts at destroying hair by other means have been made. Next to electrolysis the best method is probably by the use of what is called the *Microbrenner*, a fine needle heated to a white heat by an apparatus like the Paquelin cautery. I have had no experience with it, but some of our German confrères speak enthusiastically of it, saying that more hairs can be permanently destroyed by it in a given time than by electrolysis. Treatment by the x-ray is the most recent method. Permanent results have been reported. I should be afraid, however, to use this method on account of the danger of burning.

Depilating powders are worse than useless. They simply burn off the tops of the hair and have no effect on the roots. The consequence is that the hairs become rapidly coarser as in shaving. Those that are most used are one composed of sulphuret of barium, ʒ iss.; oxide of zinc, ʒ vi., and carmine, gr. i.; and one of sulphide of soda, ʒ ij., and prepared chalk ʒ vi. These powders are mixed with water at the time of using and thus made into pastes that are spread on the skin. The first is to be washed off in three minutes and the last in ten or fifteen minutes.

George T. Jackson.

HYPERTROPHY.—In its broadest sense hypertrophy is an increase in substance of an organ or tissue, due either to an increase in the number or size of its individual elements, or to a combination of both these changes, without other alterations of structure. An increase in size alone of the individual cells is known as *quantitative* or *true hypertrophy;* increase in the number of cells alone as *numerical hypertrophy* or *hyperplasia.* The gross changes in hypertrophy are: increase of size and weight, in the case of hollow organs a thickening of the walls; increase in consistence; and in the case of muscle a darker color due to an increased formation of muscle pigment. Hollow organs when viewed externally may not give evidences of hypertrophy, since the increase of size may take place at the expense of the cavity, as in the case of concentric hypertrophy of the heart. The weight of an organ is the most reliable standard for the judgment of hypertrophy, but it must be borne in mind that both increase in size and weight of tissues may be due to other pathological conditions than true hypertrophy or hyperplasia. It therefore becomes necessary to make sure that an apparently hypertrophic organ is of normal structure, and this is possible only on microscopical examination.

Microscopically, true hypertrophy is shown by increase in size of the individual cells with increase in size and staining power of their nuclei. Since there are individual differences in the size of cells a standard of comparison can be obtained only by the most exact measurement of the cells of the tissue in question. Hypertrophy of the nucleus may exist without enlargement of the cell body. The practical distinction between true hypertrophy and hyperplasia is often difficult; they usually exist together. Numerical atrophy may be combined with true hypertrophy, the cells may be increased in size, while diminished in number; on the other hand hyperplasia is often accompanied by a loss of bulk on the part of the individual elements. Only very rarely do all the cells of a tissue or organ show a uniform hypertrophy, atrophic cells usually exist side by side with those of increased size.

The causes leading to hypertrophy may be either intrinsic or extrinsic. In the former case morbid impulses to growth or multiplication either exist in the germinal cells or arise through germ variation. Such impulses may develop during either intra- or extra-uterine life. They may be ascribed to an increased tendency to growth and cell multiplication or to an absence of the normal inhibitory influences, but beyond such theoretical explanation we cannot as yet venture. Intrinsic hypertrophy is usually spoken of as congenital or inherited hypertrophy. The hypertrophies not dependent upon congenital tendencies are usually the result of an increased functional demand, increased nutritional activity, or of a disturbance of the normal equilibrium between growth and decay. Underlying hyperplasiæ are the factors leading to cell division.

Intrinsic Hypertrophy.—The more common forms of overgrowth due to congenital tendencies are: general and partial giantism, ichthyosis, elephantiasis, lipomatosis, hypertrichosis, hyperonychia, onychogryphosis, leontiasis, exostoses, etc. Hypertrophy due to congenital excessive impulses of growth rarely affects the internal organs; but certain hypertrophies of brain, thymus, lymph glands, spleen, etc., are at present explained as being of congenital origin. It is impossible to say to what extent the various forms of hypertrophy mentioned above as being of congenital origin are in reality the result of intrinsic forces, since similar proliferations, ichthyosis, elephantiasis, etc., may be caused by external influences. However, in those cases in which the hypertrophic growth is of hereditary nature and appears early without adequate extrinsic cause, the grounds for considering the existence of a congenital predisposition are very good. Even in those cases in which the overgrowth was excited by external injurious influences the existence of a congenital predisposition is not precluded, since we know by experience that such causes give rise to pathological changes of this nature only when there is a special predisposition inherent in the tissues.

Acquired Hypertrophy.—The most common varieties of hypertrophy due to extrinsic influences without the coöperation of congenital predispositions are: hypertrophy due to increased functional activity, hypertrophy caused by lessened wear, hypertrophy resulting from failure of involution, hypertrophy caused by removal of pressure, and finally hypertrophy caused by chronic irritation, either chemical, mechanical, or infectious.

Hypertrophy from overwork occurs most frequently in muscles and glands, rarely in other tissues. The physical and chemical changes in the muscle cell or gland cell resulting from increased function in some way stimulates cell growth. The degree of the hypertrophy depends upon the age of the individual and the general state of the nutrition. Increased work on the part of the heart due to valvular, arterial, pulmonary, or renal conditions causes a more or less marked hypertrophy of that part of the heart upon which the greater share of the work falls. Such hypertrophy being in compensation for the disturbances of circulation produced by the primary pathological condition is known as *compensatory hypertrophy.* Either side of the heart alone may be affected or the entire organ may become enlarged. Further, hypertrophy of individual muscle bands or layers may occur according to the functional demands of the case. Compensation is more nearly complete in the case of young and well-nourished individuals. Increase in bulk of the voluntary muscles follows increased muscular exercise. The fibres increase both in length and in thickness, and there is most probably an increase also in the number of the fibres. Hypertrophy of individual muscle groups occurs in certain trades or occupations (laborer's hypertrophy). Hypertrophy of the involuntary muscle occurs physiologically in the pregnant uterus, the muscle cells attaining a size of seven to twenty times the normal length and five times the normal breadth. In the case of uterine tumors and hæmatometra hypertrophy of the uterine wall may also occur but to a less degree. Hypertrophy of the muscular coat of blood-vessels occurs in conditions of increased blood pressure, particularly in the case of the dilatation of vessels in the establishment of a collateral circulation. In the case of enlarged prostate, urethral stricture, calculi, etc., the bladder walls may become greatly thickened; a similar hypertrophy of the muscularis of stomach and intestines may occur above a stricture.

Of the glandular organs the kidneys and liver are most capable of undergoing hypertrophy. In increased functional activity of the kidney, as in the case of diabetes and excessive drinkers, both kidneys may become enlarged. Compensatory hypertrophy of one organ may take place after the destruction or removal of the other, so that the remaining kidney may in size and weight equal or exceed that of two normal kidneys. The younger the individual, the more complete the compensation. On microscopical examination the enlargement is found to be due chiefly to a hypertrophy of existing structures, but in young individuals a hyperplasia of tubules and glomeruli also occurs.

Hypertrophy of the liver as a whole is extremely rare.

Destruction of a portion of the liver substance is followed by a hypertrophy of the remaining normal liver tissue. The lobules become larger and also increase in number. In animal experiments it has been shown that complete restoration of as much as half of the organ is possible. In simple or inflammatory atrophies of the liver hypertrophy of single cells is very common.

Destruction of one adrenal may be followed by compensatory hypertrophy of the other. In the case of the salivary glands, mammæ, ovaries, and testicles, compensatory hypertrophy does not take place at all or only to a slight degree, except during the developmental period. Hypertrophy of the mamma has been found in connection with galactorrhœa, and in one-sided lactation after loss of one breast.

Removal or destruction of a portion of the thyroid is rarely followed by hypertrophy of the remaining thyroid tissue, but the hypophysis suffers an enlargement which must be regarded as compensatory in nature. The writer has seen in a case of acromegaly an enormous hypertrophy of the parathyroids which might possibly be explained as being of the nature of a compensation for the hypophysis.

Agenesia or aplasia of one lung may be compensated by hypertrophy of the normal organ, and a similar compensation may occur in early life in conditions leading to disuse of one lung. In later years, however, the loss of one lung is followed only by an emphysematous distention of the other, which usually leads to atrophy of the alveolar walls and not to hypertrophy. Emphysematous distention of the air spaces with hyperplastic thickening of their walls has been observed in the lungs of athletes, singers, and players of wind instruments.

Compensatory hyperplasia of the different blood-forming organs, spleen, lymph glands, and bone marrow in conditions affecting one or the other is not uncommon. In various forms of anæmia, leukæmia, etc., where the function of either the spleen or bone marrow is inadequate, the hæmolymph glands become enlarged and suffer structural changes by which they come to resemble either splenic tissue or lymphoid marrow.

Compensatory hyperplasia of the fibula has been observed in cases in which through disease the tibia had been rendered useless in the support of the body.

Hypertrophy from lessened wear occurs particularly in the case of the nails and teeth. If the wear of the nails be prevented, or if they are left uncut, they may become very much enlarged. Teeth growing irregularly, so that the cutting or grinding surfaces are not brought into apposition develop into the so-called tusks. In animals the claws and beaks of birds, and the teeth of rodents may through disuse form extensive overgrowths.

Removal of pressure as in the case of atrophy of the brain may lead to a thickening of the inner table of the skull. Similarly in other regions of the body removal of the normal pressure is often followed by hyperplasia of the adipose tissue.

Failure of the normal involution of the uterus after pregnancy gives rise to an abnormally large uterus during the non-pregnant state. The thymus gland instead of disappearing at the usual period may persist or even show enlargement.

As the result of slight prolonged or frequently repeated mechanical irritation local hyperplasias of tissue may arise (local ichthyosis, callus, corns, etc.); hyperplastic overgrowths are also caused by chemical action (hypertrophy of bone caused by phosphorus and arsenic); and finally infective inflammations frequently give rise to overgrowths or new formations of tissue (condyloma, tuberculous and syphilitic processes, actinomycosis, etc.). Chronic inflammations of the skin are often characterized by hyperplasia of fibrous connective tissue resembling elephantiasis; in syphilis extensive overgrowths of bone not infrequently occur. In inflammatory affections of the lung and pleura, as well as in congenital heart lesions, enlargement of the terminal phalanges and articular ends of the long bones may occur (ostéoarthropathie hypertrophiante). The so-called clubbed or drum-stick fingers acquire an important diagnostic significance in these conditions. Hyperplasia of the spleen and of the lymphadenoid tissue throughout the body is of not infrequent occurrence. The nature of such overgrowth is as yet obscure, but it is most likely of infectious or toxic origin. In a number of cases the hyperplasia of the lymph glands has been shown to be an atypical tuberculous process.

The extensive hypertrophy of the bones and internal organs observed in the condition known as acromegaly forms one of the most interesting varieties of the acquired hypertrophies. The nature of this disease is as yet unknown; in the majority of the cases an adenomatous hyperplasia of the hypophysis has been present and this has been regarded as the cause of the disease. Other writers have explained it as due to a congenital predisposition, to disturbances of the pineal body, sexual organs, thymus, or thyroid, or to abnormal nervous influences.

General Considerations.—Both true hypertrophy and hyperplasia are to be regarded as being of unstable nature, inasmuch as they depend upon the duration of the cause and the increased supply of nutrition. Increase of size demands also increase of space, and in the case of some of the organs and tissues a space limit may be ultimately reached. Hypertrophic tissue requires hypertrophic vessels to furnish the increased amount of blood needed. Changes in the vessels or in the circulation by which the supply of nutrition is diminished lead quickly to atrophy and fatty degeneration of hypertrophic tissue. Similarly diminished functional activity, particularly in the case of the heart and voluntary muscles, is followed by rapid fatty degeneration of the muscle fibres. Further, the inherent vitality of cells, particularly their histogenetic vitality, is limited; tissues which have used up their reserve in compensating for some deficiency are the sooner exhausted. A heart in a state of compensatory hypertrophy may not be able to meet ordinary emergencies which under normal conditions have no effect upon the non-hypertrophied heart; that is, a heart though hypertrophic may be insufficient. Sooner or later, therefore, a failure of compensation must occur, such failure depending upon many factors: inherent cell vitality, conditions of nutrition and removal of waste products, functional activity, etc. In general it may be said that, while fully developed heart and voluntary muscles are desirable, compensatory enlargement due to excessive exercise, increased nervous stimuli, etc., as in the case of the "athletic heart," "smoker's heart," etc., must be regarded as distinctly pathological, inasmuch as such hypertrophy is at the expense of the heart's reserve power.

Aldred Scott Warthin.

HYPNOL.—This is the product of the combination of antipyrin and chloral in definite proportions. It was introduced by Bardet in 1890, who gives its preparation as follows: Mix a solution of 47 gm. of chloral hydrate in 50 c.c. of distilled water, with a solution of 53 gm. of antipyrin in 50 c.c. of distilled water, and after an hour remove the oily fluid from the aqueous layer. At the end of twenty-four hours this solidifies into a mass of rhombic prisms. The salt is colorless and soluble in five parts of water. It is said to have the combined effect of its constituent drugs and has been recommended as an hypnotic in sleeplessness, especially when accompanied by pain. The dose is from ten to fifteen or twenty grains. It has a less disagreeable taste, and is less disturbing to the stomach than either chloral or antipyrin and forms an excellent means of administering these two drugs, which are incompatible in all other proportions.

Beaumont Small.

HYPNONE.—Acetophenone, $C_6H_5CO.CH_3$. This chemical compound has long been known to chemists and classed as a ketone. It bears somewhat the same relation to chloral that ether does to alcohol. It is a colorless liquid at 70° F., very volatile, and possesses a sharp caustic taste and a penetrating odor, resembling bitter almonds. At 57.2° F. it solidifies. It is soluble in alcohol, ether, and fixed oils, but is not soluble in water or in glycerin.

Acetophenone was introduced as an hypnotic, in 1885, by Dujardin-Beaumetz and Bardet under the name of hypnone. It was thought to be of particular value in the insomnia of insanity, alcoholism, and nervous disorders. It, however, has fallen into disuse on account of the uncertainty of its action. The dose was given as from three to ten minims, but much larger quantities have been given without producing any effect. As much as twenty minims have been given hypodermically in cases of insanity. No bad effects have been recorded from its use. Experiments upon lower animals show that its prolonged use lessens the hæmoglobin of the blood and produces emaciation. Death is caused by respiratory failure, following muscular paralysis and coma.

Beaumont Small.

HYPNOSIS.—Hypnosis is a subjective, induced condition of the mind in which the normal influence of the judgment and volition are more or less restricted, while the susceptibility to suggestion is enormously increased. To the ordinary observer it seems to be a trance-like sleep, in which the mind of the subject becomes subordinate to that of the operator.

Hypnotism is that branch of mental science which deals with the phenomena of hypnosis and the methods for its induction.

Suggestion is any method of evoking in the mind of the subject an idea or association of ideas for the control of his mental activities. It becomes *hypnotic suggestion* when the subject operated upon is in a state of hypnosis. Suggestion is called *post-hypnotic* when the idea imparted during hypnosis is to be executed at a more or less remote period subsequent to awakening from the hypnotic state. It is the post-hypnotic suggestion primarily that is of therapeutic value in hypnotism.

Rapport is the relation that exists between the subject and the operator by whom the hypnotic phenomena are called forth.

To review the history of hypnotism would be beyond the scope of this brief article, but it is important to consider its salient points. Much of the mysticism and occult science of the middle ages, indeed of antiquity itself, can be explained through its employment.

Attention was first drawn to it in a definite way by Mesmer, a Viennese doctor, in the latter part of the eighteenth century. He maintained the existence of a force, which he called "animal magnetism" by means of which persons could influence one another, and it is this "animal influence" which constitutes the essential nature of mesmerism.

Much interest was manifested both by laymen and by physicians in Mesmer's claims, but in the early part of the nineteenth century Abbé Faria showed that the phenomena were wholly subjective and not at all dependent upon any unknown force.

In 1841 Braid, a physician in Manchester, England, gave the whole subject a new impetus by his more scientific experiments. His method of inducing hypnosis was by the process of fixation of attention, which resulted in a sleep-like condition, to which he gave the name "hypnotism." Under the influence of his teaching much progress was made in the elucidation of the subject, and it gained a more stable position in the domain of science.

Later, Lièbeault, of Nancy, after a thorough examination of the phenomena of hypnotism and animal magnetism, reached the conclusion that they were wholly dependent upon the influence of suggestion. Professor Bernheim, a pupil of Lièbeault, further developed this view, regarding hypnotic phenomena as physiological rather than pathological and wholly due to suggestions made by the operator.

In 1878 Charcot, the eminent French neurologist, began his studies in hypnosis as manifested in the large group of hystero-epileptics at the Salpêtrière Hospital. His observations, however, were confined to that class of subjects, and resulted in the doctrine that it was a "morbid neurosis dependent almost always on soil predisposed by hysteria." Suggestion he regarded as a "symptom of hypnosis, not its cause." (Art. "Hypnotism," Charcot, in Tuke's "Dict. Psychological Medicine," 1892, vol. i., p. 606.) Since that time the study has been taken up by psychologists as well as by physicians, the trend of opinion being rather in the direction of the Nancy school, which regards hypnosis as physiological rather than pathological. Suggestion is employed as the most important means for evoking it.

The nature of hypnosis, however, is far from being well established; neither Mesmer's assumption of a mysterious "animal force," nor Braid's doctrine of "fixed attention," nor the theory of "suggestion" of the Nancy school, nor yet Charcot's association of it with hysteria, is sufficient to explain its manifestations. The hypothesis of the dissociation of consciousness is a better attempt to furnish an explanation of its varied phenomena (see article *Consciousness, Disorders of*).

According to many psychologists much of the activity of the human mind takes place below the plane of consciousness, the so-called subconscious or subliminal mentality. In this domain lie many of the unconscious phenomena of feeling on the one hand, and of impulse on the other (see article on *Automatic Actions*). It is in the emergence of this subconscious mental field which is peculiarly susceptible to suggestion, simple or hypnotic, that Frederick Myers would explain hypnosis.

As it were, for the time being the subconscious mentality dominates the conscious mind and controls the intelligence, quite the reverse of the normal order. In this respect hypnosis is related to hysteria, the dream states of sleep, hallucinations of the insane, etc., but it is not necessarily a morbid phenomenon, nor dependent upon a morbid condition of the mind.

Suggestion serves then to call forth the phenomena. It is rather the signal for their manifestation than either the cause (Nancy school) or the symptom (Charcot).

The methods employed for the induction of hypnosis depend necessarily upon the views of the operator:

1. *Magnetic Method.*—Those who believe in animal magnetism assume that a special magnetic influence emanates from the operator upon the subject. Therefore standing in front, the hypnotist gazes fixedly upon the eyes of the subject and makes long sweeping passes from the head downward, believing that in some way the peculiar fluid streams from his fingers and thus best influences his subject.

2. *Fixed Attention.*—Braid's method consists in fixing the eyes upon a bright object placed a little above the eyes in the median line; the intent being to produce visual fatigue quickly through the undue strain of convergent strabismus.

In a successful experiment after a time the subject becomes relaxed, his eyelids tremulously close, and he appears to be in a semi-somnolent condition. This is the usual method of procedure, but is somewhat open to objection. The unusual nervous tension required at times has resulted in an acute hysterical attack.

3. *Method of Salpêtrière School.*—Charcot in his experiments upon hysterics established three more or less distinct states of hypnosis:

(1) The cataleptic state, produced—

(*a*) Primarily by the influence of a sudden intense noise, by a bright light flashed before the eye, or further by fixation, more or less prolonged, of the eyes upon any object;

(*b*) Secondarily, to the lethargic state when the eyes hitherto closed are suddenly opened to a bright light by raising the eyelids.

(2) Lethargic state, produced—

(*a*) Primarily by the influence of fixation of the eyes upon an object placed at a certain distance away;

(*b*) Secondarily to the cataleptic state, by simple closure of the eyelids.

(3) State of induced somnambulism, produced—

(*a*) Primarily in some subjects by fixation of attention, or

(*b*) Secondarily, easily with subjects already in a lethargic or cataleptic state, by making simple pressure or light friction upon the vertex.

In these various states of hypnosis certain characteristic phenomena are present. In the *cataleptic* condition the subject is immobile, he appears to be fascinated. The eyes are open, staring, and soon become suffused with tears. There is no winking of the eyelids. Very frequently there is anæsthesia of the conjunctiva and even of the cornea. The limbs and all parts of the body preserve their position for a long time, even attitudes very difficult to maintain which may have been given them—a "wax-like flexibility" very characteristic. The tendon reflexes are abolished and neuromuscular hyperexcitability is absent. While analgesia is complete, certain senses, muscular, visual, and auditory, preserve their activity. This persistence of sensorial activity makes it possible through suggestion to provoke hallucinations and develop automatic impulses at the will of the operator.

In the *lethargic* state, the similitude of profound sleep, there is complete analgesia of the skin and mucous surfaces accessible. The limbs are relaxed, and if raised fall slowly. The pupils are rolled upward, the eyes closed or half closed, while one sees an almost incessant quivering of the eyelids. The tendon reflexes are exaggerated and neuromuscular hyperexcitability is always present, though in varying degrees. This phenomenon, similar to the muscular contractions caused by the faradic current, may be produced by mechanical pressure alone, *e.g.*, by the touch of a pencil. Even muscular contractions more or less prolonged may result, which are readily resolved by stimulating antagonistic muscles.

The *induced somnambulistic* state corresponds more particularly to the condition of "magnetic sleep," so-called. It more nearly resembles the state of lethargy, yet there is no neuromuscular hyperexcitability as described above. Cutaneous analgesia is present, but at the same time there is a very remarkable hyperacuity of certain forms of sensibility of the skin, of the muscular sense and of some of the special senses, sight, hearing, and smell. It is easy through suggestion to call forth very complicated automatic actions which are induced manifestations peculiar to the state of artificial somnambulism, the active hypnotic condition (Charcot, "Œuvres Complètes," Tome ix.).

4. *Method of Suggestion.*—The method of inducing hypnosis by suggestion was practically, though not primarily, developed by the Nancy school, of which Lièbeault and Bernheim are the leaders. The idea of sleep is suggested to the subject's mind by every possible means, physical as well as mental. The subject is thoroughly reassured and placed in a comfortable position, so as to invite mental and physical repose. He is then told that he feels sleepy, that his eyelids are getting heavy, that he can scarcely keep awake, in fact he is going to sleep, etc., until a condition of semi-somnolence is established. This method has the merit of resulting in no danger to the subject, but it may require many séances before the successful end is gained.

The combination of the two methods of fixed attention with sleep suggestion is most commonly used in America, and with proper care will yield satisfactory results.

It is essential, however, to the successful therapeutic use of hypnotism that the subject be well trained as a hypnotic before suggestive treatment be given. It is just here, doubtless, that many physicians have failed while the professional hypnotizer has succeeded.

The following plan, suggested by A. E. Carpenter, merits attention and will lead to more successful results than the usual haphazard efforts for inducing hypnosis sufficiently deep for therapeutical or experimental purposes: No séance should last over long, lest undue fatigue result. The séance may be repeated, however, once or twice a day until the operator secures satisfactory results or concludes that his subject cannot be impressed. If, however, the state of semi-somnolence is developed, assure the subject that he cannot open his eyes, at the same time making a slight pressure upon the eyelids; and we find that the lids come open with more or less difficulty, or not at all. Later, the command alone is sufficient to prevent the lids being opened, and the patient becomes receptive to audible suggestion. Further suggestion both by touch and by command will affect other muscles; for example, the patient is told that he cannot open his hands when firmly clasped, pressure at the same time being made on the spine at the base of the skull. This is repeated until the experiment succeeds. Later the same condition may be produced by command alone, or again by the mere clasping of the hands together. In a similar manner control of all the muscles of the body may be secured. In turn the special senses may be educated in a similar way. The sense of feeling is most readily affected by suggestion and should be attempted first. It is important at the outset, when making suggestion, that the idea conveyed be not inconsistent with fact; for example, in a warm room it is wiser to suggest undue heat than extreme cold. After securing thorough control of the sense of feeling, subdue the sense of sight, employing the sense of feeling to aid in its control; for example, by making a suggestion which would involve both feeling and sight. In the same way one may gain control of the senses of hearing, taste, and smell, through means of others already subordinated. When once all the senses are under control of the operator, the therapeutic application of suggestion becomes simple. In some instances an impressionable subject becomes so susceptible to suggestion that hypnosis may be subjectively induced by mere concentration of attention—the auto-hypnotic state so called. Naturally it is of extreme importance to the success of the performance that the whole manner and tone of the operator convey assurance and never doubt of the result. Nor must it be forgotten that it is not impossible for the operator himself to become hypnotized by the exercise of too fixed attention upon the patient. Undoubtedly many operators have been deceived by apparent hypnotic phenomena through the reaction of suggestion upon their own minds. They see what they are "looking for."

The phenomena of hypnosis under the influence of suggestion are very variable, from the simple trance-like sleep to the complete control of the subject obtained in the condition of somnambulism. In the deeper phases the subject seems conscious only of the hypnotist and implicitly believes and follows out whatever suggestion is made. Upon awaking from the hypnotic state no conscious memory remains, yet a suggestion given during hypnosis may be implicitly obeyed at a period more or less remote. This is the post-hypnotic suggestion so called, and enables the operator to influence the subject after the hypnotic state has passed away. Thus in the treatment of dipsomania a suggestion is made during hypnosis that whenever he takes a dram he will be overcome with nausea. This associated idea is ever ready to meet the imperative habit and develops disgust and thus works a cure. This indirect or associated suggestion seems more powerful than the direct command to avoid drinking.

In the lighter phases of hypnosis the subject seems semi-conscious, but does not readily or at all respond to suggestions widely at variance with fact. He may not be able to open his eyes or shut his mouth, or raise a hand except at the will of the operator, but the assurance that his neuralgic pain is gone brings a smile or even breaks the spell. In the deeper or somnambulistic state no delusion suggested by the operator is too incredible. Every suggestion becomes an imperative idea, dominating feeling and emotion and controlling their physical expression. It is, however, a striking commentary upon the subjective nature of hypnosis that no suggestion of an idea foreign to the cognizance of the subject will gain representation. The fountain never rises above its source.

It will be readily understood how the symptoms of disease may be relieved; but that the disease itself may be arrested or cured is by no means so credible.

Its greatest service will be found in dealing with morbid psychological conditions, such as fixed ideas, morbid habits, sexual perversion, etc.

The various students of hypnotism have formulated certain rules regarding its use which it is well always to observe.

Public séances of hypnotism by professional hypnotizers should be forbidden by law.

Hypnosis should be employed only by physicians or psychologists familiar with the physiology and pathology of the mind.

It should never be induced without the consent of the subject or his legal guardian.

It should not be employed except in the presence of a third person.

Suggestions which are contrary to his moral nature should never be made.

After the employment of hypnosis the patient should always be awakened and left in a calm mood.

Regarding its medico-legal relations, it is pretty well established that in no case can a suggestion contrary to the moral nature of the subject succeed, the antagonistic instinct serving in turn as an overpowering negative suggestion.

Hypnosis is not a miraculous method of treatment to supplant other means, but rather a species of education of the mind which must be sufficiently repeated to secure permanence.

While it seems an easy way to relieve many forms of nervous trouble, in reality its permanent value is very limited. It is true that anæsthesia has been successfully induced by its means, and serious operations have been performed without pain. Medical literature teems with examples, but so few patients are sufficiently susceptible at first trial that it is of little practical value.

Hypnosis prolonged for hours, even days, has occasionally been of value in intractable forms of hysteria, and undoubtedly should be tried when other more rational measures have failed. But training of the hysteric to secure self-control is of more lasting benefit, and far more rational.

Among American neurologists the concurrent opinion is against the employment of hypnotism as a therapeutical measure. At the present time its greatest utility lies in the field of investigation of psychological phenomena rather than in the relief of pathological conditions.

Edward B. Angell.

HYPNOTICS are medicines used to induce sleep. Their utility depends upon their power of arresting the functions of the cerebrum for some time without endangering life or health.

Two views prevail as to their mode of action. According to the older one, they induce sleep by rendering the brain anæmic. The anæmia is supposed to result from a direct influence on the vaso-motor nerves, in consequence of which the cerebral vessels contract and thus diminish the quantity of blood circulating in the brain. This view was based on two facts frequently observed in experiments on animals whose brain had been exposed to view, viz., that the brain invariably *is* anæmic during natural sleep, and that it *becomes* anæmic during the artificial sleep induced by medicines. The brain presenting the same pale appearance in both forms of sleep, it was concluded that both are due to the same cause—a lessened flow of blood in the cerebrum.

But the theory that normal sleep is caused by anæmia of the brain is no longer tenable; for it has been found that the quantity of blood circulating in the brain, in the normal state of the organism, depends upon the activity of the brain, increasing in proportion to the exercise of the mental functions, and abating when the mind is quiescent. Little blood being required during the dormancy of the mental functions, the brain is comparatively bloodless, and, if open to inspection, presents a very pale appearance.

But if the brain is anæmic during normal sleep, will not cerebral anæmia, produced artificially, be followed by sleep? Of this there can be no doubt, since it has been shown experimentally that compression of the large arteries supplying the brain is speedily productive of unconsciousness. Hence, if hypnotics should cause contraction of the cerebral vessels and thus produce anæmia, sleep would necessarily ensue. But in recent experiments on animals, whose skulls had been trephined so that the brain could be inspected, it was found that hypnotics may induce deep sleep without in the least altering the quantity of blood circulating in the brain. Usually, when the sleep was prolonged, the brain gradually became pale and comparatively bloodless. The absence of cerebral anæmia during the early part of artificial sleep disproves the theory that hypnotics act indirectly through the vaso-motor system.

The fact that hypnotics may induce sleep without at first altering the quantity of blood in the brain gave rise to the more recent theory that they act directly on the cerebral cells. The nature of this action is unknown. Experiments performed by Binz seem to show that it may be attended by a very slight and transient coagulation of the protoplasm of the cerebral cells. That some decided, though not very durable, change of the cortical substance of the brain is produced is evident from the experiments of Albertoni, in which it was found that in dogs large doses of bromide of potassium reduced the excitability of the motor centres so much that electric irritation no longer caused epileptic convulsions. In some instances the brain was pale, but in others no diminution of the quantity of blood was observed, and hence the lessened excitability was not attributable to anæmia. Recently the theory has been advanced that natural sleep results from contraction of the protoplasmic processes of the cortical neurons.

The use of hypnotics is indicated, as a rule, when insomnia is continuous, and hence a source of danger; this sometimes occurs both in acute and in chronic diseases. Generally, normal sleep returns as soon as the causes of the insomnia are removed; but sometimes it is impossible to remove the causes, or sleeplessness persists after the removal of all apparent causes.

OPIUM and its preparations, in appropriate doses, usually induce sleep in one or two hours. In some cases of wakefulness, half a grain is followed by this effect; in others as much as two or three grains are required. The duration of the sleep varies from half an hour to six or eight hours, the variations depending upon the size of the dose, the time of administration, the nature of the cause of the insomnia, and the susceptibility of the patient. Given in the early part of the day, even large doses may act only for a short time; but in the evening, moderate doses often produce prolonged rest. When sleeplessness is caused by peripheral irritation of moderate intensity, small doses may induce continuous normal sleep; but when there exists intense pain, large doses are required, and sometimes must be repeated several times. Patients vary greatly in their susceptibility to the action of opium. In early childhood, especially in infancy, and in old age, moderate doses sometimes cause profound sleep bordering on coma.

The hypnotic action of opium is usually preceded and followed by numerous incidental effects. In many patients phenomena supervene, within half an hour after the ingestion of the medicine, which are due, perhaps, to a stimulant action on the brain—a free and copious flow of ideas, and an agreeable sense of well-being, followed soon by indifference to all external impressions and a feeling of fatigue. In very excitable patients, especially nervous females, there often occurs very notable mental excitement with hallucinations, and sometimes increased wakefulness and delirium. Some patients, on the contrary, particularly robust, strong men, do not manifest any of these phenomena, but are soon lost in a prolonged, quiet, and refreshing sleep.

The pulse, in from fifteen to thirty minutes after the hypnotic dose is taken, becomes accelerated by some six or eight beats in a minute, but falls again to its previous rate before sleep ensues. During the sleep, if the dose has not been excessive, it does not usually differ from its rate in normal sleep. Simultaneously with the acceleration of the pulse the skin becomes warm and moist, and the mouth dry.

After awaking the patient often complains of headache and fatigue, his appetite is diminished, and his bowels are constipated. Some patients suffer from nausea and vomiting, severe headache, and mental depression. If the hypnotic is taken repeatedly for some days, there often occur dysuria and itching of the skin.

During the sleep the patient may be readily wakened, unless the dose was excessive, when the sleep may be more profound. Then the pulse usually becomes slower, feeble, and sometimes irregular; the respirations diminish in frequency and depth, and may be stertorous; and the face becomes pale, moist, and cyanotic. The pupils are strongly contracted, unless the respiratory process is so depressed that asphyxia supervenes.

If continuously employed, opium soon loses its hypnotic action in ordinary doses.

Morphine.—The hypnotic action of the salts of morphine is identical with that of opium. In appropriate doses, administered internally, they induce sleep in about one hour. But this effect generally ensues sooner when they are injected into the subcutaneous connective tissue—often in from ten to thirty minutes.

The incidental phenomena do not differ notably from those produced by opium. Sometimes the pulse at first becomes slightly accelerated; more frequently it is not influenced at all, especially in healthy persons. In careful observations on healthy young men, Preisendörfer found no change, either in the frequency or in the tension of the pulse, after subcutaneous injections of quantities varying from one-sixth to one-half of a grain.

It is generally held that morphine produces less constipation than opium, but that it is more frequently followed by itching of the skin, dysuria, and, when administered by the mouth, nausea and vomiting.

In some patients subcutaneous injections of morphine speedily cause giddiness, headache, faintness, difficult breathing, trembling of the extremities, nausea, and vomiting.

Some persons experience only the useful hypnotic effect without any disagreeable phenomena, and can take a moderate dose—one-fourth of a grain of sulphate of morphine—night after night, for a considerable period, without loss of appetite, nausea, constipation, dysuria, or itching of the skin.

As a rule, opium or morphine may be used to induce sleep whenever insomnia endangers life or health, if no contraindications exist. They are preferable to other hypnotics when sleeplessness is caused by peripheral irritation, especially pain and cardiac dyspnœa. In such cases they act both indirectly and directly—indirectly, by removing or relieving the abnormal sensations which cause insomnia; and directly, by arresting the functional activity of the brain.

The utility of morphine in the wakefulness caused by cardiac dyspnœa has long been recognized. Allbutt and Ringer strongly recommend hypodermic injections as speedily effective in allaying the dyspnœa and inducing refreshing sleep. It is necessary, however, carefully to distinguish cardiac dyspnœa from the form of dyspnœa occurring in diseases of the air passages and lungs. According to the experiments of Filehne the immediate cause of cardiac dyspnœa is not an excess of venous blood, but a defect of arterial blood in the medulla oblongata. The medulla is excitable because it is anæmic. All heart diseases that markedly interfere with the circulation, such as valvular affections, dilatation, and pericardial effusion, cause the medulla oblongata to be insufficiently supplied with arterial blood, and hence render it excitable. The dyspnœa that results is wholly useless, as it cannot improve the heart's action; and is harmful in so far as it exhausts the strength. Morphine, therefore, should be employed in doses that will restore the breathing to the normal type. But it is otherwise when dyspnœa results in consequence of impeded arterialization of the blood in the lungs. The immediate cause of the dyspnœa is the excess of venous blood in the medulla oblongata. In consequence of the rapid breathing a larger quantity of blood becomes oxygenated in the lungs; the dyspnœa is, therefore, compensatory and absolutely necessary. Morphine, by diminishing the excitability of the respiratory centre, would increase the venosity of the blood and endanger life.

Opium and morphine are generally preferable to other hypnotics to relieve the sleeplessness occurring in the latter stage of febrile diseases, and depending upon an exhausted and anæmic condition of the brain.

Opium and morphine are contraindicated in wakefulness caused by cerebral hyperæmia. During the first stage of action they probably increase the amount of blood in the brain, and hence are apt to aggravate already existing hyperæmia. They are contraindicated in the wakefulness caused by dyspnœa, if the difficult and rapid breathing is necessary to compensate for some impediment to the interchange of gases in the lungs.

On account of the extreme susceptibility of children to the narcotic action of opium and morphine, these hypnotics are rarely employed to relieve insomnia during the first two or three years of life.

In all forms of chronic insomnia, if it be necessary to maintain a good state of nutrition, opium and morphine are contraindicated, unless it be found that they do not interfere with digestion.

The average dose of opium for adults is one grain, or an equivalent quantity of one of its preparations. As a rule, the dose should be given shortly before bedtime, and, if necessary, repeated in an hour. In cases of sleeplessness from pain and cardiac dyspnœa, smaller doses frequently induce sleep; but when these symptoms are very intense, it is often necessary to repeat the average dose several times.

The average dose of morphine is one-fourth of a grain. In many cases of wakefulness smaller doses suffice, if given at the usual bed-hour. The vomiting that sometimes results from hypnotic doses may usually be prevented by dissolving the salt in four to six drachms of water, and giving a teaspoonful of the solution at intervals of ten minutes.

Frequently morphine is administered by the hypodermic method in cases of insomnia due to pain or dyspnœa. Usually, at first not more than one-sixth of a grain is required to give relief and induce sleep. In the latter stage of acute diseases, when wakefulness is due to exhaustion, the hypodermic dose, as a rule, should not exceed from one-twelfth to one-eighth of a grain. In order to prevent as much as possible the disagreeable effects of morphine on the stomach and skin, it is customary to associate with it a very small quantity of atropine, about gr. $\frac{1}{100}$.

Codeine.—This alkaloid is a less powerful and certain hypnotic than morphine, but has been recommended as preferable to the latter when insomnia results from cough, rheumatic pains, and cancer. The quantity required to induce sleep varies greatly, sometimes this effect having resulted from one-fourth of a grain, and in other instances not from one grain repeated several times.

Small doses are usually not followed by severe after-effects, especially not by obstinate constipation. But large doses may cause nausea, vomiting, giddiness, headache, mental dulness, and tremor.

Codeine may be used as a hypnotic instead of morphine when the latter is not well borne, when constipation should be avoided, and when sleeplessness results from cough.

CHLORAL HYDRATE.—In doses of from 1 to 2 gm. (gr. xv.–xxx.) chloral hydrate usually induces sleep in from ten to thirty minutes. The sleep does not differ notably from natural sleep, the pupils being contracted and the pulse and respirations slow and regular. Generally it is quiet, dreamless, and refreshing, and continues for from two to eight hours. The patient may be readily awakened, but usually quickly falls asleep again.

As a rule, no disagreeable effects are noticeable either before or after the sleep. In irritable, weakly patients, however, a stage of excitement may precede the sleep, marked by injection of the face, restlessness, and hallucinations. These phenomena have been observed most frequently after small doses—eight to fifteen grains. After the sleep there may occur slight headache, with fatigue and somnolency. Usually the functions of the alimentary canal are not disturbed, the appetite being good and intestinal peristalsis normal. After prolonged use of chloral, especially if it is taken insufficiently diluted, symptoms of gastric catarrh become manifest. In weakly patients, and in those who have become much enfeebled by chronic diseases, ordinary hypnotic doses may notably depress the vascular system, render the heart's impulse very weak, and the pulse slow, very compressible, and irregular. These effects on the circulatory organs, due to a depressing or paralyzing action on the vaso-motor centre and the cardiac ganglia, become more marked the larger the dose. Hence, when very large quantities are taken—from one to several drachms—the heart's action becomes very feeble, and the pulse extremely weak. As a consequence, the circulation is so languid that the tissues are inadequately supplied with arterial blood, the temperature falls very low, and life may become extinct.

Although sleep usually ensues speedily from hypnotic doses of chloral, it is sometimes delayed for several hours. This is frequently observed after the continued use of the drug, the interval between ingestion and the supervention of sleep gradually becoming prolonged and marked by some excitement. As a rule, however, chloral in the same dose retains its power of inducing sleep for a long time.

After continued use of chloral very serious effects have been observed, such as erythematous blotches on the face and neck, bloating of the skin, papular eruptions, petechial spots, bedsores, an irritable pulse, severe attacks of dyspnœa, weakness of memory, dulness of intellect, paralysis of muscles, and general marasmus.

As a hypnotic, chloral hydrate presents the advantage of acting speedily and certainly, and not causing disagreeable after-effects. Its tendency to depress the vaso-motor centre and the heart makes it suitable in wakefulness associated with vascular excitement. It usually acts well in acute rheumatism, scarlatina, peritonitis, metritis, and febrile diseases generally, as well as in cerebral affections.

Chloral is preferable to other hypnotics when sleep should be speedily induced, as in cases of delirium tremens supervening soon after the receipt of a severe surgical injury. Under such circumstances it is sometimes the means of saving life.

In painful affections attended with vascular excitement, moderate doses of morphine are often associated with chloral in order to relieve the pain, as chloral alone has little analgesic power.

Chloral is a valuable hypnotic in the insomnia of children and the aged, as it does not, in appropriate doses, produce inordinate effects.

Chloral may be employed in all cases of insomnia, if no contraindications exist.

On account of its depressing action on the heart, it is contraindicated when this organ is enfeebled in consequence of fatty or other kinds of degeneration, valvular disease, dilatation, or malnutrition in the latter stages of prolonged fevers.

According to some observers, chloral sometimes produces delirium and great depression in diseases which interfere with the respiratory process, such as pneumonia, pleuritis, emphysema, and bronchitis.

Catarrhal and ulcerative affections of the stomach contraindicate the internal administration of chloral. In hysterical patients undue excitement, instead of refreshing sleep, frequently ensues from hypnotic doses.

On account of the varying susceptibility of different individuals to the action of chloral, it is prudent, when giving it to patients whose tolerance is unknown, not to prescribe more than 2 gm. (gr. xxx.), of which one-half may be taken at the usual bed-hour, and the other half, if necessary, an hour later. In states of great cerebral excitement, such as delirium tremens and acute mania, larger doses have been given with advantage—2 gm. (gr. xxx.), repeated several times, if necessary, at intervals of one hour.

As concentrated solutions disorder the stomach, it should always be well diluted with sweetened water or milk. ℞ Chloral hydratis, 2 gm. (ʒ ss.); aq. destill., 8 gm. (ʒ ij.). M. Sig.: One-half to be taken at bedtime, in a small cup of milk; and the other an hour later, if necessary. ℞ Chloral hydratis, 2 gm. (ʒ ss.); syr. aurantii, 15 gm. (℥ ss.); aq. menth. pip., 45 gm. (℥ iss.). M. Sig.: Two tablespoonfuls at bedtime; and the rest, if required, an hour later. In cases of insomnia dependent upon pain, a fourth of a grain of sulphate of morphine may be added to either of the above formulæ.

If chloral be required as a hypnotic in cases of severe disease of the stomach, it may be administered by rectal injection. Subcutaneous injections of chloral are inappropriate, except perhaps in strychnine poisoning, on account of the severe irritation which results.

BUTYL CHLORAL HYDRATE.—This substance acts like chloral hydrate, inducing quiet and refreshing sleep in from ten to thirty minutes. During the sleep circulation and respiration are normal. It is held that butyl chloral does not depress the vaso-motor centre and the heart as much as chloral hydrate, but that it exerts a more decided anæsthetic effect on the trigeminal nerve.

As a hypnotic it has been recommended in the insomnia associated with diseases of the heart, and with neuralgia of the fifth nerve.

The ordinary dose varies from ten to forty grains. It is best administered in solution with glycerin. ℞ Butyl chloral hydratis, 4 gm. (ʒ i.); glycerini, 10 gm. (ʒ iiss.); aq. destill. ad 60 gm. (℥ ij.). M. Sig.: A tablespoonful every half-hour until sleep ensues.

CHLORALAMIDE, or CHLORAL-FORMAMIDE.—Chloralamide was introduced in 1889 by von Mering as a substitute for chloral in cases of insomnia in which the influence of chloral on the organs of circulation should be avoided. He supposed that the formamide, contained in chloralamide, would effectually prevent the depressing action of chloral.

The experiments made upon animals yielded somewhat discordant results, not as to the influence of chloralamide on the brain, but as to its action on the organs of circulation and respiration. Von Mering, Zuntz, and Kny noticed no fall of blood pressure in rabbits under the influence of hypnotic doses of chloralamide. Langgaard, on the contrary, observed after moderate non-toxic doses decided lowering of blood pressure, although this effect supervened more slowly than after chloral. These contradictory results were probably due to variation in the rate of decomposition of the chloralamide in the different animals subjected to experiment.

Upon man chloralamide acts like chloral, except that it produces sleep less rapidly and less certainly. As a rule after doses of 2 to 3 gm. (gr. xxx.–xlv.) sleep ensues in half an hour and continues for from five to eight hours. During the sleep, the functions of circulation and respiration are performed as vigorously as in normal sleep. After awaking the patient presents no disagreeable effects.

Numerous deviations, however, from this ordinary action have been observed, depending chiefly upon the causes of the insomnia. Thus, in cases of intense excitement of the brain, of severe pain, of harassing cough, and of high fever, doses of 2 to 3 gm. have failed to produce sleep, and sometimes even 4 gm. (ʒ i.) have been ineffectual. Often, even when the causes of insomnia were not intense, sleep did not supervene before an hour, sometimes two hours, and in rare instances even three hours. In some cases of heart disease, especially in valvular disease with imperfect compensation, a very decided depression of the circulation has been observed. So, too, in typhoid fever a very unfavorable effect upon the pulse was noticed after 2 gm. (ʒ ss.) given in divided doses. The temperature was always found lowered from one-half to one and one-half degrees.

Generally, after-effects do not occur, or they are very trivial, consisting of headache, slight giddiness, a feeling of fatigue, and skin eruptions.

From the above, it is evident that chloralamide closely resembles chloral in action, but that it induces sleep more slowly and less certainly, and that it is less apt to depress the circulation. The differences seem to be due to slow and gradual liberation of chloral in the blood, although it is not improbable that the presence of the formate of ammonium may somewhat modify the action of the chloral on the organs of circulation and respiration. The variations in the rapidity of action doubtless result from differences in the rate of decomposition in the blood of different persons.

Chloralamide is a suitable hypnotic in insomnia not caused by intense excitement of the brain, very severe pain, or extreme dyspnœa. When severe pain causes insomnia, chloralamide alone is not very efficient, but it acts well if given together with a moderate quantity of morphine. In the insomnia associated with mild nervous excitement, with neurasthenia, and with somatic diseases in general, moderate doses, 2 to 3 gm. (ʒ ss.–gr. xlv.), are usually effectual. Such moderate doses having frequently failed in cases of intense mental excitement and severe pain, larger doses, as much as 4 gm. (ʒ i.), have been recommended; but it should be recollected that such large doses may cause dangerous depression. Even moderate doses should not be given in cases of heart disease, if the heart's action be very feeble, or if symptoms of inadequate compensation be present. In no case should the dose be larger than the corresponding dose of chloral, 3 gm. of chloralamide being equivalent in action to 2 gm. of chloral. The following are convenient formulæ: ℞ Chloral. formamide, 4 gm. (ʒ i.); aq. dest., 75 gm. (℥ iiss.); acid. hydrochlor. dil., gtt. v.; syr. aurantii, 15 gm. (℥ ss.). M. S.: One-half to be taken at bedtime, and, if necessary, a tablespoonful every hour till sleep ensues. ℞ Chloral. formamid., 4 gm. (ʒ i.); Spir. frumenti, syr. rubi idæi, āā 15 gm. (℥ ss.). M. S.: One tablespoonful at bedtime.

Sulphonal.—This remedy was recommended as an efficient hypnotic by Kast in 1888. He had tried it in numerous cases of insomnia, and nearly invariably quiet and deep sleep ensued and lasted for from five to eight hours. During the sleep the functions of circulation and respiration were somewhat slowed as in ordinary sleep, but no deviation from the normal could be observed. After awaking the patients presented no after-effects, except that in a few instances some fatigue and languor existed on the following day. After the publication of Kast's observations, sulphonal was very extensively used. It proved very effective in nervous sleeplessness and generally also when the insomnia was caused by disease of the brain, disordered circulation, and neuralgia. It was not so successful in delirium tremens and often failed when the sleeplessness was caused by severe cough, dyspnœa, or intense pain, though when given together with small doses of morphine, it also acted well in the latter conditions. Usually no disagreeable effects were observed during or after its action, or at most some languor and drowsiness on the following day. In a few instances, especially when the doses were large, and after repeated administration of moderate doses, there followed headache, vertigo, tinnitus aurium, and staggering.

Further experience with sulphonal caused its use to become much restricted, as it was found, in cases requiring its administration for a long time, frequently to produce severe toxic effects and in a few instances death. Bad effects were observed in some cases after doses of 1 to 2 gm. given daily for some weeks or months, though in most cases of prolonged administration no notable disorder resulted. In many cases the urine presented an intensely red color, from the presence of hæmatoporphyrin, and its quantity was notably lessened. Besides great general debility, there were observed anorexia, severe pain in the epigastrium and right hypochondrium, vomiting, obstinate constipation, sometimes diarrhœa, headache, drowsiness, disorders of sight, diminution of reflexes, staggering gait, ascending paralysis and coma.

The supervention of toxic effects is more apt to occur in weakly, anæmic, old patients, and those having notable disorder of the alimentary canal, such as gastric and intestinal catarrh and constipation.

The dose of sulphonal is 1 or 2 gm. dissolved in about six or eight ounces of hot liquid—water, milk, bouillon, soup, tea—and given a short time before retiring. In most cases of insomnia it is best to begin with 1 gm.; if this should not have the desired effect, the next dose may be 1.3 gm. (gr. xx.); and, if necessary, the subsequent doses may be gradually increased to 2 gm. (gr. xxx.). Should this dose not act, some other hypnotic should be resorted to. Under no circumstances should sulphonal be given every night for any length of time.

Trional is closely allied to sulphonal in chemical constitution, physical properties, and physiological action. It is somewhat more soluble, acts more rapidly and certainly, and is less frequently followed by disagreeable and toxic effects when continually used for months. Hence it is now very extensively used and in many asylums has entirely supplanted sulphonal. Like sulphonal it produces during the sleep no notable aberrations in the organic functions of respiration and circulation. The sleep is sound and refreshing, and as a rule is not followed by any obvious disorder, except in rare cases, generally feeble patients, who may be somewhat drowsy or complain of headache and giddiness. In some instances the long-continued use of trional has been followed by gastric disorder, vomiting, constipation, delayed hypnotic action, oliguria, and hæmatoporphyrinuria.

The dose of trional is from 1 to 2 gm. (gr. xv.–xxx.). If 1 gm. (gr. xv.) should fail to produce satisfactory sleep, the next dose should be 1.3 gm. (gr. xx.). It will rarely be necessary to give more than 1.5 gm. (gr. xxiiss.). The dose found necessary should be given in six or eight ounces of hot liquid just before retiring, and should be repeated not oftener than every other night. If a hypnotic be required in the intermediate nights, chloral, chloralamide, or amylene hydrate may be used.

It is not necessary to increase the dose of trional; on the contrary, often the dose may be somewhat diminished.

Paraldehyde.—Vincenz Cervello, in 1882, recommended this substance as an efficient and safe hypnotic, which might be substituted for chloral hydrate in all cases in which depression of the heart should be avoided. In numerous experiments on animals and human beings he had found that it induced quiet, prolonged sleep, without altering the functions of circulation and respiration, and without causing excitement or disagreeable after-effects.

Since recommended by Cervello, paraldehyde has been tested by numerous careful observers. It was found, as a rule, to act satisfactorily in mania, delirium tremens, hysteria, hypochondriasis, and other ordinary diseases. In cases of cardiac disease, in which the heart's action was very weak, it caused no notable depression. The observations thus far made have confirmed the results obtained by Cervello, that paraldehyde is a powerful hypnotic which does not unduly act on the heart or respiratory centre, and that it should be preferred to chloral hydrate in all cases of decided cardiac weakness.

It cannot be substituted for morphine in cases of insomnia caused by pain, as it seems to possess no marked analgesic action.

The dose required for hypnotic purposes varies greatly with individual susceptibility. Cervello found that 1 gm. sometimes had a quieting effect in women, while 4 gm. often failed to induce sleep in strong men. From experiments on animals he supposed that the hypnotic dose might be three times as large as that of chloral hydrate, and from his trials on healthy men and patients he concluded that 10 gm., administered in divided doses, might be given to adults without causing any notable disorder.

Being very acrid, paraldehyde is contraindicated in irritable states of the throat and stomach.

If administered in a concentrated form, it produces a strong sensation of burning in the mouth. Cervello gave it in very dilute solution in sweetened water, and observed that solutions containing more than three per cent. have a disagreeably pungent taste.

As a rule, it is necessary to give at least fifty minims to induce sleep, and in most cases this quantity must be repeated once or twice at intervals of half an hour or an hour.

At the temperature of 59° F. paraldehyde is dissolved in eight parts of water, but it is less soluble at higher temperatures. It may be prescribed in concentrated solution; but each dose should be diluted with about two and a half ounces of water before ingestion. ℞ Paraldehyd., 10 gm. (ʒ iiss.); syr. aurantii, 15 gm. (℥ ss.); aq. destill., 75 gm. (℥ iiss.). M. Sig.: Two tablespoonfuls at bedtime; afterward, if necessary, one tablespoonful every half-hour until sleep ensues.

Hodgson recommends the following formula: ℞ Pulv. trag. co., 4 gm. (ʒ i.); syr. aurantii, 15 gm. (℥ ss.); paraldehyd., 4 gm. (ʒ i.); sp. chloroform., ♏ xv.; aquæ, q.s. ad 90 gm. (℥ iij.). M.

Amylene Hydrate was recommended as a hypnotic by von Mering in 1887. In experiments upon animals he had found that moderate doses act chiefly on the cerebrum, producing sleep for hours without notably modifying respiration or circulation, and that large doses affect also the spinal cord and the medulla oblongata, arresting the reflexes, breathing, and heart action.

Von Mering administered it to sixty patients afflicted with insomnia. After doses of 3 to 6 gm., sleep ensued within half an hour and continued for from six to eight hours. Only four times was the hypnotic action unsatisfactory. No disagreeable incidental effects occurred, and only one patient complained on the next morning of slight headache. When the sleeplessness was caused by pain, amylene hydrate did not act well; but the simultaneous administration of a small quantity of morphine rendered the action satisfactory. Von Mering considered 2 gm. of amylene hydrate equivalent to 1 gm. of chloral hydrate and to 3 gm. of paraldehyde.

Since von Mering's recommendation of amylene hydrate it has been frequently used especially in asylums and has been found safe and efficient; but owing to its disagreeable odor and taste and occasional untoward action, it can be used only to a limited extent in private practise. Some patients refuse to take it on account of its pungency; others complain, after taking it for some time, of discomfort after eating—a disturbance of digestion that may in part be due to irritation but more to interference with the action of the pepsin. In a few instances it has caused effects resembling alcoholic intoxication before sleep ensued, and after the sleep nausea, headache, and giddiness. In some cases it accelerates, in others slows, the heart's action and renders it somewhat irregular. In some instances its action is prolonged, the patient being drowsy on the next day. Sometimes also it fails to act efficiently after it has been given five or six times. But notwithstanding these defects, amylene hydrate is an excellent hypnotic adapted to occasional use in cases of insomnia requiring the prolonged use of hypnotics.

The dose of amylene hydrate is 2 to 4 gm. (ʒ ss.–ʒ i.) mixed with water and syrup or liquorice. ℞ Amyleni hydrat., 6 gm. (ʒ iss.); Aq. dest., 60 gm. (℥ ij.); Extr. glycyrrh., 10 gm. (ʒ iiss.). M. S.: One-half to be taken before retiring. ℞ Amyleni hydrat., 6 gm. (ʒ iss.); Aq. aurantii florum, 45 gm. (℥ iss.); Syr. aurantii, 30 gm. (℥ i.). M. S.: One-half to be taken at bedtime.

Bromides.—The bromides of potassium, sodium, lithium, and calcium, and hydrobromic acid, are efficient hypnotics in some kinds of insomnia, although in the normal state of the organism, administered during the daytime, they do not induce sleep except in very large doses. Their hypnotic action is not attended or followed by disagreeable effects, unless they are given in a too concentrated form or their use is continued very long. Administered when the stomach is empty, they quickly produce disorder of digestion, unless diluted with a large quantity of water. When used continuously they often cause eruptions on the skin, catarrh of the air passages, fetor of the breath, pallor of the face, emaciation, debility, depression of the sexual function, and dulness of the intellect with weakness of memory. But these effects speedily subside when their use is discontinued.

The bromide of potassium in large doses diminishes the frequency and force of the pulse and lowers the temperature. In healthy persons Krosz found the pulse diminished in frequency from eleven to twenty-two beats in the minute after doses of 10 gm., and as much as thirty beats after 15 gm. The pulse was weak and sometimes irregular. The temperature fell from 0.5° to 0.8° C. after doses of 10 gm., and 1.2° C. after 15 gm. The maximum effect on the pulse and temperature occurred between the second and third hour after the ingestion of the salt. Bromide of sodium in large doses did not lessen the frequency of the pulse nor lower the temperature.

The bromides are preferable to other hypnotics in the wakefulness depending on abnormal excitability of the brain. They are usually efficacious in the early stage of delirium tremens, in hysteria, insanity, hypochondriasis, and the night terrors of children. As they are harmless, they should be preferred in the insomnia caused by severe mental strain, intense emotions, and worry.

Bromide of potassium frequently induces sleep in febrile affections. As long as the temperature is abnormally elevated, and the pulse strong, it is more suitable than other bromides. But in the latter stages, when the heart's action is notably weakened, bromide of sodium is the more eligible salt. In all cases of chronic sleeplessness in which depression should be avoided, bromide of sodium should be preferred to the bromide of potassium.

The bromides are usually given in doses of from twenty to forty grains, shortly before bedtime, and repeated at intervals of two hours if necessary. In many cases of chronic wakefulness it is better to give fifteen or twenty grains soon after each meal, and before retiring. Each dose should be diluted with several ounces of water. ℞ Potassii brom., 8 to 12 gm. (ʒ ij.–iij.); Sacch. albi, 4 gm. (ʒ i.). M. Div. in part. æq. No. vi. Sig.: One powder in a wineglassful of water at bedtime. ℞ Sodii brom., 15 gm. (℥ ss.); Aq. menth. pip., 45 gm. (℥ iss.). M. Sig.: One teaspoonful at bedtime in a wineglassful of water; repeat the dose every two hours if necessary.

Hyoscyamus.—The preparations of hyoscyamus, in large doses, sometimes induce sleep; but on account of the uncertainty of their action and the disagreeable incidental effects, they are rarely employed to relieve insomnia in adults. They are frequently used to quiet the restlessness incident to the diseases of children, who tolerate larger doses proportionally than adults. Recently the alkaloids obtained from hyoscyamus have been recommended as powerful hypnotics in some forms of insomnia.

Hyoscyamine has been used chiefly in excited conditions of the brain, such as delirium tremens and mania. Generally, doses of one-sixteenth to one-eighth of a grain suffice to induce sleep of several hours' duration; but frequently larger doses are necessary—from one-sixth to one grain. Sleep follows very rapidly after the largest dose, often in fifteen minutes; it becomes very deep, may continue ten or twelve hours, and is sometimes attended by marked prostration.

The incidental effects consist chiefly of hallucinations, delirium, dryness of the mouth and throat, marked acceleration of the pulse and respirations, and great dilatation of the pupils.

Ringer found small doses of hyoscyamine inefficient in delirium tremens; larger doses produced many hours' sleep, but without improving the delirium and general condition of the patients.

Hyoscine Hydrobromate (Scopolamine hydrobromate).—This salt has lately been recommended as a very efficient hypnotic. In doses ranging from gr. $\frac{1}{120}$ to $\frac{1}{70}$ it promptly induces sleep, which lasts from one to four hours if the medicine is given in the daytime, and from six to ten hours if given at night. Wetherill found that even smaller doses, gr. $\frac{1}{200}$, frequently produced prolonged rest in cases of insomnia. It is rarely necessary to repeat the dose, or rapidly to increase it.

The following incidental effects have been observed: slowing of the pulse and respiration, slight elevation of temperature, hoarseness, suffusion of the face, sweating, dilatation of the pupils, relaxation of the muscles, impaired co-ordination, and a sense of fulness in the head and of wretchedness.

Occasionally moderate doses are followed by nausea, vomiting, anorexia, dysuria, syncope, with small, rapid, irregular pulse, and with symptoms of partial paralysis of the pneumogastrics (Wetherill).

Hyoscine has been used in the insomnia of acute delirious mania, of agitated melancholia, neurasthenia, chronic mental disorder, the morphine habit, alcoholism, and in confirmed cases of insomnia from unascertained causes. As a rule, it promptly induced quiet and prolonged sleep.

For internal use the following formula is convenient: ℞ Hyoscin. hydrobr., 0.01 gm. (gr. $\frac{1}{6}$); Aq. dest., 80 gm. (ʒ xx.); Syr. aurantii, 20 gm. (ʒ v.). M. S.: One teaspoonful once or twice daily.

Cannabis Indica.—Cannabis indica has been used as a substitute for opiates when the latter do not agree with the patient, and in cases of acute and chronic mental derangement. The susceptibility of different individuals to its hypnotic action varies greatly. Fronmüller, who administered it in 1,000 cases, found that it succeeded completely in 530, incompletely in 215, and had little or no effect in 255. In careful experiments Preisendörfer found that doses of one grain and a half of an alcoholic extract sometimes acted well, but in other cases had no effect. Larger doses, in no case exceeding five grains, usually produced more or less deep sleep.

Generally, hypnotic doses of cannabis indica produce decided incidental effects, such as giddiness, headache, hallucinations, delirium, slight redness of the face and conjunctiva, dilatation of the pupils, and brilliancy of the eyes. Very large doses often cause intense headache, nausea, and vomiting. In the experiments of Preisendörfer marked alterations of the circulation were observed. Two or three hours after the medicine had been given there occurred palpitation of the heart, with general relaxation of the arterial tension and increase of pulse rate from eleven to twenty-two, sometimes even forty, beats per minute. Sleep usually ensued at the time when the changes in the circulation began.

The hypnotic action of cannabis indica seems to be increased by bromide of potassium. As a result of experiments Clousten found that forty-five minims of the tincture of cannabis indica, with forty-five grains of bromide of potassium, were fully equivalent to a drachm of laudanum as a means of allaying maniacal excitement.

Hedonal, according to recent reports, seems to be a useful hypnotic in light forms of sleeplessness. In appropriate doses it usually induces sleep in about half an hour, though sometimes its action is delayed for one or two hours. The sleep may continue for from two to eight or nine hours, depending upon the size of the dose and the condition of the patient. After some time, several days or weeks, the dose must be somewhat increased to obtain the hypnotic effect. Usually no incidental effects are observed either during or after the sleep—the pulse, the breathing, and the temperature not deviating from the normal. In a few instances, on the day following the sleep, complaint is made of headache and giddiness.

The dose of hedonal is from 2 to 3 gm. (gr. xxx.–xlv.) given as a powder, which may be placed upon the tongue and swallowed with some cold water. It is supposed that 2 gm. act as efficiently as 1 gm. of trional and 2 gm. of chloralamide.

Dormiol has been found to produce sleep in about half an hour, which may continue for from one to ten hours, but on the average continues five hours. No notable depression of the functions of circulation and respiration occurred. Usually the doses given varied from 1 to 4 gm. of a ten-per-cent. solution. It was better to give one large dose than several small doses at intervals. Dormiol is held by some observers to be quick, safe, and sure in action.

Chloretone causes sleep in about half an hour, and this effect may continue for from one to twelve hours, the average being about four and a half hours. After large doses the pulse becomes depressed both in volume and in frequency. The breathing also becomes lessened in depth and volume, and the temperature lowered.

In experiments on warm-blooded animals it was found that chloretone in hypnotic doses diminishes the frequency and volume of the inspirations; depresses the vaso-motor centres and dilates the blood-vessels, thus lowering blood pressure, and also depresses the heart and lowers temperature.

Some recent writers, however, state that they have obtained good results from the employment of this remedy in the persistent insomnia of the aged, and in cardiac disease with renal complication and high arterial tension. In some cases sleep ensued after doses of 1.3 to 1.6 gm., but in most cases it was necessary to repeat this dose once or twice.

Chloralose acts as a hypnotic in smaller doses than chloral, but seems also to be more toxic and less certain. In a child the small dose of 0.2 gm. caused trembling of the hands and arms, and severe dyspnœa. Very grave symptoms have followed 0.3 gm.—coma, oscillatory movements of the head and the arms, and Cheyne-Stokes breathing.

It is given in doses of 0.2 to 0.3 gm. in capsule.

Samuel Nickles.

HYPODERMATIC MEDICATION.—The hypodermatic method of administering drugs, now so commonly employed, was first introduced by Dr. Alexander Wood, of Edinburgh, in 1843. It was gradually evolved, by the patient labors of numerous observers, from the endermic or endermatic mode of using certain soluble remedies formerly much in vogue, and, as the term clearly indicates, consists in the injection of solutions of suitable medicaments under the skin by means of a small syringe specially adapted to this purpose.

To insure success, care should be taken in the choice of the syringe. The essential qualities are, uniformity of calibre of the barrel, a properly fitting piston, and a sharp needle attached to the nozzle by means of a water-tight joint. These instruments are now made of glass, celluloid, hard rubber, and metal.

Since the earlier days in the history of this subject, important improvements have been wrought in the construction of hypodermatic syringes, so that of late years they have been offered in great variety; and manufacturers have displayed much enterprise and ingenuity in bringing them to the present state of completeness. Excellent instruments may now be readily obtained at very moderate cost.

The original syringes, and those of inferior quality still made, consist of a glass barrel with a metal or hard-rubber cap at each end.

This kind of instrument is not to be recommended. It is frail; the mountings, of metal or hard rubber, are liable to be separated from the barrel by very slight force; it is apt to become leaky, and the diameter of the glass tubing is rarely uniform throughout its length; but even in this class of instruments, some superior workmanship is now shown in the best specimens offered by dealers.

A decided improvement upon this make is illustrated by Fig. 2772. The glass barrel is enclosed in a fenestrated, sometimes a double fenestrated, metal sheath, which reveals the contents of the syringe when charged, and renders an otherwise weak instrument sufficiently strong for ordinary use. It is easily taken apart for cleaning, and to those who prefer the glass barrel it is recommended. Nevertheless, it is open to other objections urged against glass syringes. Unequal diameter of the cylinder and likelihood of leakage are the principal defects.

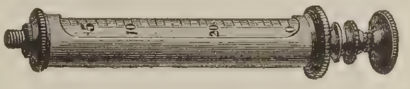

FIG. 2772.

Neither the celluloid nor the hard-rubber syringes have given entire satisfaction, and the specimens usually found in the market cannot be indorsed as trustworthy or desirable instruments.

The metal syringes are to be preferred to all others on account of their superior strength and durability, the even diameter of the bored cylinders, freedom from leaks, and compactness of construction. The metals used in their manufacture are German silver or brass—plated inside and outside with nickel—pure silver, and gold.

Fig. 2773 illustrates an instrument which meets fully the demands for a first-rate hypodermatic syringe. It has a nickel-plated German silver barrel, which is not corroded or injuriously affected by any solution which it is proper to inject into the tissues.

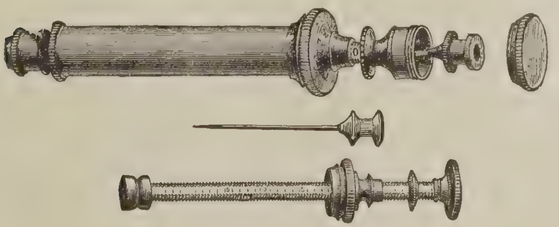

FIG. 2773.

The minim scale, in this instrument, is placed upon the semi-cylindrical piston rod, which is made hollow to receive the needle, and is provided with a screw-thread and traverse nut, designated to regulate, when set, the extent of downward movement of the piston. A cap should be screwed upon the nozzle when the needle is removed. If desired, a drop or two of water may be put in the cap to prevent inconvenient drying of the packing.

These syringes require no case for their protection, but may simply be slipped into a chamois-skin pouch and carried, without injury, in the pocket. More recently the leather-packed piston has been superseded by a solid metal plunger, which is so accurately adjusted to the barrel that no packing is required. Thus the annoyance of a dry and consequently an insufficient packing is obviated and a thoroughly aseptic instrument may be insured (see Fig. 2774).

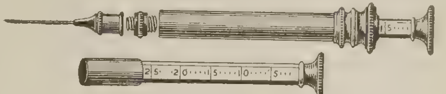

FIG. 2774.

It is prudent to be provided always with an extra needle, which may be enclosed and held by a screw-thread, in a small metal sheath, furnished by instrument-makers for this purpose.

The gold and silver syringes are not superior in practical utility to the instrument above described, and are unnecessarily expensive. The syringes provided for diphtheria antitoxin are similar in construction to the ordinary instrument, but are considerably larger. The packing of the piston is made of rubber and by a simple but ingenious mechanical device may be tightened at will. The syringes used for subarachnoid injections are substantially the same as the antitoxin syringes.

The needles for hypodermatic syringes are usually made of steel, plated with gold or nickel. Some advantages are claimed for gold or platinum needles. The needles are attached to the nozzle of the syringe by a screw or slide joint. The former is the more convenient style. A fine wire should be passed through the needle when it is not in use, to prevent occlusion of the calibre, either by the deposit of crystals from any solution that may have been employed, or by the accumulation of rust. The needles ought to be of small size, with large relative calibre, and it is desirable to have the tips strengthened at the junction with the sockets. The points should be lancet-shaped and free from any groove, depression, or shoulder-like projection.

The use of these instruments requires no special skill, though the dextrous performance of the little operation materially diminishes the discomfort of the procedure to the patient. The skin may be pinched up between the thumb and forefinger of the left hand, while the needle, held perpendicularly to the surface, is thrust rapidly through it. After penetration, the point of the needle should be passed obliquely to the desired depth into the areolar tissue, and the contents of the syringe slowly discharged. The operator, before making the puncture, must be careful to expel all air from the syringe by inverting the instrument, and at the same time depressing the piston sufficiently to cause a drop of the contained solution to appear at the point of the needle. It is scarcely necessary to urge the importance of rinsing out the barrel and of thoroughly cleansing the needle, immediately after using the instrument.

The injection may be made under the skin in almost any portion of the body; but the neighborhood of large vessels and nerves, bony prominences, and specially sensitive or inflamed regions should be avoided. The places ordinarily selected are the arm, near the insertion of the deltoid muscle, and the outer surface of the thigh. The rapidity with which absorption takes place is regulated somewhat by the vascularity of the part into which the injection is made. It is stated by some writers that a prompter effect may be expected from injections into the inner aspect of the limbs, or into the pectoral region, than from similar injections into the outside of the limbs or into the back. If this difference really exists, it must be so slight that it is scarcely worthy of serious consideration.

The injections may be superficial, into the subcutaneous areolar tissue merely, or they may be deep, into the body of a muscle, or, as has been recommended in some obstinate cases of sciatic neuralgia, a concentrated solution of morphine may be forced into the very substance of the nerve itself. Injections are sometimes made into diseased tissues and into abnormal growths. Intravenous and intraspinous or subarachnoid injections are also practised, but a consideration of these procedures, and of hypodermatic alimentation, is incompatible with the scope of this article.

The remedies most commonly used hypodermatically are morphine, codeine, atropine, hyoscine, hyoscyamine, strychnine, eserine, pilocarpine, caffeine, cocaine, apomorphine, ergotin, quinine, arsenic, mercury, chloral, digitaline, nitroglycerin, alcohol, and ether.

Morphine thus employed has a wide range of usefulness, and, on account of its power to allay pain, is far more frequently given hypodermatically than any other drug. The sulphate is the salt generally used. It makes a solution which is in every respect well adapted to subcutaneous administration. The ordinary dose is from one-sixth to one-fourth of a grain.

Codeine is used to meet the same indications and is sometimes a desirable substitute for morphine. It is not so likely to nauseate or to constipate, though as an anodyne it is not so trustworthy. The usual dose of either the phosphate or the sulphate is from one-half to one grain.

Atropine, in minute doses, is often combined with morphine, as it is capable of correcting, in some instances, the occasional unpleasant after-effects of the opiate when taken alone, besides possessing valuable therapeutic properties of its own. As an antidote to opium in toxic quantity it is superior to any other drug. The dose ranges from gr. $\frac{1}{150}$ to gr. $\frac{1}{60}$. Duboisine has been recommended as an advantageous substitute for atropine in about the same doses.

Hyoscine is a most valuable cerebral and spinal sedative and hypnotic in doses of gr. $\frac{1}{100}$ of the hydrobromate. It may be administered alone or combined with other anodyne and narcotic drugs. In combination with codeine its hypnotic effect in cases of cerebral excitement is most gratifying.

Hyoscyamine is closely allied in its action to atropine, but it has been found peculiarly effective in allaying maniacal excitement. The usual hypodermatic dose is gr. $\frac{1}{60}$. It should be cautiously administered at first. Testimony is not lacking of its value in various forms of motor excitement—as muscular tremor, laryngismus, hiccough, etc.

Strychnine produces more decided, and often more satisfactory, results when injected subcutaneously. A simple aqueous solution of the sulphate answers this purpose well. One grain to the ounce of water makes a convenient solution, which will keep without change for a considerable time. Fifteen drops—representing gr. $\frac{1}{32}$ —gradually increased when required,—is a proper initial dose.

Eserine, the active principle of calabar bean, acts more promptly when given hypodermatically than when administered by the stomach. The dose of the sulphate or muriate is from gr. $\frac{1}{100}$ to gr. $\frac{1}{50}$. In effect, it diminishes the reflex excitability of the spinal cord.

Pilocarpine is administered in doses of from one-eighth to one-quarter or one-half of a grain. The nitrate is the salt most commonly employed. It is freely soluble in water, and acts, when used hypodermatically, with great promptness.

Caffeine—the sodio-benzoate—may be exhibited in one-grain doses in conditions of mental and physical depression, for nervous headaches—especially for such as are dependent upon the omission of the accustomed cup of coffee—and in addition to atropine in cases of opium poisoning. It has also been used with some success in the treatment of neuralgia.

The hydrochlorate of cocaine is used hypodermatically mainly for its local anæsthetic effect. Its use is not free from danger. Excessive depression of the circulation sometimes follows its administration. The dose is from one-eighth to one-half of a grain, dissolved in water. The latter quantity has produced alarming symptoms, but is ordinarily safe, especially when preceded by generous alcoholic stimulation. It seems, however, that in smaller doses it reduces the frequency, but increases the force, of the pulse. More or less nausea may be experienced during its action. The extent of its anæsthetic influence is very limited, probably including only the absorbing tissues which may be brought into immediate contact with the solution. It is more than likely that the drug supplied by the trade is of variable strength. Herein lies a danger that should be watched.

Apomorphine is serviceable in conditions requiring a prompt emetic, and when, from unconsciousness or from some other circumstance, deglutition is rendered impracticable. It is conspicuously useful in some cases of narcotic poisoning. In consequence, however, of its depressing influence upon the system it should be used with caution, more especially in cases of profound narcotization, in which the respiratory and cardiac movements are feeble. The usual dose is one-tenth of a grain for adults.

Ergotin is given subcutaneously in doses of from two to five or ten grains, or even in larger quantity in cases of extreme urgency. One drachm of water will dissolve twenty grains of ergotin—which, in fact, is only an aqueous extract of ergot. A more concentrated solution may be made by rubbing up the purified extract with distilled water until one minim represents one grain. It should be carefully filtered to remove all solid particles. One-half grain of carbolic acid added to each ounce of the solution will prevent destructive changes, which, without it, will take place very rapidly. In the absence of the aqueous extract the fluid extract may be used. Ergotin injected under the skin is beyond doubt a most potent remedy in hæmoptysis, hæmatemesis, metrorrhagia, and, indeed, in many forms of hemorrhage beyond the reach of surgical control. It is valuable also in congestions of the brain and spinal cord, in the early stages of meningitis, and in a number of uterine and other disorders. Sclerotinic acid has been prescribed as a substitute but it does not represent ergot.

The sulphate of quinine—the salt of quinine commonly prescribed in this country—requires for its solution seven hundred and forty parts of water, which fact is an insuperable obstacle to its satisfactory hypodermatic administration. It has been proposed to dissolve the disulphate of quinine in water by means of heat and of dilute sulphuric acid—two minims to the grain—so that one drachm of the solution would contain six grains of the quinine. The solution is to be filtered immediately and a few drops of carbolic acid added to insure sterility.

The official bisulphate of quinine, as commonly supplied, while freely soluble in water—one part in ten—contains an excess of acid, and, consequently, like the foregoing, is very irritating to the tissues.

The kinate of quinine has been used, and, although it is dissolved by four parts of water to one of the salt, it is not free from objections.

The hydrobromate of quinine is soluble in the proportion of one part to sixteen of water at a temperature of 59° F. Heat, or the addition of a little alcohol, increases its solubility. It is neutral in reaction, and is well adapted for hypodermatic use.

Of all the preparations of quinine at present known, the muriate of quinine and urea is the most available for subcutaneous injections. It is not official and is but little known in this country, yet it is used with the most satisfactory results in Germany (Hager's "Handbuch der pharmaceutischen Praxis"). This double salt is made by adding three parts of urea to twenty parts of hydrochlorate of quinine dissolved in fifteen parts of muriatic acid of a specific gravity of 1.061. It is soluble in its weight of water at ordinary temperatures. A fifty-per-cent. solution is used with prompt effect, followed by very slight local irritation and only a transient stinging sensation at the point of insertion.

The most important field for the hypodermatic use of quinine will probably be found in the pernicious types of malarial fevers, where the utmost promptness in securing its full effect is often requisite, and in the more common malarial derangements attended with gastric disturbances, which preclude its use by the mouth. The dose varies greatly according to the indications to be met. It may be stated as from one to twenty grains.

The official solution of the arseniate of potassium is the form in which arsenic is generally exhibited subcutaneously. It produces less local irritation if diluted with an equal quantity of water. The dose is three minims—equivalent to about gr. $\frac{1}{35}$ of arsenious acid. It may be gradually increased to a much greater amount.

Some advantages are claimed for the arseniate of sodium for hypodermatic use. The official solution may be given in the same dose as the preceding preparation.

The hypodermatic method is ordinarily not an available mode of using mercury in private practice, though the visible lesions of syphilis undoubtedly disappear under its use in this manner more rapidly than when it is given by the mouth. Nevertheless, from the force of circumstances, recourse to this means of treatment must be reserved for exceptional cases. The corrosive chloride dissolved in water is the favorite preparation of the drug. The dose, to commence with, may represent gr. $\frac{1}{40}$.

The great and persistent pain which accompanies and follows the hypodermatic administration of chloral seriously militates against its use in this manner. A fifty-per-cent. solution in water is generally employed. A more liberal dilution of a full dose, while it diminishes the local irritation, at the same time inconveniently increases the bulk of the injection. An anodyne effect is said to follow the subcutaneous use of chloral, which is not observed when it is taken by the mouth. In cholera—both epidemic and sporadic—it yields excellent results. Bartholow reports a "very formidable case, in which there seemed but little hope; sixty grains were administered hypodermatically in two hours, with the effect to stop the cramps, restore warmth, and to remove indeed all unfavorable symptoms." The same author says: "There is no means of treating cholera now known so effective as this."

Chloral may be injected in combination with morphine, or morphine and atropine. The combination constitutes a powerful anodyne hypnotic. The dose of chloral is from five to ten grains or more.

Digitaline is administered to meet the indications for which digitalis is used.

Nitroglycerin is a diffusible cardiac stimulant.

Alcoholic stimulants may be given hypodermatically in the form of brandy, whiskey, or diluted alcohol, when an immediate effect is required, and when administration otherwise cannot be accomplished. A syringeful may be injected.

Ether is extolled as a diffusible stimulant in conditions of collapse or of profound physical depression. It may be given in doses of fifteen to thirty minims undiluted.

The strength of the solutions employed for hypodermatic injections is a matter of some consequence. If too free dilution should be resorted to, the mere bulk of the injection is annoying on account of the pain consequent upon distention of the tissues or upon successive punctures of the skin, which may be necessary for its introduction. If, on the other hand, the solution should be too concentrated, it may prove very irritating. Then, again, it should be remembered that a few drops of the solution may remain in the nozzle and in the needle. This residuum will, of course, be of more importance if taken from five than from twenty drops. Two drops, for instance, will represent in the former case nearly one-half of the dose, which might be a serious loss, while in the latter it would be a waste of only one-tenth, and possibly be inappreciable so far as the effect of the drug is concerned.

As most of the remedies used hypodermatically are concentrated poisons, accuracy of dose is very necessary.

Distilled water is not essential in making the solutions; indeed, it is inferior to river, cistern, or well water, either of which will answer every requirement, if only free from visible impurities.

Strong acid and strong alkaline solutions are unfitted for hypodermatic administration. The solutions should be as nearly neutral as possible and free from irritant qualities. "Metallic salts have their irritating properties diminished or removed by being combined with albumen or with an alkaline citrate or tartrate, so as to form double salts" (Brunton).

Solutions of the alkaloids undergo subtle and unknown changes when kept for a considerable time. They develop also a fungous growth—*penicillium,*—a minute organism which multiplies at the expense of the alkaloid, and the solution deteriorates in proportion to the increase of this formation. The evaporation of the menstruum will also influence the strength of the solution. Therefore fresh solutions only should be employed, or, better still, they may be extemporaneously prepared from powders of known quantity, or from hypodermatic tablets, which are now manufactured by a number of responsible parties whose established reputations may be accepted as a guarantee of absolutely reliable products. Simple tablets, composed of a single drug or several combinations of different drugs, may be procured. They are pre-eminently adapted to the convenience of practitioners and possess many advantages over the ready-made solutions.

The use of cherry-laurel and of eucalyptus waters as menstrua for the alkaloids serves to prevent the destructive changes that render the simple aqueous solutions unstable and unreliable. The antiseptic influence of carbolic acid and of salicylic acid has been invoked for the same purpose. One to four grains of either to the ounce will not prove objectionable, and will preserve the solutions for several months. Boric acid is also employed with a like object.

The solution injected should be entirely free from solid particles. To insure this point it is well to warm the mixture before drawing it into the syringe, as heat increases the solvent action of water, and, besides, a moderately warm injection is less disagreeable to the sensations of the patient. This heat may be conveniently applied by holding the spoon containing the solution for a few moments over a gas jet, a lamp flame, or a burning match.

The prominent advantages which accrue from the hypodermatic method of exhibiting drugs consists principally in the prompt effect obtained; the opportunity which it affords to surmount the obstacles of nausea and vomiting so commonly encountered, and to overcome also any voluntary or involuntary resistance on the part of the patient, the consequence of unwillingness or inability to swallow. In many cases, too, from some idiosyncrasy of the individual, a peculiar susceptibility exists to unpleasant after-effects of certain medicinal agents when taken by the mouth. This result may, not infrequently, be moderated or obviated by the subcutaneous injection of the same remedy, and a smaller dose may be depended upon to yield given results; moreover, it is possible that a special therapeutic effect may sometimes be secured. Absorption from the subcutaneous cellular tissue is less likely to be modified by the condition of the organism than absorption from the stomach and intestines. In the alimentary canal the condition of the circulation, the presence or absence of foods, the state of the lining membrane, the nervous supply, etc., influence, regulate, and determine absorption.

With a sharp needle, of not too great size and free from rust, properly managed in a suitable locality, the pain from the operation is, as a rule, insignificant. The danger of provoking inflammation either by the puncture or by the presence of the injected liquid, of the resulting cicatrices, of conveying through the medium of the syringe specific disease, and of injecting air into a vein, are all objections that have been urged against the procedure; but with the exercise of ordinary skill, prudence, and cleanliness, the risks are so remote and so improbable that they need not be seriously considered in estimating correctly the great, palpable, and immediate advantages pertaining to this accepted and indispensable therapeutic resource. *James B. Baird.*

HYPODERMOCLYSIS.—There are few therapeutic procedures which have sprung into such well-deserved popularity as hypodermoclysis. So frequently is it employed to meet urgent surgical and medical conditions that it is difficult for us to realize that less than ten years ago it was an almost unknown method of treatment. While it had been employed sporadically, so to speak, by a number of continental investigators at various times, and very occasionally by a few American physicians and surgeons, it was not until Hildebrand, of San Francisco, published a paper upon this matter that it received the attention that it deserved. Soon after the appearance of Hildebrand's paper, the writer of this article, having become much interested not only in the employment of hypodermoclysis but in the question of the most suitable fluids for use in conditions in which hypodermoclysis was indicated, carried out a series of clinical experiments which confirmed him in his belief that we had in hypodermoclysis a ready means of supplying the body with fluid and in flushing the kidneys, thereby aiding the excretion of effete materials by these organs, and also aiding in the elimination of them through the skin.

Clinical applications of intravenous injection and hypodermoclysis side by side have, it seems, convinced the profession that for most cases hypodermoclysis is much the more useful method, and that only in very urgent cases with peculiar conditions present is it to be substituted by intravenous transfusion. In the majority of instances in which hemorrhage requires the speedy injection of normal saline fluid, it is found that the employment of hypodermoclysis is equal to the occasion and that absorption from the subcutaneous tissues takes place with sufficient rapidity to supply the blood-vessels with a proper amount of fluid. It is only when the hemorrhage is very profuse and the condition is most urgent that intravenous injection can be employed as a satisfactory measure in its place.

The conditions in which hypodermoclysis can be resorted to most satisfactorily are hemorrhages, as just mentioned; in cases of uræmia not associated with dropsy; in certain cases of pneumonia in which the infectious aspect of the case is most marked, and the action of the kidneys is imperfect; and in all of the acute infectious diseases in which it is impossible for the patient to take enough liquid by the stomach to supply his tissues and eliminating organs with a sufficient quantity of fluid. Hypodermoclysis can also be satisfactorily employed in cases of gastric ulcer, and after abdominal operations, when it is necessary to provide the body with fluid and yet in which it is impossible for fluid to be taken by the ordinary channels. Used in this way in cases of obstinate vomiting, saline infusions will very frequently relieve much suffering, allay thirst, maintain urinary flow, and in every way tend to support the patient through a trying ordeal.

Another very useful employment of saline infusions by the hypodermic method is its use in the treatment of threatened collapse in cholera infantum, in cholera morbus of a severe type, and particularly in Asiatic cholera. In the latter disease its employment has undoubtedly saved life in many instances; the saline infusion taking the place of the fluids which are purged out of the body, and diluting the toxins of the disease which are then more readily eliminated by the kidneys. Still another instance in which hypodermoclysis may be employed with great advantage is in the treatment of severe burns, not only for the purpose of overcoming shock, but, more important, for the relief of the toxæmia which seems to be the true cause of death in many cases of this character.

In regard to the employment of hypodermoclysis in the treatment of surgical shock or that which follows severe injuries, it is important to bear in mind that the condition of the patient is one in which there is a complete relaxation of the vaso-motor system. Or, in other words, he who is suffering from shock is being bled to death into his own blood-vessels. Under these circumstances the administration of fluids, either by hypodermoclysis or even by intravenous injection, is of no value so far as their bulk is concerned, unless in association with them are administered drugs which will overcome the vascular relaxation and tend to restore normal arterial tension. Many physicians ignore the well-known physiological fact that the vascular system is capable, when completely dilated, of holding many times the quantity of blood contained in the body. This fact is emphasized when we remember that at an autopsy we are wont to find practically all the blood in the body in the great veins of the thorax and abdomen. When it is recalled that not only are these great veins capable of holding all the blood which the body contains, but that the capillaries of the skin, the capillaries of the muscles, and the capillary systems of large glands, as the liver, are capable of holding immense quantities of blood when relaxed, it will readily be seen that an enormous quantity of liquid would have to be placed in the patient's body before this liquid could by its presence actually fill the widely dilated blood paths. And even if it were possible to fill the blood-vessels of the body by the profuse administration of normal salt solution, this would be of no advantage to the patient, since, under these circumstances, his heart would not be able to pump so much of a bulk of fluid and his tissues would be practically drowned. When, therefore, the use of normal salt solution by hypodermoclysis is followed by good results in the treatment of shock, it is to be clearly understood that these good results accrue not so much by the presence of an additional quantity of fluid in the blood-vessels as upon the stimulant effect which the injection may have directly or reflexly upon arterial tension and cardiac activity, and the therapeutic point is to emphasize that it is wise, under these circumstances, to employ a normal salt solution which is not absolutely indifferent, but one which really possesses some slight stimulant power over the cardio-vascular apparatus.

Another important point to be remembered in the use of hypodermoclysis is that it is not safe to infuse a greater quantity of liquid than one drachm to each pound of body weight in each fifteen minutes; as, if this amount is exceeded, the accumulation of the liquid in the system is so great that the tissues become drowned because the kidneys cannot excrete the liquid fast enough. Hypodermoclysis is also contraindicated in œdema of the lungs due to either cardiac or renal disease, in cases of chronic bronchitis with excessive secretion of mucus and fluid. In stout old persons, and in young children in particular, it must be used with great caution, if at all, and the same remark applies to parenchymatous nephritis, because the tissues are usually dropsical in this affection; and even if they are not, there is a tendency to œdema of the lungs and an imperfect eliminative action of the kidneys so that fluids rapidly accumulate in the tissues. It is hardly necessary to add that in patients having a high arterial tension hypodermoclysis is also contraindicated unless perchance uræmia or puerperal eclampsia is present, under which circumstances arterial tension should be reduced by bleeding or, in the case of puerperal eclampsia, by the administration of full doses of veratrum viride, since by this means arterial pressure is reduced and an active secretion on the part of the skin aids the kidneys in eliminating both fluid and materials from the patient's body.

Physiological experiments made by many investigators, and particularly by Dr. Sydney Ringer, of London, and Dr. Locke, of Harvard University, have proved that a most useful combination is the one which follows, and, at the suggestion of the writer, large manufacturing chemists have put this formula upon the market dissolved in one ounce (31 gm.) of sterile water in such strength that when this quantity of concentrated solution is added to a quart (litre) of pure water, it forms a normal physiological salt solution. The writer has employed this concentrated saline, after diluting it, in a great many cases with the most satisfactory results, and believes that it is the best solution for the purposes named. The formula is as follows:—℞ Calcium chloride, 0.25 gm.; potassium chloride, 0.1 gm.; sodium chloride, 9 gm.; water, 31 gm. This, when added to a quart (litre) of pure water, constitutes what is known as "normal saline solution."

The proper means of introducing normal saline solution under the skin is to employ an ordinary clean glass irrigating apparatus and rubber tube. In the distal end of the rubber tube is inserted, and if necessary tied in, a needle having a calibre about that of the ordinary antitoxin needle. The reservoir is filled with normal saline solution and hung about eighteen inches or two feet above the level at which the needle is inserted. The salt solution should be at about 110° F. in the reservoir, since it cools rapidly in its slow passage through the tube. Or, better still, it may be placed in a warm reservoir at the temperature of 100°, and the rubber tube may be coiled in a basin of water at the same temperature so that the fluid in it is maintained at the temperature of 100° during its flow. The skin where the needle is to be inserted should be thoroughly cleansed before the puncture is made, and the most satisfactory site for the injection is a little above the groin, about half-way between the navel and the anterior superior spine, or, in stout persons and in women, in the submammary region, and sometimes it may be employed on the inner side of the thighs, care being taken to avoid the great vessels. If even moderate antiseptic precautions are maintained abscess practically never results, and the operation is quite painless, although some tenderness may exist in the region of the injection for a few hours after the absorption of the fluid. The process is not a painful one at any stage. When it is wise to inject a considerable quantity of liquid into the patient at once, more than one needle and tube may be employed simultaneously. *Hobart Amory Hare.*

HYPOGLOSSAL NERVE.—(Synonyms: Nervus motorius linguæ; Nervus hypoglossus; Par nonum of Willis and the older writers; Par duodecimum; *Nerf hypoglosse* (Fr.); *Zungenfleischnerf* (Ger.).

The twelfth or hypoglossal nerve, whose name is derived from the Greek ὑπο, beneath, and γλῶσσα, the tongue, is the motor nerve of the muscles of the tongue and of those of the hyoid bone, with the exception of the digastric, stylo-hyoid, mylo-hyoid, and the superior constrictor of the pharynx. It also supplies the sterno-thyroid muscle. According to the old nomenclature it was termed the *ninth* nerve.

For the anatomy of the hypoglossal nerve consult the article on *Cranial Nerves.*

Physiology.—The hypoglossal nerve is the motor nerve for the muscles of the tongue, the sterno-thyroid muscle, and all those attached to the hyoid bone, with the exception of those mentioned above. Through its connection with the upper cervical ganglion of the sympathetic, vaso-motor fibres for the muscles of the tongue pass into it. From the gangliform plexus of the vagus and its lesser lingual branch are derived its fibres of muscular sensation. Whether any such come from the cervical nerves or through the anastomosis with the lingual is still doubtful, though Lewin says: "Recurrent fibres run from the lingualis to the hypoglossus, and these in part ascend as far as the anterior condyloid foramen, in part descend in the ramus descendens." As a rule, no influence reaches the tongue through the ansa hypoglossi, and, on the other hand, little effect is produced on the muscles supplied by the ramus descendens (the sterno-thyroid, omo-hyoid, and sterno-hyoid) by irritation of the roots of the hypoglossus.

Pathology.—Injury or disease of the hypoglossal nerve or its nucleus produces either spasm or paralysis of the muscles which it supplies.

(*a*) *Spasm of the Muscles Supplied by the Hypoglossal Nerve; Lingual Spasm.*—This is rarely idiopathic and is very infrequent as an independent affection. On the other hand, it occurs not uncommonly in certain affections of the brain, and more rarely in some of those of the spinal cord. In all forms of general convulsions, in eclampsia, epilepsy, chorea, and hysteria, we meet with it frequently, and it is often seen in company with spasms of the muscles supplied by the motor branch of the fifth nerve, and by the facial and spinal accessory nerves. At times it accompanies facial neuralgia, or is coincident with stuttering. It is not rare in bilateral athetosis, and it occurs in trismus. It may also be dependent on a definite pathological condition of the brain or its membranes, and is found in meningitis and in certain forms of cerebral and bulbar paralysis. It sometimes occurs in certain diseases of the spinal cord, as progressive muscular atrophy, in which the disease probably extends upward and involves the hypoglossal nucleus.

In many of these cases we may suppose some injury of the nucleus, or, possibly, of the nerve itself, but we must not forget that lingual spasm may in all probability be produced by lesion of the cortical motor centre of the tongue at the base of the ascending frontal convolution, or possibly of some of the fibres which connect this with the hypoglossal nucleus. The spasm is also at times apparently due to peripheral or reflex causes, as in some cases in which it occurs with tic douloureux or in company with the spasms of neighboring muscles. In one case it was apparently caused by caries of the teeth, which had produced an ulceration of the gums.

The spasms vary in character in different cases. They may be either tonic or clonic. They may consist in mere protrusion of the tongue. Sometimes the tongue is thrust violently forward against the teeth, or it may be protruded and rapidly retracted, as in Berger's case, in which this occurred as often as fifty or sixty times a minute. Sometimes the tongue seems to be simply rolled round in the mouth. Again, the movements may be very varied and irregular. These spasms may also affect the sterno-thyroid, sterno-hyoid, and thyro-hyoid muscles. There is usually no pain or swelling, but the spasms may be preceded by a sensation of numbness in the tongue, or discomfort and oppression about the throat above the larynx. The tongue sometimes feels too big for the mouth. The spasms are for the most part independent of the acts of speaking, masticating, and swallowing, neither affecting them, unless when at their height, nor being affected by them. In certain cases, however, the spasms are induced or greatly aggravated by such acts.

The tonic spasms likewise may either occur independently, or they may be induced by voluntary efforts to move the tongue. Those of the latter class have been divided into articulatory and masticatory spasms, according as they were produced more especially by attempts to move the tongue in speech or in eating. These articulatory spasms are known as articulatory hypoglossal cramp or aphthongia (aphthongie, Fleury), from the Greek, *a* privative, and φθογγός, the voice. In some cases the tongue is glued to the hard palate whenever the patient attempts to speak; in others (masticatory cramp) the food is ejected from the mouth by the involuntary action of the tongue during mastication. In Ganghofner's case, in which there was spasmodic contraction of the tongue in ordinary speech, singing, rapid speech, and the declamation of previously known pieces were more easily accomplished.

The *prognosis* of independent lingual spasm is generally good, though the disease may be obstinate and persistent.

Treatment. There is no symptomatic treatment, as such, for lingual spasm except the application of electricity. The constant current may be applied directly to the tongue or to the hypoglossal nerve in the neck. The faradic may also be used in the same manner. These are the most useful means of direct treatment. When the spasm occurs as a symptom, or in the course of some other disease, the primary disease is, of course, to be treated. In independent spasm our first care should be to remove, as far as possible, all predisposing or exciting causes. The teeth and gums should be carefully examined, and any source of reflex irritation should be allayed. Means should also be taken to improve the general health, and to strengthen the resisting powers of the nervous system. Thus fresh air, good wholesome diet, change of scene, and general tonics and sedatives—quinine, iron, and bromide of potassium or sodium—should be our principal aids.

(*b*) *Paralysis of the Muscles of the Tongue ; Glossoplegia.*—Section of the hypoglossus in dogs, when bilateral, causes total paralysis of the tongue. The animals cannot drink, and are apt to bite the tongue, which hangs loosely out of the mouth (Landois).

In man paralysis of the muscles of the tongue is usually central. It may be produced by lesions of the cortical motor centre of the tongue, or of the fibres which connect it with the hypoglossal nucleus, or by lesions of the nucleus itself or of the hypoglossal nerve. Hence it is found in cases of cerebral or bulbar hemorrhage or softening, and in certain other forms of cerebral disease, in progressive bulbar paralysis, and in those forms of spinal disease in which the ganglion cells of the hypoglossal nuclei are affected. Thus it is sometimes seen in the advanced stage of tabes dorsalis and in descending secondary sclerosis. The hypoglossal nerve itself may be affected either intracranially, as by the pressure of tumors at the base of the brain, or extracranially, either at its exit from the cranium or in the neck. This may be done by injuries of the upper cervical vertebræ, such as fracture of the atlas, or by tumors or wounds of the neck, by aneurism of the vertebral artery, or by carious or syphilitic processes.

Symptoms. Hypoglossal paralysis may be either unilateral or bilateral, according as one or both nerves are involved, though bilateral paralysis *may* be caused by a unilateral *cortical* lesion. In unilateral paralysis the tongue, when protruded, deviates to the affected side. This is due to the unbalanced action of the healthy genioglossus muscle, which in contracting not only throws the tip of the tongue forward, but directs it at the same time to the opposite side. In bilateral paralysis the tongue cannot be protruded, but lies perfectly motionless in the mouth. It is relaxed, anæmic, often atrophied, and deeply furrowed. Not infrequently there are fibrillary twitchings. In unilateral paralysis these symptoms may appear on the affected side of the tongue. "When the tongue is paralyzed it falls backward in the cavity of the mouth as the patient lies on his back, and the glottis becomes partially or wholly closed by it. Paralysis of the tongue thus contributes to the production of stertorous breathing in cases of apoplexy, and may even cause asphyxia, when the paralysis is bilateral and more or less complete." Thus closure of the glottis may be produced in deep narcosis.

In lingual paralysis the speech is much affected, and the power of articulation greatly impaired. In bilateral paralysis, with atrophy, the speech is said to be completely inarticulate and unintelligible, and even when the paralysis is slight, the singing of high notes and falsetto is impaired. Ross states that difficulty is first experienced in pronouncing the letters, s, sh, l, e, i, and at a later period k, g, r, etc.

Mastication is interfered with also to a certain extent, as the tongue cannot direct the food nor compress it against the teeth. Deglutition is likewise affected by the falling backward of the tongue, and also because the food cannot be properly collected on its dorsum and pushed back into the pharynx. Hence regurgitation into the mouth occurs. The salivation of the affected side, which is a prominent symptom in certain cases of lingual paralysis, has not yet been shown to be due to anything more than reflex action. The slight diminution in the tactile sensibility of the affected side, sometimes noticed, seems in certain cases not to exist.

Diagnosis. This is usually very easy. Hutchinson's method of testing the condition of the lingualis muscle is very simple. He holds it between his thumb and finger and bids the patient protrude the tongue. If either side be paralyzed, the muscle of that side will be flaccid and relaxed, and will not harden like the healthy one on contraction.

The *prognosis* is naturally dependent on the cause.

Treatment. This must, of course, be directed against the primary cause. Locally, the galvanic or faradic current may be applied either to the tongue itself or to the nerve in the neck. *William N. Bullard.*

HYPOPHOSPHITES.—I. GENERAL MEDICINAL PROPERTIES OF THE HYPOPHOSPHITES.—Physiologically, salts of hypophosphorous acid are simply bland saline representatives of their respective bases, and produce no special effect whatsoever, due to the hypophosphorous acid of their composition. What place they hold in medicine has been from theoretical considerations purely. The idea has been that because these salts contain phosphorus in a comparatively low state of oxidation, they will affect the system after the manner of phosphorus itself, and, especially, will yield phosphorus in such chemical combination as to be assimilable for the nutrition of nerve tissues. Clinical experience, however, has failed on the one hand to get the expected results, while on the other it has shown that nearly all of a dose of a hypophosphite, swallowed, reappears in the urine unchanged. Those who prescribe these salts, do so in cases of neuralgia and of nerve exhaustion or malnutrition generally, and in phthisis.

With the exception of the potassium salt the hypophosphites are harmless, and they are, with manufacturing pharmaceutists, favorite ingredients of emulsions of cod-liver oil.

II. THE HYPOPHOSPHITES USED IN MEDICINE.—The hypophosphites official in the United States Pharmacopœia are the iron, potassium, sodium, and calcium salts. Ferric hypophosphite will be found treated of under *Iron.*

Potassium Hypophosphite, KH_2PO_2. The salt is official in the United States Pharmacopœia as *Potassii Hypophosphis,* Potassium Hypophosphite. It occurs in "white, opaque, hexagonal plates, or crystalline masses, or a granular powder, odorless, and having a pungent, saline taste; very deliquescent. Soluble at 15° C. (59° F.) in 0.6 part of water, and in 7.3 parts of alcohol; in 0.3 part of boiling water, and in 3.6 parts of boiling alcohol; insoluble in ether" (U. S. P.). If triturated or heated with an oxidizing agent, such as a nitrate, the mixture will explode. Because of deliquescence, the salt must be kept in well-stoppered bottles.

Potassium hypophosphite follows the rule of potassic salts of being irritant in large concentrated dosage, but in therapeutic doses it is locally bland enough. Again, because a potassic salt, it may tend to induce retrograde metamorphosis of lowly organized material, and hence lead to softening of cheesy deposits in the lungs. This particular hypophosphite is therefore, theoretically at least, not without a possible dangerous tendency in phthisis. The salt is administered in solution, aqueous or syrupy, in doses of from 0.65 to 2 gm. (gr. x.–xxx.) three times a day. A convenient form of giving it is in the official *syrup of hypophosphites* (see *postea*).

Sodium Hypophosphite, $NaH_2PO_2H_2O$. The salt is official in the United States Pharmacopœia as *Sodii Hypophosphis,* Sodium Hypophosphite. It occurs in "small, colorless, transparent, rectangular plates of a pearly lustre, or a white granular powder, odorless, and having a bitterish sweet, saline taste. Very deliquescent on exposure to moist air. Soluble at 15° C. (59° F.) in 1 part of water, and in 30 parts of alcohol; in 0.12 part of boiling water, and in 1 part of boiling alcohol; slightly soluble in absolute alcohol, insoluble in ether" (U. S. P.). Like the potassium salt, this also will explode on trituration and with an oxidizing agent, and must be kept in well-stoppered bottles.

This sodic salt is a generally serviceable and permissible hypophosphite, having, as usual with compounds of sodium, no active individuality due to the basic radical. It may be given in the same manner and dosage as the potassic salt.

Calcium Hypophosphite, $CaH_4(PO_2)_2$. The salt is official in the United States Pharmacopœia as *Calcii Hypophosphis,* Calcium Hypophosphite. It occurs as "colorless, transparent, monoclinic prisms, or small, lustrous scales, or a white, crystalline powder, odorless, having a nauseous, bitter taste, and permanent in the air. Soluble at 15° C. (59° F.) in 6.8 parts of water, and in 6 parts of boiling water; insoluble in alcohol" (U. S. P.).

Being a salt of lime, which salt is assumed to have a reconstituent tendency in phthisical conditions, this hypophosphite is theoretically the one to be preferred for administration in consumption. It is also the one best borne when the stomach or bowels are irritable, as so often happens in the disease mentioned. The salt is given in the same manner and dose as the potassic salt.

The following pharmaceutical preparations of the hypophosphites are official in the United States Pharmacopœia; *Syrupus Hypophosphitum,* Syrup of Hypophosphites. This is an aqueous solution of potassic, sodic, and calcic hypophosphites (wherein the latter salt has been made fully to dissolve by the addition of a little hypophosphorous acid), made into a syrup by the addition of sugar, and flavored with spirit of lemon. By weight the preparation contains fifty per cent. of sugar, and, of the hypophosphites, 4.5 per cent. of the calcic salt, and 1.5 per cent. each of the potassic and sodic. By measure 4 c.c. (fl. ʒ i.) contains about 0.18 gm. (gr. iij.) of the calcic hypophosphite, and 0.06 gm. (gr. i.) each of the potassic and sodic salts. This syrup forms a convenient preparation for prescription, and may be ordered in doses of from one to two or three teaspoonfuls, several times a day. *Syrupus Hypophosphitum cum Ferro,* Syrup of Hypophosphites with Iron. This preparation is simply the foregoing syrup charged with one per cent. each of lactate of iron and potassium citrate—this particular iron salt being selected for pharmaceutical reasons only. This syrup forms a convenient combination of hypophosphites with a chalybeate, and may be given, where such combination is indicated, in doses the same as those of the simple syrup. *Edward Curtis.*

HYSSOP.—See *Labiatæ.*

HYSSOP, HEDGE.—See *Scrophulariaceæ.*

HYSTERECTOMY (from ὑστέρα, the womb, ἐκ out, and τέμνειν, to cut) is the removal of the uterus by a cutting operation and may be accomplished through an incision in the abdominal wall (cœlio-hysterectomy), by way of the vagina (kolpo-hysterectomy), or by a combination of both methods.

Cœlio-hysterectomy includes (*a*) supravaginal amputation and (*b*) the complete removal. Kolpo-hysterectomy at the present time practically always means the complete removal of the organ.

While dim records of the operation are found as early as 100 A.D., when Soranos[1] is said to have removed the uterus per vaginam, yet as late as 1882, when Ahlfeld[2] collected the records of sixty-six cases in which the uterus had been removed through the abdomen with only thirteen recoveries, the recorded cases were very few and the mortality was frightful, ranging from eighty to ninety per cent. In its present form, and with its very low mortality of from three to five per cent. when done for the same indications, the operation is essentially a modern one, and as such has been developed during the last fifteen years, and largely in America by Baer, Goffe, and Kelly. With the improved technique and lessened mortality the range of *indications* for its performance has widened, until now it may include:

For the Abdominal Operation.—All solid or cystic tumors of the uterus; cancer; uterine rupture during labor; certain conditions of puerperal sepsis; pregnancy complicated by pelvic deformity, cancer, or other serious obstacle to the passage of the child; uterine prolapse or inversion; and incidentally as a step in the removal of complicated suppurative conditions of the uterine appendages.

For the Vaginal Operation.—Bilateral suppurative conditions of the appendages; prolapse; cancer; pregnancy with cancer before the sixth month; certain septic conditions of the uterus; certain rare conditions which may require the ablation of a small movable uterus.

For the Combined Operation.—Cancer; certain complicated fibroids; failure to secure hæmostasis from below.

For the details of these indications the reader is referred to the articles treating of the various conditions mentioned.

The operation of hysterectomy is always formidable, and as conditions may arise at any time which tax the resources and nerve of the most skilled, and where hesitation or lack of expedient may mean the immediate death of the patient, it should not be undertaken without an adequate practical knowledge both of aseptic surgical technique as applied to abdominal surgery and of the anatomy of the pelvic contents, particularly of the relations of the bladder, ureters, rectum, uterine and ovarian arteries, and large venous trunks.

TECHNIQUE OF CŒLIO-HYSTERECTOMY.—The patient is prepared as for any abdominal operation; the intestines are thoroughly emptied; for several days she is encouraged to drink water freely; the skin of the abdomen is carefully disinfected; the vulva and vagina are cleansed and packed with 1 to 4,000 bichloride gauze for two days, and the limbs covered with cotton and a bandage to prevent chilling of the surface.

The instruments needed are: Two scalpels, two pairs of strong blunt-pointed scissors, two anatomical forceps, six traction forceps, twelve short hæmostatic forceps, eight long clamp forceps, pedicle needle, retractors, long and small curved needles, strong silk or kangaroo tendon, slightly chromicized catgut nos. 1, 2, 3.

The patient is put in the Trendelenburg position. The abdomen is opened by a median incision beginning half an inch above the pubes and extending upward, as far as may be necessary to allow the delivery of the tumor. In making this incision care must be taken not to injure the bladder which sometimes is drawn high up. Remembering that any injury to the capsule of fibroids will cause free and troublesome bleeding, adhesions are carefully detached, slight ones being wiped free by a bit of gauze and firmer ones divided between two ligatures. Dense adhesions to intestine may require that small areas be detached from the surface of the tumor. The tumor being freed from adhesions is lifted up and out off the abdominal cavity. Large flat gauze pads with strings attached are wrung out of hot sterile salt solution and placed so as to protect and cover the intestines. The finger is passed under the broad ligament on the more accessible side, and, guided by it, the pedicle needle, threaded with a long, strong ligature, is passed through a portion free from veins, so as to include the ovarian artery. This ligature is then firmly tied and occludes the artery and the adjacent large venous trunks. The ovary is to be left outside the ligature, unless it is so diseased that its removal is desirable. A second bite with the same ligature ties off the round ligament. A long clamp is now placed so as to control the vessels on the uterine side and the tissues between clamp and ligatures are divided with the scissors. If the ovarian artery on the other side is easily accessible, it is tied in the same way. Careful inspection of the anterior surface of the uterus will now determine the upper limit of the bladder, and a transverse incision through peritoneum only is made a third of an inch above this point, running from the lower edge of the cut in the broad ligament across the uterus to a corresponding point on the other side. The bladder is freed from the uterus by being carefuly wiped down with a piece of gauze held by fingers or forceps. The uterine artery is now exposed, and a finger passed down by the side of the cervix can feel its pulsation. This artery is to be carefully ligated on one side and then on the other, *close* to the side of the cervix, the pedicle needle being passed forward and not outward, so as to avoid the ureter. The cervix is then divided and the uterus and tumor are removed.

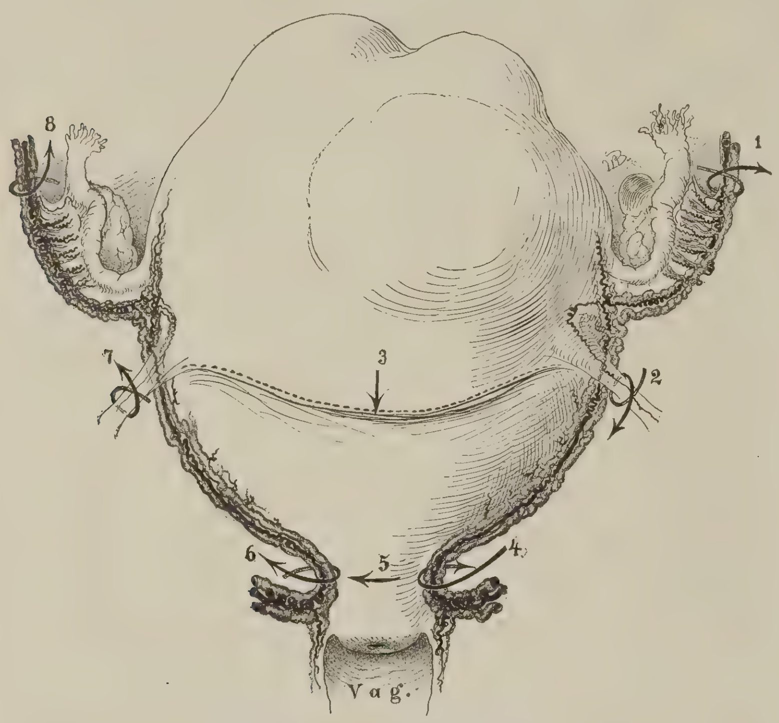

FIG. 2775.—Showing Diagrammatically the Blood Supply to the Uterus and the Successive Steps in Kelly's Method of Supravaginal Hysterectomy.

When the operator has attained confidence in his technique, the procedure is greatly simplified especially in difficult cases, by first securing the ovarian and round ligament arteries on the more easily accessible side, freeing the bladder, securing the uterine vessels, cutting freely across the cervix until its tissue is nearly divided, catching the lower portion of the cervix with traction forceps so as to have it under control in case of unexpected hemorrhage. Tearing carefully the last fibres of the cervix, the operator will see the remaining uterine artery arching across the torn space. After this has been clamped or ligated, and the remainder of the broad ligament has also been clamped, the tumor is removed (Fig. 2775). All bleeding points having been secured by ligatures the edges of the cervical stump are carefully approximated with catgut, and the anterior and posterior peritoneal edges of the pelvic wound brought together, so as to cover in all raw surfaces and leave finally only a seam across the pelvis. The abdomen is then closed.

When it is considered best to remove the entire cervix after securing the arteries by ligature or clamp, the uterus or the cervical stump is drawn away from the vagina and the dissection is carried down by scissors, keeping close to the cervix so as even to leave a slight ring of its tissue in place. When the cervico-vaginal junction is reached the scissors are pushed through into the vagina and with this opening as a guide the remaining tissues are easily divided. All bleeding points having been secured, a piece of sterile gauze is pushed down into the vagina so that the upper part comes just above the cut vaginal edges, and the peritoneal edges are drawn together and sewed so as to close off the peritoneal cavity as in the supravaginal operation. The gauze drain is left in place five or six days.

In certain instances, especially when there are inflammatory disease of the appendages and extensive adhesions so that the tumor masses are fixed in the pelvis and the vessels covered in out of reach, it becomes necessary to incise the uterus anteriorly, always keeping strictly in the middle line, and rapidly to enucleate the tumor or tumors. The uterus then being collapsed and its relations easily recognized, the vessels can be secured and the operation completed.

Very large subperitoneal tumors under the vesical peritoneum, or in the broad ligament, are often best removed by a bisection of the tumor, as this allows the tumor to roll up and out on to the surface with the least handling and injury to its cellular investment.

Howard Kelly,[3] in a case of fibroid reaching the umbilicus and with extreme adhesions to the colon and

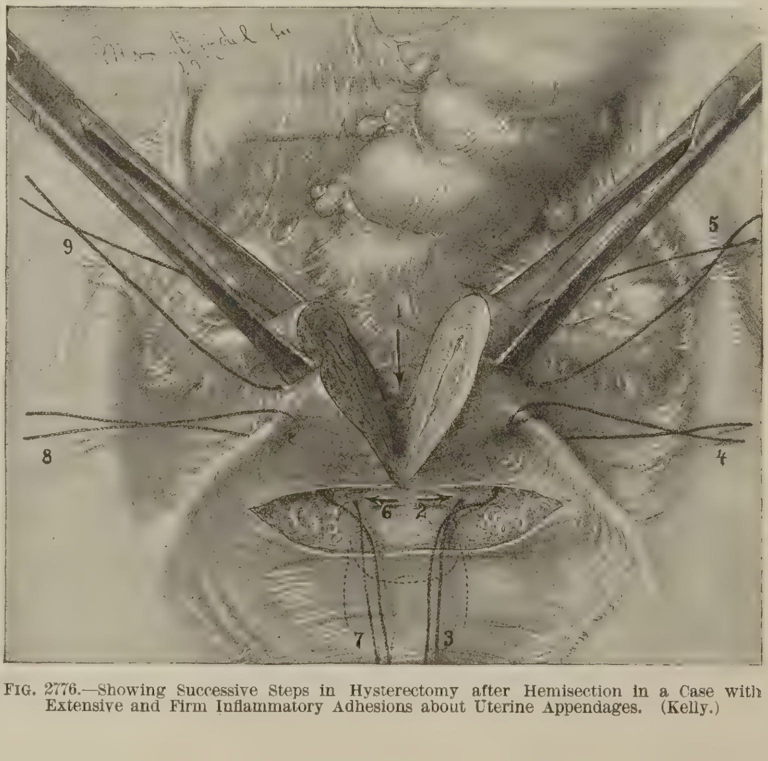

FIG. 2776.—Showing Successive Steps in Hysterectomy after Hemisection in a Case with Extensive and Firm Inflammatory Adhesions about Uterine Appendages. (Kelly.)

adjacent structures, first dissected the bladder from the cervix, then cut cautiously through the cervix transversely, tearing the last few fibres on each side, and as the uterine vessels came into reach clamped them with short-jawed forceps, compressed the vessels and cervix above the incision with long-jawed forceps, cut the vessels, and as the tissues could be pulled into reach after the cervix was loosened, secured the vessels up to the upper edge of the broad ligament, dealing with the adhesions to the colon after the mass had been entirely freed from below and lifted out of the abdomen.

Where there is double pyosalpinx with dense adhesions covering the uterine appendages and all contiguous structures, very great advantages are secured by a preliminary bisection of the uterus as described by Faure,[4] of Paris, and Howard Kelly,[5] of Baltimore. Kelly proceeds as follows: If the uterus is buried out of view, the bladder is first separated from the rectum and the fundus found; large abscesses, cysts, or hæmatomata are evacuated by puncture or aspiration; the abdominal cavity is carefully packed off from the pelvis. The uterine cornua are each seized by traction forceps and lifted up; the uterus is incised antero-posteriorly in the middle line, while its cornua are pulled up and drawn apart (Fig. 2776). With a third pair of forceps the uterus is grasped at one side on its cut surface as far down in the angle as possible, including both anterior and posterior walls. The traction forceps of the same side is then released and used for grasping the corresponding point on the opposite cut surface. In this way two forceps are constantly in use at the lower point. The bladder being pushed down or away from the uterine surface, the bisection is carried down to the cervix, or, if the operator prefers, into the vagina. The uterine canal must be followed in the bisection, using a director, if necessary, to keep it in view. Forceps now grasp the uterus well down in the cervical portion, if it is to be a supravaginal amputation, and the cervix is bisected on one side. As soon as it is divided and the uterine and vaginal ends begin to pull apart, the under surface of the uterine end is caught with a pair of forceps and pulled up, and the uterine vessels, which can now be seen, are clamped or tied. As the uterus is pulled farther up the round ligament is exposed and clamped, then a clamp is applied between the cornu and the tubo-ovarian mass and the half uterus removed. The same is done on the other side, and there are left only the tubo-ovarian masses for enucleation under the best possible conditions. Often the tube and ovary can just as well be taken out with the corresponding half of the uterus, leaving the separate enucleation for the most difficult cases. The most critical point in the operation is the bisection of the cervix and the securing of the uterine vessels. The cervix must be slowly and cautiously severed with steady, careful traction on the uterus, so as to prevent sudden tearing out and rupture of the vessels with frightful hemorrhage. By cutting so as to leave a tongue on each side of the cervix the vessels can be caught at a higher level and farther from the ureters.

Kelly also states that if the uterus is densely adherent to the rectum all the way up to the fundus the anterior portion of the uterus should be bisected, the cervix divided, the uterine vessels caught, and the rest of the uterus carefully divided up its posterior surface in a direction from the cervix toward the fundus, leaving a thin layer of uterine tissue on the gut at any point where it may seem necessary.

When the uterus is retroflexed with the fundus low in the pelvis and the cervical end thrust up near the symphysis, it may be caught at any convenient point on its anterior surface and drawn up toward the incision. The vesical fold of peritoneum is cut across and pushed down, and the cervix exposed and caught with two traction forceps, one above and one below. As the cervix is drawn up it is cautiously divided across its axis so as to sever the vaginal from the corporeal portion. As the ends are pulled apart the uterine vessels are exposed and clamped. The uterus may then be bisected from below upward or removed *en masse.*

Cœlio-hysterectomy for Cancer.—Cullen[6] states that this operation should be preferred in all cases when the patient is not too stout, but that to employ it in very fat individuals is unsatisfactory, both on account of the large quantity of adipose tissue in the abdominal wall, which materially increases the distance to the pelvic floor, and on account of the deposition of fat between the folds of the broad ligament and beneath the peritoneum of the pelvic floor, which renders the free dissection of the ureters and uterine arteries exceedingly difficult.

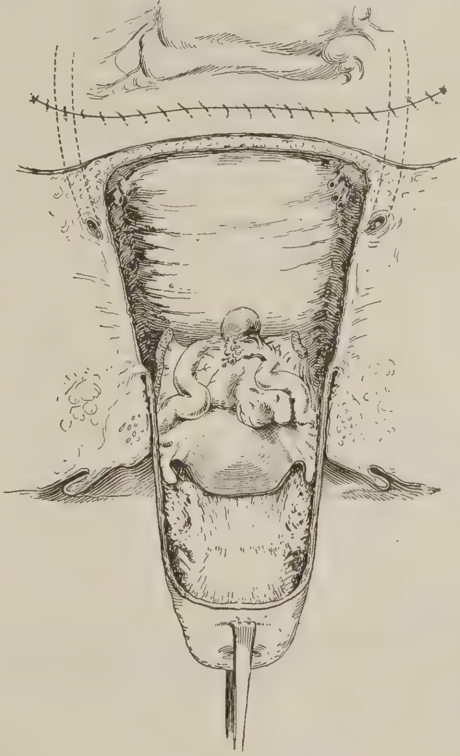

FIG. 2777.—Werder's Operation. The uterine attachments have been separated from above and the uterus pulled down through the vagina by a traction forceps attached to the cervix. The vesical and rectal peritoneum has been united by a running suture. The operation is completed by dividing the vagina at its reflection an inch within the vulva.

The great advances in the technique of hysterectomy for cancer have been made by Ries,[7] Clark,[8] Rumpf,[9] and Werder.[10] Ries, in 1895, published a method involving the removal of the pelvic lymph glands after slitting the peritoneum back to the posterior pelvic wall as far as to the point at which the common iliac artery divides, Rumpf being the first to carry out this procedure on the living subject. Clark in 1895, having made the ureters prominent by the insertion of bougies, carried the operation to the point where the uterine artery is exposed, then spread the layers of the broad ligament apart, dissected the uterine artery out for a distance of 2.5 cm. from the uterus to beyond the vaginal branch and tied it, removing the broad ligament close to the iliac vessels and carrying his dissection well down on the vagina even if the disease did not apparently extend beyond the cervix. With all these methods there is the grave disadvantage that the carcinoma is very apt to come in contact with peritoneal or raw surfaces, so that there is always the risk of septic infection or of implanting carcinoma cells in healthy tissue. In 1898 Werder, to avoid this, devised a method by which, after the careful separation of the structures from above, the *uterus and vagina* are removed *en masse* from below (Fig. 2777).

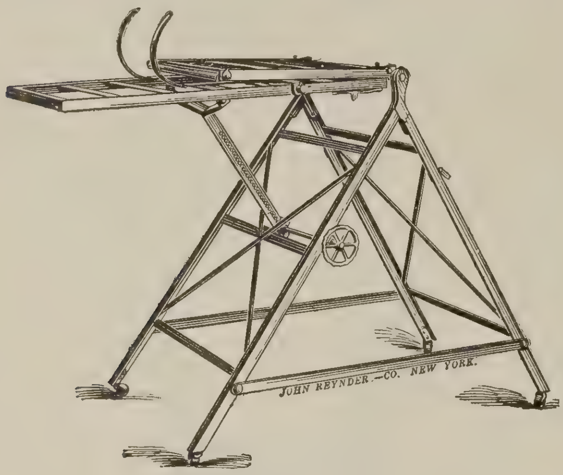

Fig. 2778.—Pryor's Table Arranged for Vaginal Hysterectomy in the Lithotomy Position.

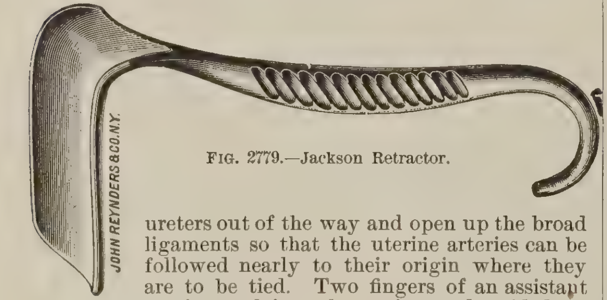

Fig. 2779.—Jackson Retractor.

The plan of the operation now is: To scrape away the broken-down carcinoma tissue, preferably several days before the operation, the bleeding surface being seared over with the thermo-cautery. If desired, bougies can be passed into the ureters. The patient is then placed in the Trendelenburg position, the abdomen is opened, the ovarian arteries are secured, and the bladder is separated not only from the front of the uterus but from the broad ligament on either side as widely as possible, so as to get the ureters out of the way and open up the broad ligaments so that the uterine arteries can be followed nearly to their origin where they are to be tied. Two fingers of an assistant are inserted into the vagina, and guided by them the dissection is carried down in front between bladder and vagina to within an inch of the vulva. The uterosacral ligaments are divided with scissors, and the rectum is separated from the vagina to the same level. The lateral walls of the vagina are then freed, and lastly the bases of the broad ligaments are divided. This step is generally conceded to be the most difficult in the operation. The uterus and vagina, being now completely freed, are pushed down into the pelvic outlet, an assistant making strong traction on the cervix from below. The removal of the pelvic glands after slitting the peritoneum of the posterior pelvic wall to the point where the common iliac artery divides, and the stitching of the anterior and posterior peritoneal flaps so as to close off all raw surfaces from the peritoneal cavity, complete the abdominal part of the operation, and the abdominal incision is then closed. The patient is now placed in the lithotomy position and, guided by a finger in the rectum and a sound in the bladder, the surgeon amputates the inverted vagina with the knife or with a thermocautery and places a light gauze dressing in the space left in the vaginal vault.

Technique of Kolpo-hysterectomy.—The patient is prepared in every way as for the abdominal operation, so that in case of failure to secure hæmostasis, or of other complication, there need be no delay in opening the abdomen. A final scrubbing of the vulva and vagina is made with a one-per-cent. lysol solution by means of a long soft brush or piece of sterile gauze wound around the ends of two fingers. While the operation may be done on any ordinary table, it is very desirable to be able at any time to tilt the patient into the Trendelenburg position so as to free the pelvis from abdominal viscera. This is easily accomplished with the table shown in Fig. 2778, which is strong, portable, and useful for any gynæcological work.

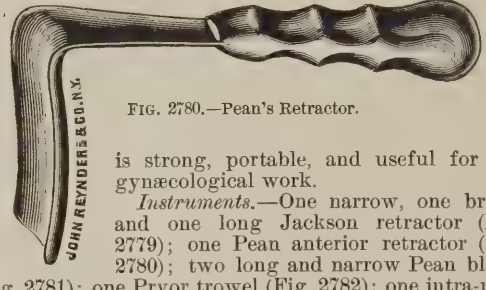

Fig. 2780.—Pean's Retractor.

Instruments.—One narrow, one broad, and one long Jackson retractor (Fig. 2779); one Pean anterior retractor (Fig. 2780); two long and narrow Pean blades (Fig. 2781); one Pryor trowel (Fig. 2782); one intra-uterine traction forceps; two strong bullet forceps; four traction forceps (Fig. 2783); Pryor's retracting director (Fig. 2784); two strong scalpels with good bellies; long, strong, sharp and blunt-pointed scissors, curved on the flat; eight pairs of Pryor's hysterectomy forceps (Fig. 2785); and other material as under *cœlio-hysterectomy.*

The most frequent and imperative indication for removal of the uterus per vaginam is the presence of bilateral suppurative disease of the appendages, and the clamp operation for this condition will be described first.

The steps of the operation are: The curetting of the uterine cavity; the opening of the posterior cul-de-sac; the incision in front of the cervix and separation of the bladder from the uterus; the hemisection of the uterus; the freeing of the appendages; the bringing down of first one and then the other half and its appendages, clamping its arteries and removing it; the dressing.

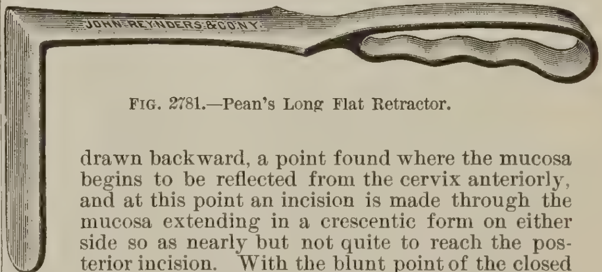

Fig. 2781.—Pean's Long Flat Retractor.

The patient is put in the lithotomy position with the coccyx well over the edge of the table. The uterus is curetted and irrigated; the instruments used are discarded and the hands washed. A posterior retractor is introduced, the cervix exposed and drawn forward with a pair of traction forceps or, better, with Pryor's intra-uterine traction forceps, and a transverse incision the width of the cervix made with knife or scissors at the point where the vaginal mucosa is reflected posteriorly from the cervix. This incision is kept close to the posterior surface of the uterus until the peritoneal cavity is opened, which is usually accomplished without much difficulty. The index fingers are then passed in and the opening is sufficiently enlarged by tearing. An exploring finger is passed through this opening and the condition of the appendages learned. A gauze pad with string attached is passed up to protect the intestines. The cervix is then drawn backward, a point found where the mucosa begins to be reflected from the cervix anteriorly, and at this point an incision is made through the mucosa extending in a crescentic form on either side so as nearly but not quite to reach the posterior incision. With the blunt point of the closed scissors directed toward the cervix and used as one would a periosteal elevator the tissues are pushed up along the anterior surface of the uterus, aided after a little by the finger. This is done carefully and gently so as not to injure the bladder, and over a width of about two fingers, the fact being kept in mind that at the side it is easy to tear into the arteries or lateral venous trunks. When some little separation has been obtained, a long anterior retractor, or trowel, is inserted beneath the bladder so as to lift it up out of the way, any restraining fibres being snipped with scissors. The finger can sometimes be pushed up to the reflection of peritoneum from bladder to uterus and on through the tissues into the peritoneal cavity, or the peritoneum at this point may be opened with scissors. At other times it is not easy to reach as high as this.

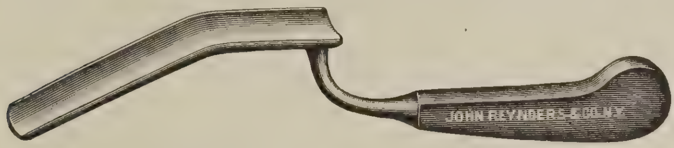

FIG. 2782.—Pryor's Trowel Anterior Retractor.

The tissues having been separated anteriorly and posteriorly, the fundus can sometimes, when small and movable, be turned forward and brought through the anterior incision by taking higher and higher grasps with traction forceps, so that clamps or ligatures can be applied to the vessels of one side and after division with scissors between clamp and uterus the other side easily secured, but usually it is better first to divide the uterus in the middle line. This is accomplished by grasping the anterior lip of the cervix on either side with traction forceps, cutting upward through the anterior uterine wall in the middle line as far as convenient, taking a fresh grasp higher up on either side, cutting again, and repeating this until the fundus is reached. Then the broad-curved director is passed behind the cervix close along the posterior wall of the uterus, care being taken by a finger passed over the fundus that no folds of intestine are between it and the uterine body, and an assistant pressing the handle firmly backward against the perineum while the bladder is held up out of the way by the trowel; the end of the director then appears above the fundus. With a strong bistoury the groove in the director is entered from above and the uterus split in the middle line. One half, usually that on the patient's right, is then dragged down with traction forceps while the other is pushed up by four fingers of the operator's right hand. These fingers, having been passed behind the dragged-down side, free the appendages by pushing and working from below upward and bring them out into the vagina. The half uterus and appendages being free, a long clamp forceps is passed from below upward over the broad ligament so as to clamp the uterine artery, and a second forceps from above downward to occlude the ovarian. The tips of the forceps should overlap a trifle but should be laterally a third or half inch apart so as not to tear the tissues when the upper forceps is turned down parallel with the lower. The half uterus and its appendages are then cut away, and finally the remaining side is freed, brought down, clamped, and cut away in the same manner.

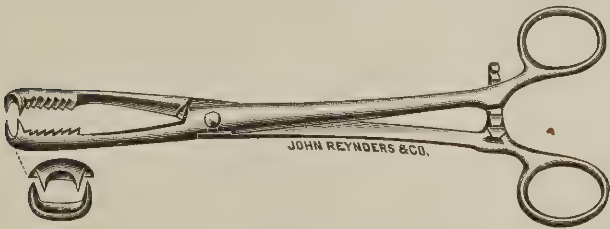

FIG. 2783.—French Traction Forceps.

It is to be noted that the first attempt at hæmostasis is made after the uterus has been divided and the appendages have been freed and brought down into the vagina. Occasionally a posterior vaginal artery will need immediate control, but usually the hemorrhage is not serious. If preferred, stout silk ligatures may be used in place of the clamp forceps, while some surgeons favor the angiotribe or Skene's electric clamp.

During the whole operation as few instruments as possible are to be in the vagina. Any premature attempt to use the clamps adds greatly to the difficulties. In applying the forceps to the uterine artery the cervix is to be drawn sharply to the opposite side so as to straighten the artery and increase the distance between the cervix and the point where the artery is in relation with the ureter.

Gauze pads secured by strings are now introduced above the forceps, the perineum is retracted, and the bladder held up by a trowel. The head of the table is lowered and a careful inspection made of the stumps and pelvic contents. Any bleeding points are secured. The gauze pads are removed and the pelvis, especially the cul-de-sac, is carefully cleansed. A piece of iodoform gauze is inserted between the forceps and the vaginal wall on each side. Each set of forceps is then drawn toward the lateral pelvic wall by means of a long, narrow, flat retractor. Between them enough strips of folded gauze are inserted snugly to fill the space. These strips extend above the forceps and down to the vulva. As each strip is inserted it is pressed to one side by one of the long retractors, and this is done until the whole cavity is firmly packed from side to side. A self-retaining catheter is introduced; the sphincter ani is dilated, and the patient lowered to a horizontal position. As a final step, a piece of plain gauze is wrapped about the projecting ends of the forceps and tied. Pryor[11] considers this careful packing of the vagina a very essential portion of the operation, both as a means of securing efficient drainage and in preventing the retraction of the upper portion of the stump after the forceps has been removed.

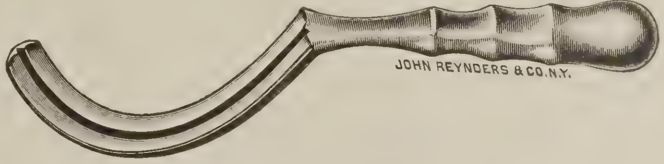

FIG. 2784.—Pryor's Retracting Director.

In cases in which the uterus is small and movable or in which the presence of cancer of the fundus or sepsis makes the hemisection inadvisable, the procedure may be as follows: After it has been curetted, the cervix is to be closed by three or four stout silk sutures, the ends of which are left long, so as to be used as tractors. An incision is then made through the vaginal mucous membrane

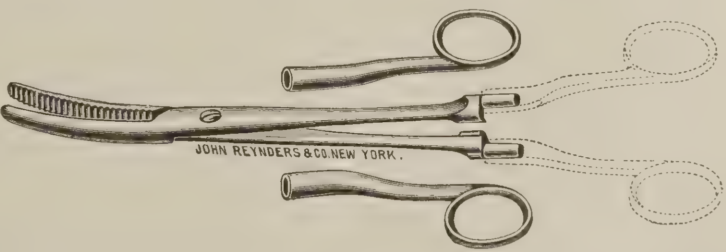

FIG. 2785.—Pryor's Hysterectomy Forceps with Removable Handles.

entirely around the cervix and extending into the posterior cul-de-sac. Then, in order to secure the greatest amount of space, a longitudinal median incision is made for an inch or more toward the base of the bladder, and the bladder stripped away from vaginal wall and uterus. Gauze sponges with strings are now pushed up to protect the intestines and the appendages are freed by two fingers working upward through the posterior cul-de-sac. The uterus is then held only by the tissues of the broad ligaments. The cervix is drawn firmly down and toward the left, and the lateral vaginal wall held out of the way by a retractor. The left index finger is placed beneath the right broad ligament, and a stout silk ligature is passed about 1 cm. up and away from the cervix and securely tied. The included tissue is cut near the cervix with stout scissors and a second and third bite are taken and the tissues divided. The uterine arteries having been secured and divided, one may often, by pushing the cervix back, bring the fundus and appendages down into the vagina and then ligate the remainder of the right broad ligament from above. After one side has been freed the uterus comes down lower or out of the vagina and the remaining broad ligament may then be more easily tied off and the uterus removed. The field of operation is now sponged clean. Each ligature is examined and any that seems at all loose is at once replaced. Especial care is to be given those placed around the upper portion of the broad ligament. All bleeding points having been secured, the gauze sponges are removed, the anterior and posterior peritoneal folds are brought together by one or two points of suture, the ligature ends are gathered together in two bunches and cut just inside the vagina, and the cavity is packed moderately firmly with gauze. If clamps are used the packing is to be as already described. When the fundus cannot be inverted into the vagina the ligating and cutting may have to be done alternately on either side until a ligature can be passed over the top of the broad ligament.

Kolpo-cœlio-hysterectomy, or combined hysterectomy, is accomplished by freeing the cervix from below and finishing the remaining steps of the operation from above. It is most strongly indicated in cases of cancer of the cervix when the body of the uterus is considerably enlarged, as by a complicating pregnancy or fibroids. In a case of this nature the breaking-down cancer tissue is removed with the curette, the raw surfaces are seared with the Paquelin cautery, the lips of the cervix are closed with sutures or, if the disease has spread too far to allow this, a piece of dry gauze is packed against it. The vagina is then carefully sponged clean and ringed by a knife cut at a level an inch or more below the level of the growth. The vaginal walls are carefully dissected off up to the level of the cervix, and their edges sewed closely together so as to retain the gauze and prevent if possible any subsequent infection of the peritoneal cavity. Any bleeding points in the vagina are secured by ligature and the vagina is lightly packed with gauze. The instruments and gloves used in this part of the operation are discarded and the operation is finished through an abdominal incision as already described.

In any case in which it is probable that one must finish from above, ligatures and not clamps should be used in securing the uterine arteries, as the presence of the long clamp forceps in the vagina markedly increases the difficulty of any subsequent work through the abdomen.

After-Treatment.—After an abdominal hysterectomy, before the patient is taken off the table, and while still under the influence of the anæsthetic, a high enema of a pint of decinormal salt solution is introduced into the rectum, and if there is shock this is repeated every three to six hours. Nothing is to be given by mouth for six or eight hours, and then hot water in half-ounce doses with ten drops of lemon juice added is allowed every hour. If the stomach will retain it, half-ounce doses of hot broth or hot milk may be given at hour intervals. If the case progresses favorably, it is not necessary to begin to move the bowels until at the end of forty-eight hours; but if there is evidence of intestinal distention, salines should be started as soon as twelve hours after the operation. Many good operators give calomel or a saline an hour before the beginning of the anæsthetic. Rubinat or Apenta water in half-ounce doses followed by a half ounce of cool water, or drachm doses of Rochelle salt are to be given every hour for twelve doses. Three hours after the last dose an enema of an ounce of glycerin and eight ounces of water is given. In desperate cases with dangerous and increasing distention the author has seen brilliant results follow the enema recommended by Hardon[12] of an ounce of alum in a quart of hot water. Strychnine is often useful in one-fortieth to one-twentieth grain doses hypodermically. After the bowels have moved freely and when there is no distention, the food is to be cautiously increased, and the patient gets the treatment employed after abdominal operations in general. She can usually be allowed to lie on the back or side, as she may prefer. The urine is to be passed naturally if possible, but often has to be drawn for a few days by catheter. The catheter should be used for four days when it has been necessary to drain through the vagina.

After the *vaginal clamp operation* the patient is usually kept on the back with the knees supported by a firm pillow. At the end of forty-eight hours the keys are applied to the lower forceps and the catch is separated a quarter of an inch. The keys are then removed and the forceps is rotated gently and slowly about ten degrees in either direction while very gentle traction is made. If the forceps does not come away readily no force must be used. If the gauze is adherent, it is to be separated from the forceps by a blunt, flat instrument. When all the forceps have been removed the patient is kept quiet on her back for six hours, and then is allowed to turn on the side if she wishes. On the eighth day she is put in the Sims position and the dressings are carefully removed and renewed. The instruments used are a long-bladed Sims speculum, Pryor's trowel, and a dressing forceps. The gauze strips in the centre are removed first so as to loosen those next the vessels. When all the gauze has been removed the red, oozing, lymph-covered rectum and blackening lateral stumps are seen. These sloughing tissues smell bad unless kept dry by repeated and ample dressings of gauze. This gauze is to be renewed as often as a free discharge comes through it, which is usually every fifth or sixth day. Sloughs are not to be pulled off but must be allowed to separate spontaneously. Patients are usually allowed out of bed at the end of three weeks.

After abdomino-vaginal hysterectomy, or Werder's operation, the vagina is loosely packed with gauze until granulation begins and is then kept clean by irrigation with warm boric-acid solution.

The *complications* peculiar to the operation, met with during and after abdominal or vaginal hysterectomies, are mainly due to injuries to ureters, bladder, or intestine. The main causes of death are hemorrhage or sepsis, leading to fatal exhaustion or general peritoneal inflammation with intestinal atony. The supravaginal operation undoubtedly gives the most satisfactory finished result, but the recent observations of Broun[13] and others seem to prove that the chances of a secondary infection, possibly of a fatal character, are slightly less when the entire cervix has been removed. The statistics of mortality vary greatly, but in general, in the hands of properly skilled operators, it varies between four and eight per cent. The author's operations have shown a mortality of a little less than five per cent. for the supravaginal operation and five and a half for the vaginal. *Brooks H. Wells.*

HYSTERIA.—The disorder to which this name is given is evidenced by an almost innumerable variety of symptoms, which may be grouped in a general way into signs of increase, diminution, or perversion of the various nervous functions. In *hysteria major* convulsive and emotional seizures often occur with intervening signs called *stigmata*, especially including paralysis and anæsthesia, or the stigmata may appear alone. Hysteria is a psychosis. Post-mortem investigation gives no clew to the morbid process, and theoretical study of its nature has led, as yet, to little more than conjecture. The ancient view that a disordered uterus lay at the bottom of the trouble (whence the name, from *ὑστέρα*, uterus) has been long since discarded, and although the symptoms may be exaggerated, or even brought on, by disease of the uterus or its appendages, such disease is not an essential factor, the strongest proof of which lies in the fact that men, as well as women, suffer from hysteria. Whatever the exact nature of the disease, its seat must be regarded as the nervous system. It is generally considered that all parts of the nervous system—brain, spinal cord, peripheral nerves, and sympathetic—are implicated. The most marked symptoms are referable, however, to cerebral disturbance, and it seems justifiable to assume that the cortical structures are the principal sufferers from altered irritability. Most of the paralytic symptoms, for example, are best explained on the supposition of decreased irritability of the cortical centres, while the spasmodic symptoms allow of explanation in part on the ground of their exalted irritability, and in part on that of diminished inhibition. The psychical symptoms can, of course, be referable only to cerebral disorder.

Etiology.—Hysteria may exist as a primary neurosis, significant of degeneration, or it may be acquired. It appears commonly among females, but typical examples are found in the opposite sex. Briquet considered that fully half the women possess an impressionability differing little from hysteria. It is more frequent between the ages of ten and thirty, most frequent between fifteen and twenty, but may appear in infancy and also in advanced life. A most constant and important factor in the etiology is heredity, under which head must be included not only hysteria in the parent, but also other nervous and mental diseases. Extreme sensitiveness, irritability, emotional tendency, and allied traits in the parents indicate also a type of nervous organization in the family, which may lead to the development of hysteria in the individual. Other predisposing causes are, for example, ill-directed training, depressing influences, unhappy surroundings, desires ungratified, and all causes of continued anxiety and disquiet, especially if joined with excessive bodily fatigue. The advent of other disease may hasten the approach of hysteria, most frequently, perhaps, disease of the reproductive organs. Too much importance should not, however, be attached to coexisting disease of these organs; in many cases the coexistence is merely a coincidence, and in many the local symptoms are secondary to the general nervous disorder. The advent of menstruation and of the climacteric, as well as of pregnancy, may usher in the first signs. A mental or physical shock, a violent emotion or irritation, are common immediate and determining causes. Severe trauma, especially that resulting from falls blows, and railway collisions, is not an infrequent exciting cause. Many of the cases formerly classed under "railway spine" are now recognized as hysterical, and the former term has been largely replaced by traumatic neurosis, which includes traumatic hysteria. Predisposition is not essential, but in those cases in which the violence and duration of symptoms is out of all proportion to the violence of the trauma, the latter is probably only the excitant, not the fundamental, cause of the condition. In many of these cases the term "litigation neurosis" would be appropriate, inasmuch as the circumstances accompanying the suit for damages often play a greater part in the etiology than the original shock. While the disease is by no means confined to the upper class of society, it not infrequently appears there in young ladies whose comparatively aimless lives alternate between the excitement incident to balls, theatres, etc., and complete mental and physical idleness. This manner of life tends to the cultivation of the emotions and favors morbid introspection, while offering little opportunity for the exercise of will power. An irritability of the nervous system is thus produced which predisposes to hysteria.

Clinical History.—The disease in most cases is of so gradual growth that it is impossible to date its commencement. The patient inherits a neurotic tendency, which is fostered in childhood and youth by some of the predisposing causes already mentioned. It follows that, although the first decided symptoms, as paralysis or convulsions, may appear later in life, apparently on account of some trifling mental shock or bodily injury, the existence of the disease must date much farther back. Any or all the symptoms to be enumerated may appear in the given case, and in almost any order. In some cases the persistence of certain symptoms is a marked feature; in others the symptoms appear and disappear with great rapidity, without order in respect to locality or to sequence. The distinction between *hysteria major* and *hysteria minor* is largely one of degree, for both are characterized by exaltation and depression of nervous function with tendency to crises. In hysteria minor, however, the persistent symptoms do not extend beyond morbid sensitiveness, mental or physical, clavus, globus, backache, flushes and chills, while the crises are limited to emotional outbursts of moderate violence such as attacks of laughing and crying, followed by copious discharge of pale urine of low specific gravity. For convenience of description, the leading symptoms may be divided into disturbances of sensation, motion, circulation, secretion, and excretion, and of the mind.

Disturbances of Sensation.—Hyperæsthesia is one of the most constant symptoms of hysteria. When it is of a high degree the lightest touch causes signs of extreme distress, and even convulsive movements. When spread over a large surface the hyperæsthetic region is generally sharply bounded by lines which do not define the distribution of any particular nerves. These regions show no tendency to bilateral distribution, being often limited to one side of the body, and not infrequently bounded accurately by the median line. A common peculiarity of these tracts is to change their boundaries and situations, spreading gradually over one side of the body, disappearing in one place to appear in another, or passing from one side to the opposite. Circumscribed areas of anæsthesia, or of normal sensibility, may appear in the midst of an hyperæsthetic region. The sensitiveness is often limited to certain spots. Such spots are found most constantly over the vertebræ at varying heights, and on the scalp, but appear also on the neck, breast, abdomen, in the genital region, over the joints, and elsewhere. Hyperæsthesia of the larynx causes spasmodic coughing to be brought on by the least irritation, as the inhalation of cold air. The mucous membrane of the nasal, buccal, and faucial cavities, the conjunctiva, the meatus externus, and the tympanum may, any or all, be found hyperæsthetic, with exaggeration of the physiological reflexes. Spontaneous pains are common and may assume the character of superficial neuralgias, or appear to lie deeper, as in muscles, periosteum, or abdominal viscera. Hysterical patients are especially prone to headache and to the so-called clavus hystericus, a boring or burning sensation at or near the vertex, a symptom not more common in hysteria, however, than in neurasthenia and allied nervous states. An infinite variety of disagreeable, though not absolutely painful, sensations are complained of, often of the most vague and indescribable character, and again more or less typical, as the globus hystericus, and the sense of pressure in the epigastrium or over the chest, combined with a feeling of anxiety, or even the symptoms characteristic of angina pectoris. Sensitiveness and pain in the ovarian region (*ovarie*) are often found, generally on the left side. Pressure over this region sometimes produces a convulsive attack; and again, continued pressure is said to cut short such an attack when under way. The constancy of seat, together with the fact that the irritable spot rises and falls with the uterus before and after pregnancy (Féré), renders it probable that the irritability lies in or about the ovary rather than in the abdominal walls. Sensitiveness about certain joints (knee, hip, ankle, wrist), both with and without swelling, constitutes the "hysterical joint," a phenomenon which may be mistaken for more serious disease, but which generally disappears spontaneously, sometimes suddenly. Hyperæsthesias of the special senses are not rare. That of vision is shown by dread of light and of certain colors, and by hallucinations of sight. The auditory centres may be so irritable that all sounds are disagreeable, and that sounds are distinguished which are not audible in the normal condition. Tinnitus aurium, auditory hallucinations, and vertigo, resembling that of inner-ear disease, appear, the former frequently. Smell and taste may be abnormally acute. Certain odors and tastes agreeable to others may cause distress, and again the most offensive substances may be pleasurable. Hallucinations in these senses also occur. Psychical hyperæsthesia rarely fails; peculiar and excessive likes and dislikes are of every-day occurrence, and violent emotions, both pleasurable and the opposite, are excited by minimal stimuli. Anger, horror, dread, disgust, are produced by objects to others comparatively or quite inoffensive.

Anæsthesia.—All forms of sensation, general and special, may be impaired. The anæsthesia may rapidly change its boundaries, suddenly disappear, or remain for a long time stationary. It sometimes appears after convulsive attacks. Analgesia is most frequently noted, but all varieties of general sensation suffer, including the so-called muscle sense. Loss of "electro-muscular" sensibility is common, but not diagnostic. The anæsthetic regions are generally sharply defined, and vary from limited spots to large tracts. In hemianæsthesia the boundary is generally sharply drawn at the median line, back and front. Sometimes both sides of the body are anæsthetic in different degrees. In hemianæsthesia the special senses generally disappear on the affected side, and in a degree corresponding to the loss of general sensation. This form of anæsthesia is easily overlooked, owing to the patient being unaware of its existence; it should therefore be systematically sought for; if genuine, it proves an invaluable aid in diagnosis. Single extremities may be anæsthetic, or separate spots on the trunk, limbs, hands, or feet. The mucous membranes are apt to be included, and to lose their reflex irritability (sneezing, vomiting). Anæsthesia of the larynx is common. The bladder and rectum may lose their sensibility, as shown by the accumulation of fæces and urine without the patient's knowledge. The urethra and vagina may also take part. The blood-vessels are sometimes contracted over the anæsthetic areas, the prick of a pin being followed by less bleeding than normal. Anæsthesia of the special senses is apt to occur coincidently with anæsthesia of the skin about the organ of special sense affected. Visual anæsthesia is evidenced by retraction of the field of vision, central amblyopia, and loss of color perception. Ophthalmoscopic examination reveals nothing of note. Hysterical deafness has been long noticed, but less extensively investigated than hysterical blindness. The writer has found loss of hearing by the bone and impaired perception for high tones in a series of cases. Taste and smell may be affected, the loss being generally unilateral. The application of a magnet to the anæsthetic region either touching or within a few centimetres of the skin is followed in some cases by return of sensibility, general and special, and sometimes by a transfer of the anæsthesia to another part, most frequently to the corresponding region on the other side (transfer). In hemianæsthesia the entire disturbance may pass from one side to the other and in susceptible cases oscillate from side to side until equilibrium is reached. The time occupied by the transfer varies from a few minutes to an hour or more, becoming shorter with repetition. The same phenomenon has been brought about with other substances, as blisters, metals, or pieces of wood, and in certain cases the patient's expectant attention alone doubtless suffices.

Disturbances of Motion.—Spasmodic contractions appear in almost every part of the muscular system. They may be limited to one muscle or set of muscles, or be widely spread, as in general hysterical convulsions. The contractions are sometimes tonic, sometimes clonic; they may come in attacks, or last for a long time (contracture). They vary in severity from firm contractions, resisting all efforts to overcome them, to the slight twitchings popularly termed "fidgets." Between these degrees come the movements of hysterical chorea, which are generally confined to the face and neck. Spasms not occur only in the extremities, and in the muscles of the trunk, head, and neck, but in deeper-seated parts. The "globus hystericus" is caused by contraction of the muscles of the œsophagus, pharynx, or both, giving rise to the sensation of a lump rising in the throat. The tongue may be included in these spasms and be drawn upward, backward, or to one side. Peculiar sensations in the abdomen, as of a body rising from the uterine region to the stomach, or of something moving about in the abdomen, probably are caused in part by increased peristaltic movements in the intestines. "Phantom tumors" are produced by intestinal distention combined with spasm. Hysterical vomiting, which occurs both with and without loss of appetite, both after eating and while the stomach is empty, is another symptom of convulsive action in the digestive tract. Spasm of the bronchial muscles is evidenced by difficult respiration. Attacks of this nature are sometimes brought on by irritation of the diseased uterus (*asthma uterinum*, Jolly). Convulsive laughter and weeping are familiar symptoms of hysteria, both isolated and preceding or following severer convulsive attacks. Attacks of shrieking are not uncommon, and spasm of the glottis may even appear to threaten life by asphyxia. Spasmodic action of the sphincter vesicæ not infrequently causes retention of urine.

General convulsive seizures come on sometimes as a result of physical or mental shock, or of strong emotion, and again without apparent exciting cause. They are often preceded by peculiar sensations, as of suffocation, or of abdominal pain, and sometimes by a cry. The onset is generally gradual, and the patient is rarely injured by a sudden fall. Tonic spasms gradually ensue, involving a part or the whole of the body. Extreme opisthotonus may be reached and maintained for a considerable time, also emprosthotonus or pleurothotonus. The patient may gradually change from one of these positions to another. The consciousness is generally impaired, sometimes appears to be entirely suspended. The attack varies in length, sometimes persisting for hours. The tongue is rarely bitten, and stupor rarely supervenes, but pain and stiffness are complained of for some time after. Gesticulations, emotional language, and more or less purposeful movements are not uncommon. Although these convulsions cannot be called voluntary, the patient often has it more or less in her power to resist their onset, and is apt to postpone the seizure until a convenient occasion. The power of resistance lessens with the continuance of the trouble. A sudden shock may prevent or cut short an attack, and pressure on one or the other ovary may cause relaxation of the spasms.

Paralysis may attack any or all of the extremities. It may appear as hemiplegia, or as paraplegia, or may attack single muscles or groups of muscles. The face is commonly exempt, not being drawn to one side in otherwise complete hemiplegia. The degree of paralysis varies from slight impairment of power to complete loss of motion. The electrical reactions are not materially affected. The appearance and disappearance of paralysis are generally sudden, sometimes gradual. Change of seat is rapid and frequent in some cases; in others the same form persists for a long time. Contractures sometimes accompany and follow paralysis, and it has been claimed that organic changes (sclerosis) may result from persistent functional disease. Paralysis, like other hysterical symptoms, may disappear upon the application of powerful stimuli. Tremor is sometimes present in the head or extremities. Anæsthesia generally accompanies paralysis of motion, although the converse is less uniform. In general, disorders of motion are less frequent than those of sensation. Paralysis of the pharynx and œsophagus may necessitate artificial feeding. Paralysis of the intestinal muscles is evidenced by tympanites and obstipation. Paralysis of the vocal cords generally appears suddenly under mental excitement, and sometimes disappears in a similar manner. It is often most persistent, and when it is combined with lingual paresis the patient is unable even to whisper. The laryngoscope reveals nothing abnormal about the cords, but generally paralysis of their contracting muscles on one or both sides. The thyro-arytænoideus internus is often affected. Paralysis of the bladder is not infrequent. Paralysis of ocular muscles in hysteria is not common, but paresis of the levator palpebræ is frequently seen, causing a drooping of the lid, which is characteristic, usually bilateral.

Circulatory, Secretory, and Excretory Disorders.—Palpitation ensues in some cases upon slight exciting cause, and again, the heart beat is reduced to the minimal as in the cataleptic condition. Variations in the peripheral circulation are frequent and rapid. The pulse is sometimes small and tense, sometimes full and soft. The skin varies from cold and pale to red and hot. In the former case less blood than normal follows the prick of a pin, and the perspiration is apt to be lessened, increasing with the dilatation of the cutaneous vessels. The regions over which these changes take place vary from circumscribed spots to the half or the whole of the body. "Flushes" are common, and redness and heat of the head are liable to coexist with coldness of the extremities. Fainting is common, due probably to cerebral anæmia. Swelling of the extremities, with œdema, sometimes appears suddenly, to disappear as suddenly, without disease of the heart or kidney or other complication. These swellings are classed under the term angioneurotic œdema, and are sometimes quite persistent. The skin may be of waxy pallor, and may pit, or be dark colored and brawny. Gangrene does not follow. Most of these phenomena owe their origin probably to vaso-motor irregularities. Possibly similar changes in the cortex of the brain are at the bottom of some of the symptoms referable to that organ. Actual bleeding follows congestion in various localities. Menstrual irregularities are common. Increased or decreased flow of saliva has been noted, and the vomiting of large quantities of fluid without ingestion points to increase of gastric secretion. The urine varies in quantity from greatly increased (especially after convulsive attacks) to notably diminished. Cases of genuine anuria have been established. The presence of urea in the vomitus points to vicarious excretion. It seems probable that the difficulty, whether vascular or purely nervous, lies in the kidney itself, although spasm of the sphincter vesicæ may be also present (Charcot). Increased and irregular lacteal secretion has been noted, and more frequently leucorrhœa without local disease, particularly after convulsive seizures.

Mental Condition.—Hysteria occurs in persons of every grade of intelligence, and by no means implies deficient intellectual power. Lack of balance and of will power, however, is generally apparent even when combined with quick perception and excellent memory. The emotional side of the nature is generally disturbed; on the one hand, the least stimulus is sufficient to bring about an exalted state of happiness or deep melancholy, and on the other hand emotion may seem quite wanting, the patient exhibiting the utmost indifference to her surroundings. Extreme sensitiveness is common, the patient takes offence easily, and is easily made unhappy by neglect. In general such patients are extremely egotistical and selfish, and while demanding, directly or indirectly, the most extreme attention from others, fail to exhibit the least consideration for those about them. Lack of application is a common failing, yet once aroused the patient may show a persistence and untiring energy far in excess of that demanded by the occasion, or of that which a person of good judgment would display. These patients often persist in making themselves martyrs, and in drawing attention, directly or indirectly, to their peculiarly trying circumstances and sufferings. The regard for veracity is often diminished, and the desire for sympathy may lead to the most outrageous deceptions—a fact which has caused the name hysteria to bear with it a degree of opprobrium which it by no means necessarily deserves. Hysterical patients, especially hystero-epileptics, are prone to somnambulism, hypnotism, ecstasy, and allied conditions. The step from hysteria to insanity is often a short one and hard to define. Hysterical delirium leads to fixed delusions. Melancholy, mania, *folie raisonnante,* and even dementia may follow.

Hystero-epilepsy (for the analysis of which, as of all phases of hysteria, we are especially indebted to the efforts of Charcot and his pupils) is the severest form of convulsive seizure to which hysterical patients are subject. It is distinctly a symptom of hysteria, and in no way to be confounded with epilepsy when it assumes its typical form, although certain cases, in which hysteria and epilepsy coexist, may offer difficulties in diagnosis. The seizure is generally preceded by change in disposition, perhaps for some days, and more directly by an aura, abdominal or epigastric, which affords the patient time to seek a position of safety. The attack proper is divided into four periods: (*a*) the epileptoid, (*b*) the period of contortions and great movements, (*c*) the period of emotional attitudes, (*d*) the period of delirium. The (*a*) epileptoid period is generally ushered in by a cry, the consciousness is lost, the patient falls to the ground, the face is pale, the features are distorted. Tonic spasms ensue, affecting all extremities. Clonic spasms follow, resembling those of epilepsy. The face becomes tumefied and violet. The patient sometimes froths at the mouth and bites the tongue. A short period of relaxation follows, with coma. In the second period (*b*) various extraordinary positions are maintained for some minutes, with great force, for example, that of extreme opisthotonus. In this stage the respiration is not interfered with, and the face is not turgid. The great movements which follow are distinguished from the clonic spasms by their greater extent, and the non-rigidity in the parts affected. These movements may be executed by the whole of the body or by a part. Most characteristic are flexion and extension of the trunk, rapidly alternating, the forehead striking the knees on flexion, the head and back being thrown violently on the bed in extension. Such a movement may be repeated fifteen or twenty times. The next period (*c*) follows generally without intervening repose, the great movement, or the contortions, merging into the emotional attitudes. These attitudes, representing gayety, sadness, etc., seem to result from hallucinations, and to express a delirium of the imagination. The period of delirium (*d*) represents the more or less gradual return to equilibrium, and is analogous to the initiatory period. Sadness pervades this stage, in which the patient dwells on events of her past life with lamentations. After the attack, large quantities of pale, clear urine are voided. The duration of the attack proper, exclusive of the stage of delirium, varies from fifteen to twenty minutes, the epileptoid period lasting from one to three minutes, the period of contortions and great movements about the same, or a little longer, the period of emotional attitudes from five to fifteen minutes. The supervening delirium varies from a few minutes to a considerable time. Hystero-epileptics generally present marked constant symptoms, contractures, motor and sensory paralyses, notably hemianæsthesia, and the mental characteristics of hysteria are apt to be particularly well marked in these patients. The *ovarie* is commonly present, firm pressure over this spot during an attack causing complete relaxation and return of consciousness, to be followed by relapse into the previous condition on removal of the pressure. Other hysterogenic zones are found in various parts, as above and below the breasts, less constantly, however, than in the ovarian region.

DIAGNOSIS.—The diagnosis of hysteria from organic disease of the nervous system is of the greatest practical importance, and is in general not difficult, especially when the course of the disease is known. The predominance of subjective symptoms over objective disturbance is noteworthy. There is, in general, absence of such definite signs of organic disease as local atrophy, electrical change, pupil irregularities and loss of light reflex, of ankle clonus and the Babinski reflex, of bedsores and cystitis, as well as of facial, ocular, and bulbar paralyses. There may be rapid and complete change in seat and character of the symptoms, a nervous history and nervous antecedents. The presence of globus, clavus, ovarian and spinal tenderness, hemianæsthesia, segmental anæsthesia, aphonia, convulsive attacks, and characteristic contractions, assist in the differentiation of hysteria from most organic diseases with which it is liable to be confounded. Hysterical hemiplegia differs from the common form of organic hemiplegia in the exemption of the facial muscles, in the absence of spasticity, and in the sharp boundaries of the anæsthesia if present, whether occupying half the body, a single extremity, or spots of irregular distribution. The anæsthesia of organic cerebral disease is most marked at the extremities and shades off gradually as the trunk is approached; it is more apt to impair the power of recognizing objects in the hand with eyes closed (stereognostic sense, with its factors, spacing, localization, and posture senses) than the sense of pain, of touch, or of temperature. The latter are more often lost in hysterical anæsthesia, and the hysterical patient will often handle intelligently, and use with dexterity, an instrument which she states is not felt. This offers marked contrast to the hemiplegic, who states that the knife or pen is felt, but who neither recognizes its character nor uses it naturally.

Hysterical hemianæsthesia is easily recognized by its typical distribution, and by the fact that the special senses are generally involved to a corresponding degree. It is important to avoid mistaking the transient loss of power accompanying *myasthenia gravis* (pseudo-bulbar paralysis) for hysterical paralysis. The paralyses of myasthenia gravis are prone to appear in the latter part of the day, and are peculiarly liable to attack the ocular and bulbar muscles, regions ordinarily spared in hysteria. It must always be remembered that hysteria does not preclude the coexistence of organic disease, as tumor, abscess, or meningitis. Hysterical symptoms occurring in elderly women, not hitherto subject, should always suggest the possibility of malignant or other exhausting disease. The diagnosis should never be limited to hysteria till organic disease has been carefully excluded. Convulsions of hysteria are generally distinguishable from epileptic seizures by their longer duration, by the absence of the characteristic clonic spasms of epilepsy, and by the greater excursion of the movements. The hysterical patient rarely injures herself in falling, and only exceptionally bites the tongue or froths at the mouth. Stupidity rarely intervenes, but a large quantity of pale urine with low specific gravity is often voided directly after an attack. Doubtful cases are more apt to prove epileptic, and should generally be given bromide treatment. Aphonia, of hysterical origin, may be distinguished by the rapidity of onset and recovery, together with the absence of symptoms pointing to organic disease of the larynx. The diagnosis between hysteria and other functional nervous diseases is not so important, and the line is often hard to draw. The hysterical has many symptoms in common with the neurasthenic patient. The presence of paralyses, contractures, convulsions, hyperæsthetic regions, and of well-marked circulatory, secretory, and excretory symptoms, places the case under hysteria, the name *neurasthenia* applying to patients suffering from nervous exhaustion and irritability without the so-called hysterical stigmata. On the boundary line fall certain irritable, worn-out patients, prone to laughing and crying, and other lighter emotional symptoms. In such cases it is difficult and unnecessary to make an accurate classification. The essential peculiarity of the *hypochondriac* is his undue attention to, and anxiety regarding, his own condition. Either the hysterical or the neurasthenic patient may, therefore, suffer also from hypochondria.

PROGNOSIS.—Life is threatened only in the rarest instances. Patients have died with hysterical symptoms, but it is doubtful if hysteria itself can be said ever to be fatal. Radical cure of well-established tendency to hysteria, when primary and degenerative, is hardly to be expected, though separate attacks are likely to disappear spontaneously or under treatment. Attacks of hysteria with definite exciting cause, as trauma, or exhaustion, without predisposing tendency, promise more favorably than cases of the same severity resulting from hereditary tendency. Cure may be generally expected in such cases in a period varying from a few months to a few years. Litigation seriously delays recovery. In general, the longer the disease has persisted the worse the prognosis. This is especially true when convulsive attacks are present.

TREATMENT.—The early training of children predisposed by inheritance to functional nervous disease is important. Too great indulgence and solicitude are as bad on the one hand as severe punishment and ridicule on the other. Every means should be taken to cultivate the child's self-control, and for this purpose removal from its home will often be found beneficial, inasmuch as bad example is there added to faulty training. Physical development should be encouraged. Anæmia should be treated if present. Early marriage should not be encouraged, for it is as liable to aggravate as to lessen the tendency.

Given a case of hysteria once developed, the first aim is to remove the causes which foster it. Anæmia and debility must be combated; arsenic in small doses may prove of benefit, besides the ordinary tonics. The German Eisenzucker (ferrum oxidatum saccharatum) will be found an agreeable preparation of iron for persons of delicate digestion. Disease of the uterus and its appendages, when present, must be rectified, although scepticism is always in place regarding local disease as an etiological factor, and unnecessary manipulation of the genitals should be avoided. Flatulence, indigestion, and constipation should be treated. Atony of the alimentary canal may be benefited by nux vomica, strychnine, or quinine. If the presence of family and friends is believed to be deleterious, the surroundings should be changed. The patient should neither receive excessive sympathy nor be ridiculed as an imaginary sufferer. An endeavor should be made to gain the patient's confidence and rouse her to the systematic exercise of will power and self-control, not only regarding her symptoms, but also in the ordinary duties and disturbances of her life. Regular employment and physical exercise, such as bicycling or horseback riding, should be encouraged. Valerian and asafœtida will be found useful in spasmodic conditions, the latter especially in hysterical tympanites and colic. As a rule, neither bromide of potassium nor chloral will be found of sufficient benefit to justify continued use, though they must sometimes be resorted to for sleeplessness. Opium and alcohol are likewise to be avoided. To relieve individual attacks of pain by morphine is only to weaken the patient's own power of resisting pain, and perhaps to add a craving for the drug. Hyoscyamus, conium, and cannabis indica may be substituted. Good diet, cold baths, the douche to the back, massage, regular exercise in the open air, mental diversion, and avoidance of excesses are important. Electricity sometimes proves of value, especially the static current. Application of the magnet and of various metals, while of great physiological interest, as in the study of "transfer," will hardly prove of much therapeutic value. During convulsive attacks over-solicitude will tend only to aggravate and render them more frequent, excepting when the consciousness is entirely lost. The severer attacks can sometimes be cut short by a sudden shock, as pouring cold water on the face, and the memory of such treatment doubtless lessens the probability of recurrence; there are, however, many objections to this proceeding, and it will rarely be found advisable. The inhalation of ether or the subcutaneous injection of apomorphine may cut short an attack. Judicious neglect will often hasten recovery. Firm pressure over one or the other ovary will sometimes cause cessation of hystero-epileptic or other convulsion. Removal of the ovaries must be kept in mind as a last resort when disease of those organs is present. Nutrition should be kept up during cataleptic conditions, rectal alimentation or the stomach tube being resorted to if necessary. In obstinate cases, especially when malnutrition exists, after other methods have been tried in vain, it will be often advisable to adopt the plan (perfected by Mitchell) of seclusion, rest, massage, electricity, and full feeding. *George L. Walton.*

IBIT, bismuth oxy-iodo-tannate, a close relative of airol, bismuth oxy-iodo-gallate, is an odorless, tasteless, fine, greenish-gray powder. It is permanent in diffuse light, but in direct sunlight or in contact with water or animal fluids slowly decomposes with the liberation of iodine. This change is more rapid with warm water. Ibit is insoluble in ordinary solvents, but dissolves in acids or alkalies. It is used for wounds as a dusting powder, salve, or lotion. *W. A. Bastedo.*

ICHTHALBIN, ichthyol albuminate, is an odorless, almost tasteless, fine grayish-brown powder, insoluble in water and acid solutions, and soluble in alkalies and the intestinal fluids. It is prepared by adding ichthyol to fresh albumin and washing the resulting precipitate till it is free from ichthyol. It sets free in the tissues ichthyol, of which it is said to contain seventy-five per cent.

On account of its antiseptic and stimulating properties it has been used by Mack, Binder, Martin, and others internally for gastric and intestinal fermentation and for enteric fever. Sack says it sets free ichthyol in the intestine, but not in the stomach. It is claimed to be neither irritating nor toxic. Locally it may be applied in powder form. Binder uses it by insufflation for gonorrhœal or catarrhal vaginitis, endometritis, or erosions of the cervix. For chronic hypertrophic rhinitis it may be used as snuff two or three times a day. Mack obtained good results in eczema and furunculosis from the internal dose of 0.12–0.3 gm. (gr. ij.–v.) three times a day. Rollay places the dose at 0.3–0.7 gm. (gr. v.–x.) for a child of one year, while Homburger considers 0.1–0.2 gm. (gr. iss.–iij.) sufficient. No untoward effects were noticed from administering 0.5 gm. (gr. viij.) three times a day to a five-months-old child.

W. A. Bastedo.

ICHTHARGAN, ichthyol silver, silver thio-hydrocarbosulfonate, is a brown, odorless, amorphous powder of neutral reaction, containing thirty per cent. of silver and fifteen per cent. of sulphur. Its odor is wanting, or slight, suggesting chocolate, and it is somewhat sternutatory. It is easily soluble in water, glycerin, or dilute alcohol, slightly soluble in ether or chloroform, and insoluble in absolute alcohol. On exposure to light it is slowly decomposed, so must be kept in dark bottles. It is precipitated by sodium chloride or albumin, the latter precipitate dissolving in excess of albumin.

Aufrecht showed this drug to be more strongly antagonistic to anthrax, gonococcus, and other bacteria than is silver nitrate. In 0.3–0.5-per-cent. solution it prevents the decomposition of meat, bouillon, etc. With frogs, guinea-pigs, rabbits, and dogs it is much less toxic than silver nitrate. It is also more penetrating. Lohstein uses it in gonorrhœa as an irrigation in 1 to 4,000 to 1 to 2,000 strength. Leistikow considers its results in gonorrhœa remarkable; he uses a 0.02 to 0.2-per-cent. injection. For posterior urethritis Fürst employs an instillation of six to ten drops of three-per-cent. solution by Guyon's urethral syringe. As a prophylactic following suspicious coitus he instils three or four drops of a ten-per-cent. solution. It is said to be much less irritating than silver nitrate, and to be followed by no desire to urinate. Unna says that, unlike silver nitrate, it does not favor granulation, but favors rather the production of epithelium. The best results are obtained in clean ulcers and in old hard ulcers with callous margins after the horny layer has been removed by salicylic plaster mull. It is a strong astringent for indolent, œdematous, or hemorrhagic granulations. Falta uses a half to three per cent. solution for granular conjunctivitis. *W. A. Bastedo.*

ICHTHOFORM is a blackish-brown, amorphous, almost odorless and tasteless powder, resulting from the action of formaldehyde on ichthyol. It is insoluble in all ordinary solvents. Aufrecht has made a comparative study on bacteria and animals, especially frogs, rabbits, and dogs, and finds it to have a greater antiseptic power than iodoform and analogous compounds, and to be comparatively innocuous. Goldmann uses it locally for endometritis in ten-per-cent. glycerin mixture on tampons, and as a deodorizer in ozæna. Internally he employs it in atonic or functional digestive disorders. Five grains (0.35 gm.) may be given every three hours for acute gastro-enteritis and intestinal tuberculosis, in which conditions it is highly recommended. Polacco employs 0.5 gm. (gr. viij.) in capsule up to twelve capsules a day for enteric fever. It has no action on the nervous system, and its continued use in large dose is said to be without effect on the kidneys. In conditions of indicanuria with headache and malaise, its administration is quickly followed by disappearance of the indican from the urine and the relief of the symptoms. On account of its irritating properties in vaseline mixture, Unna prefers it made up with zinc ointment in one-per-cent. strength as an application in eczema capitis of children, psoriasis, eczemas of seborrhœic origin, and in pityriasic forms of eczema. As its hardening powers lead to superficial necrosis, it can be used only in affections which tolerate the desquamation of the horny layer. *W. A. Bastedo.*

ICHTHYOCOLLA. See *Isinglass.*

ICHTHYOL.—This is the trade name of a compound described as ichthyo-sulphonic acid in combination with ammonium. It is obtained by the distillation of a bituminous mineral deposit of the Tyrol, which contains an abundance of the fossil remains of fish and other marine animals. During dry distillation there passes over, between 100° and 225° C., a crude volatile oil. This is treated with an excess of concentrated sulphuric acid, which forms ichthyo-sulphonic acid, and this is precipitated by the addition of brine. The product, in addition, contains an uncertain percentage of unchanged oil, which cannot be removed without producing decomposition of the whole compound.

Ichthyo-sulphonic acid forms salts with ammonium, sodium, zinc, lithium, calcium, iron, silver, and various other metals, but the ammonium salt is that generally understood by the title ichthyol.

Ammonium-ichthyol-sulphonate, $C_{28}H_{36}S_3O_6(NH_4)_2$, is a thick, brownish fluid, with a smoky bituminous odor and taste. It is soluble in water, oil, glycerin, and a mixture of alcohol and ether. Its virtues are ascribed to the large amount of sulphur that is present, about sixteen per cent. It has a great affinity for oxygen and is a powerful reducing agent. It is stated to be an active germicide and to be free from any toxic action, but an instance is recorded in which the applications of one part of ichthyol to two parts of glycerin, to the curetted surface of the uterus, produced very alarming symptoms. The patient complained of the taste of the drug, tachycardia, and depression, and remained prostrated for twelve hours.

The therapeutic value of ichthyol depends upon three factors: its antiseptic action, a contractile effect which it exerts on the vascular system, and its reducing property.

It was introduced in 1883, by Unna of Hamburg, as a remedy for the treatment of various forms of skin disease. He described it as the remedy *par excellence* for acne. He advised fifteen drops twice a day internally, and a ten-per-cent. lotion to be painted on the affected parts at night; each day the lesion was to be bathed with hot water and ichthyol soap. In eczema and other forms of skin disease he advised it to be used more cautiously and in weaker solutions. In all these conditions its internal administration is also advised, as it is supposed to possess valuable alterative properties, which assist its local action. Ichthyol has come into very extensive use for all forms of skin diseases, and for the removal of the product of inflammatory processes, in chronic rheumatism and in cases of enlarged glands. In skin diseases it is applied as an ointment of the strength of five to ten or fifteen per cent. A varnish of ichthyol is a favorite method of using the drug. It is made of ichthyol 10 parts, starch 40 parts, solution of albumin 1 part, and water to 100 parts. The starch is mixed with the water, the ichthyol is then well rubbed up with it, and lastly the albumin is added. For inflammatory deposits stronger preparations are employed; ointments containing fifty per cent. may be used, or a mixture of ichthyol and glycerin is applied and the part is covered with lint and bandaged. Ichthyol plasters and ichthyol wadding may also be obtained.

The remedy has not been much used in general surgery, but in gynæcology it is a favorite application in all uterine and vaginal inflammations. It may be applied in a glycerin solution, or in its pure state on tampons, or medicated pessaries may be introduced after antiseptic and astringent douches have been used. When gonorrhœa is a factor the drug is thought to be especially beneficial. It has also been employed in inflamed states of the prostate gland, a ten-per-cent. solution being injected into the rectum.

In a paper presented at the Fourth International Medical Congress, Unna dwelt upon the value of ichthyol in the treatment of leprosy. His conclusions were: (1) Lepra tuberosa, even of universal extension and of more than one year's standing, can be cured; (2) the cure can be effected in a comparatively short time by the energetic internal and external employment of reducing remedies; (3) among these may be specially recommended ichthyol, chrysarobin, pyrogallol, and resorcin; the only one of which that can be administered internally, for a length of time, without danger, is ichthyol. He advised the application of a fifty-per-cent. ointment, and also the internal administration of fifteen to twenty-four minims (1.0 to 1.6) during the day.

Internally ichthyol is administered in pill form in capsules, the dose being up to twenty minims (1.3) daily for an adult. The dose for a child of two years is given as two minims (0.13) daily. *Beaumont Small.*

ICHTHYOSIS.—DEFINITION.—Ichthyosis is a congenital cutaneous deformity in which the skin is dry and rough and the epidermis thickened and scaly.

ETIOLOGY.—Almost all observers agree in regarding ichthyosis as a congenital disease, and the arguments in favor of this view are: That the disease commences early in life and endures throughout life, is only temporarily benefited by treatment, and immediately recurs on the cessation of treatment; that the disease is not inflammatory, as infective and toxic diseases are, but acts more like an anatomical deformity; that it is often a family disease, two or more brothers or sisters being frequently similarly affected, and even when the immediate family is free, more distant relatives may be found afflicted.

It is hardly necessary to draw attention to how characteristic this skipping over individuals is in hereditary affections, one or two members of one branch of a family and one or two of some other branch being picked out, the rest escaping. Nevertheless it must be admitted as remarkable how frequently cases of severe ichthyosis are reported in which the parents are said to be perfectly healthy, and this has been noted even when several of the children have ichthyotic skins.

An objection has been raised to calling ichthyosis a congenital disease, because it usually does not appear until the second or third year of life or even later. This, however, is not a valid objection, because ichthyosis agrees exactly in this particular with other congenital deformities. Nævi, for example, although certainly congenital, frequently do not appear until a considerable time after birth; not, indeed, until the gradual development of the affected individual or the growth of the lesion itself brings the blemish to view.

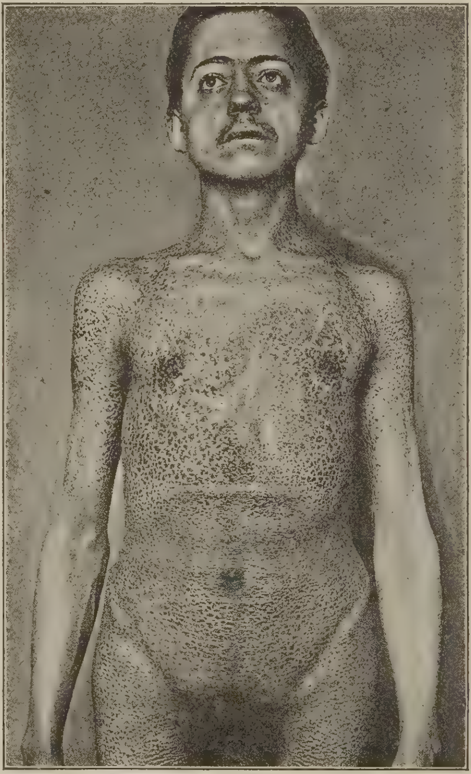

FIG. 2786.—Ichthyosis. (From A. Neisser's "Stereoscopischer medicinischer Atlas.")

Undoubtedly ichthyosis depends in a great measure on defective action of the sweat and sebaceous glands. Three of its features point decidedly in this direction, viz.: the dryness and lack of unctuousness of the skin; the improvement of the symptoms during the summer months when the sweat glands are most active; and the tendency to the localization of the disease in those parts where the sweat and sebaceous glands are least active, as on the extensor surfaces of the limbs, leaving the articular folds, such as the bend of the elbows, the axillary, inguinal, and popliteal folds, unaffected.

Although ichthyosis is an hereditary and congenital affection, yet it probably may be accentuated by diseases which are not in their true sense hereditary. Syphilis is not in the true sense of the term an hereditary disease. What we call hereditary syphilis is an "infective disease" caught congenitally. The way that syphilis, for instance, may possibly accentuate ichthyosis is shown by two cases reported by Gaston and Emery. The father of these children had a slight ichthyosis and also had syphilis. The children acquired syphilis congenitally, and became after birth markedly ichthyotic. Besides ichthyosis, however, the children had microsphygmia, and the authors entertained the opinion that the small pulse was owing to a generalized, congenital, syphilitic arteritis, and that this affection of the arteries so interfered with the nutrition of the fœtus as to accentuate the hereditary tendency to ichthyosis.

Recently Edward Fournier has collected from the literature nine cases, and has added one of his own, in which patients having hereditary syphilis also had ichthyosis. The author clearly states, however, that he does not believe ichthyosis to be a symptom of hereditary syphilis, but explains the coincidence by the theory that hereditary syphilis is at times one of the causes of degeneration in the individual, and that ichthyosis is a symptom of degeneration.

Interesting, particularly in its connection with treatment, is the relationship between defective development of the thyroid gland and ichthyosis. As one of the symptoms of cachexia strumipriva is a rough dry skin; a mistake in diagnosis might easily occur, or defective action of the thyroid gland might accentuate an already existing ichthyosis.

SYMPTOMS.—As ichthyosis is a congenital deformity there are necessarily all grades of it, from almost inappreciable manifestations up to disgusting monstrosities. Dryness of the skin and desquamation are, however, never absent in ichthyosis, and in fact in the most attenuated form of the disease, in xerodermia, extreme dryness of the skin, a very fine desquamation, and obstruction with epithelial cells of the pilo-sebaceous orifices are the only symptoms present. It is this last symptom, the accumulation of epithelial cells about the points of emergence of the hairs, that gives those having ichthyosis their "goose-flesh" appearance. This same permanent "goose-flesh" appearance constitutes the disease called keratosis pilaris, and it is because the same appearance is produced by the same kind of plugging of the same orifices, and also because the favorite situation of both keratosis pilaris and ichthyosis is on the extensor surfaces of the upper arms and thighs, that some authors regard keratosis pilaris, when it exists alone, as constituting the very lightest form of ichthyosis, even lighter than xerodermia.

Of the two symptoms, dryness and desquamation, Thibièrge considers dryness the more essential, even thinking dryness without desquamation often indicative of ichthyosis; therefore he would classify congenital permanent anidrosis as a form of ichthyosis, and this for the following reasons: In both diseases the skin is unusually dry, both are congenital, both occur in families as hereditary diseases, and some members of the same family may have anidrosis while others have ichthyosis. He thinks that many cases of ichthyosis which are supposed to develop during adolescence or later, are simply cases in which anidrosis was at first the sole symptom and which remained comparatively unnoticed, the more disagreeable symptom of scaliness supervening later.

Apart from the two general characteristics of dryness and a tendency to adhere and form masses, the superficial epithelium in ichthyosis shows many variations. It is sometimes powdery, and the cheeks for example may look as if dusted with white face powder; this constitutes a variety of the pityriasis simplex of some authors. This form of ichthyosis when more marked shows a diffuse granular coating, chalky and white, which is particularly apt to show itself on the outer surfaces of the upper and lower extremities. Instead of the granular powdery condition there may be scaling, and the scales may be clear gray or grayish-black, thick or thin, lustreless, hard or soft, but as above stated they frequently show a tendency to adhere with their flat surfaces tightly to one another, sometimes forming thick, uniform, lamellated, corneous deposits. When the epidermis accumulates in thick horny masses as it does in ichthyosis hystrix, pigment may develop in it, which may be a dirty green, a bright green, dark green, or greenish-black. The green may be so bright as to be startling, even seeming to have been artificially applied. The edges of the scales may be separated from one another by little furrows, or they may overlap like fish scales. Sometimes the surface of the skin looks like the finely crumpled tissue paper called crêpe paper used for lamp shades, where the ridges run in every direction, crossing one another and dividing the surface into a vast number of quadrilateral areas. The wrinkled epidermis in such cases looks as if too large for the cutis. Sometimes instead of there being ridges there are fine shallow cracks, passing through the superficial layers only. These cracks fill with dirt and, just as under the finger nails, this dirt assumes a dirty greenish-gray color, marking the skin off into lozenge-shaped areas by a dirty greenish-gray network. The lines may crack down deeper than indicated above, and the superficial epidermis may be broken and upcurved along the edges of the enclosed lozenge-shaped areas resembling the bark of some trees. The surfaces of these lozenge-shaped areas may glitter and reflect light like the facetted skin of some reptiles. Sometimes the surface looks unnaturally smooth and polished, with lines running across it at all angles, as if the surface had been varnished or had collodion poured over it, and had cracked in the drying.

Frequently the skin does not crack, but has running across it a vast number of criss-cross furrows dividing the surface in the same way into quadrilateral or irregular areas. These furrows are really the natural markings of the skin exaggerated, and are frequently chalky white and powdery; in such skins if the finger nail be drawn sharply across the surface it will leave a chalky white, crumbly, permanent mark.

Sometimes the papillary layer of the skin is hypertrophied, and when this occurs, and corneous masses or spines are formed over them, it gives rise to one of the varieties of ichthyosis hystrix. Another variety of such horny spines is formed by a great accumulation of the epithelial cells projecting from the pilo-sebaceous orifices, constituting the keratosis pilaris above named; this occurs generally on the extensor surfaces of the arms. Ichthyosis hystrix is never universal, although it may occur over large tracts of the skin. Usually it occupies only certain regions, while the intervening skin is xerodermatic. A child at present under treatment in the University Clinic has ichthyosis hystrix only on the ankles, while other regions show several different varieties of ichthyosis. This condition of ichthyosis hystrix, literally "hedgehog, fishy disease," is considered particularly undesirable in a bed-fellow.

The true skin may be atrophied, tightly stretched, and thin, and the subcutaneous fat layer may be thin and poorly developed.

The face is frequently unaffected except by a transitory powderiness, a pityriasis. The palms and soles are dry and powdery but not scaly, with the furrows more marked and more numerous than normal, and this condition may remain after treatment has improved the skin in every other locality.

The hair is frequently normal, of good color, lustre, quality, and quantity, but it may be dry, frail, and thinly scattered, constituting an expression of the same fault of development that gave rise to the ichthyosis. Sometimes there is nearly complete alopecia, even the eyebrows and eyelashes being almost entirely absent (Thibièrge). The nails may be strong and in every way normal. They may, however, be thin, brittle, and either transversely or longitudinally ridged, or there may be an accumulation of dry, brittle, corneous substance under the nails.

These patients sometimes give off a flat, stale, penetrating, disagreeable odor, such as is met with in other cases of generalized hyperkeratosis with maceration of the epidermis, as in Darier's disease for example (Thibièrge).

Usually the only subjective symptoms of ichthyosis are itching and a sensitiveness to cold; chilly feelings being experienced on the slightest lowering of the atmospheric temperature.

A patient usually presents examples of a number of the conditions enumerated above; for instance, the hair may be good, but the scalp is usually in a condition that cannot be distinguished from dry seborrhœa. The outer surfaces of the arms and thighs and the skin of the trunk may be dry and scaly and criss-crossed with furrows, and studded with dry papules that look like "goose flesh." The buttocks and upper portions of the thighs may be covered with "crêpe-paper" skin. The roughness of the skin increases down the extensor surfaces of the thighs until over the front of the knees one finds immense corneous masses. Below the knees the skin may be tightly stretched over the tibiæ, smooth, shiny, and with markings on its surface dividing it off into small quadrilateral areas.

Course and Duration.—Usually ichthyosis does not become appreciable until the second or third year of life, although cases have been reported in which the malady was apparent at birth or shortly after. The first symptom, according to Peukert, is the appearance of keratosis pilaris that shows itself on the extensor surfaces of the extremities in earliest childhood in these individuals. It is simply this early appearance of the keratosis pilaris and its greater development later in life that distinguish it at all from the ordinary form of keratosis pilaris. Ordinary keratosis pilaris of moderate development is so common later in life, especially at adolescence when the lanugo hairs begin to sprout more vigorously, that it is practically a normal condition. Ichthyosis continues to grow more marked from two or three years of age until adult life, when it may remain stationary or subject only to the mutations of the seasons, becoming severe in winter and milder in summer, till the natural dryness and harshness of the skin of old age again accentuate it. In summer, in fact, the plates, scales, and fluffy epidermis may all fall off as a "moulting," leaving the skin almost normal. Sickness and a lowered condition of health may also increase the dryness and harshness of the skin, and there is reason to believe that inactivity or absence of the thyroid gland can contribute decidedly to the severity of the symptoms. The symptoms of ichthyosis may disappear completely after one of the eruptive fevers, measles for instance (Joseph), only to reappear in a short time, however. This same amelioration may also occur during pregnancy.

Quinquaud has reported a case in which the patient got an ichthyotic skin following a generalized eczema of two years' duration. He says that such acquired ichthyotic states may after a time disappear. It is doubtful, however, if such ichthyotic states as described by Quinquaud should be included in the disease ichthyosis at all.

Unna and Tommasoli believe that ichthyosis is an acquired disease that has its time of onset, development, and disappearance, but this view finds very little support among other observers.

Unusual Symptoms and Course.—The flexures of the articulations, particularly the axillæ, the bends of the elbows, the groins, the scrotal thigh folds, and the poplitea are usually unaffected. In fact, Georges Thibièrge would make the freedom of those localities a sharp diagnostic feature. Recently, however, a number of cases have been reported in which one or several of these localities have been affected, and there happen just now to be in the University Clinic two patients in whom the axillæ, the groins, the scrotal thigh and vulvar thigh folds respectively, and the politea are affected, as shown by the presence of pityriasis. In both patients there is an eczema of the upper extremities that involves the bends of the elbows, making it impossible to say whether these are ichthyotic or not. The appearance and stubborn character of the eczema, however, would lead one to infer that the condition is also present there. Joseph has reported a case in which only the flexures were affected. Usually ichthyotic patients do not sweat, but Peukert thinks the dryness of the skin is in some cases not due to lack of perspiration, but to an increase of evaporation from the more extensive cutaneous surface of these people. In some instances there is vicarious sweating of certain regions as of the face for example (Goldzieher), or of other regions not implicated in the ichthyosis, as the axillæ, or the palms and soles. This sweating may be abundant. The mucous membranes are rarely affected in ichthyosis, unless the susceptibility to catching "colds" and to bronchitis be looked upon as the particular way they show their inherent weakness. There are atrophic forms of the disease, which Hallopeau considers simply an exaggeration of the form in which the skin is like crêpe paper. The skin is very thin and has little elasticity, so that when pinched it retains the impress of the fingers for a long time. The skin may appear too large for the patient, or on the contrary it may be too small, not permitting the closure of the eyelids, exaggerating the cutaneous folds, especially in the movements of the facial muscles, and impeding the flexion and extension of the fingers. In two of the cases so reported the skin seemed glued to the subjacent aponeurosis. Kaposi has shown a case which he called ichthyosis hystrix pterygoides s. plumiformes, in which there were hundreds of little growths from 0.5 to 1.5 cm. long that looked like feathers. These growths consisted of a central core of connective tissue with tufts of cornified epithelial tissue depending from them. The patient was a girl six years of age and the palms and soles were thickened, cracked, and warty. This case stands alone in literature, and it is not at all certain that it should be included among the ichthyoses.

Those having ichthyosis and those that are scrofulous have in common a tendency to inflammation of the respiratory tract, and besides that, Unna has noted with great particularity in one of his cases an unusual growth of hair down the cheeks in front of the ears. An unusual growth of fine downy hair in this situation was considered by the late Professor Horner, of Zurich, a symptom of scrofula.* A little girl suffering from ichthyosis, and at present attending the University Clinic, has quite a little beard of fine long hair growing down in front of each ear.

Diagnosis.—The first disease to be sharply differentiated from ichthyosis is nævus linearis, and this is not because there is any great similarity between the diseases, but because some writers persist in describing nævus linearis under the name ichthyosis hystrix. Nævus linearis is a warty congenital disease, in which the warts are frequently covered with horny masses, but here the similarity ceases. Nævus linearis occurs in lines or in localized areas, and is usually asymmetrical, and the skin between the patches or lines is absolutely normal. In ichthyosis the disease is symmetrical, and almost always the whole skin is affected, with the exception of the folds of the articulations. Another good point of differentiation lies in the fact that nævi, nævus linearis included, have generally a buff or a slate-colored pigmentation, and the pigment lies in the connective tissue of the skin, usually in the affected papillæ, while if there is a black or other color in ichthyosis, it looks more like dirt in the horny layers or pigment in the epithelium, rather than like pigment in the papillæ or in the true skin. In ichthyosis the palms and soles are almost always unnaturally dry with a powderiness of the surface, while in nævus linearis the palms and soles are normal, when not directly the seat of the nævus, which they rarely are. Furthermore nævus linearis does not attack several members of a family, but occurs irregularly here and there throughout a community; in other words it is not a family disease.

There is another disease, however, which is hereditary, which occurs in families, and which consists of an exaggerated development of the horny layer of the skin. This disease, keratoma hereditarium palmare et plantare, it seems desirable to keep separate from ichthyosis. This is all the more difficult to do because, besides the above points of similarity with ichthyosis, there is also in ichthyosis thickening of the horny layer of the palms and soles. In keratoma, however, the thickening is limited sharply to the palms and soles, and there may be increased action of the perspiratory glands of the affected surfaces. It therefore lacks the generalization of ichthyosis and also the dryness, two important features. Furthermore, in keratoma the thickening of the horny layer of the palms and soles is frequently much greater

---

* He used frequently to say "they, the scrofulous, all wear a beard."

EXPLANATION OF
PLATE XXXIII.

EXPLANATION OF PLATE XXXIII.

Dr. Douglass W. Montgomery's Case of Ichthyosis Hystrix.

The faint redness, the swelling, and also the violet hue in the neighboring skin seen in the plate were all due to an accompanying dry eczema.

The patches of thick green crusting were caused by epithelial masses covering the papillomatous skin, and constituted the ichthyosis hystrix. It was only on the ankles that the child had the papillomatous or hystrix variety of ichthyosis. In other situations, as on the upper parts of the legs, on the thighs, trunk, upper extremities, face and scalp, the ichthyosis was of other types.

OF THE
UNIVERSITY of ILLINOIS

than even in the severest forms of ichthyosis. Joseph suggests that this keratoma may really be ichthyosis, in which a "moulting" process similar to that which takes place in some patients every summer, has taken place in utero, over all the surface excepting the palms and soles, leaving those parts alone affected.

The atrophic form of ichthyosis resembles somewhat the lesions found in the skin in some cases of scleroderma. It differs from scleroderma, however, in the absence of induration and of interstitial cicatrices, and also in the fact that it does not progress.

There are a number of desquamative inflammatory diseases of the skin, such as psoriasis, pityriasis, exfoliative dermatitis, and the dry eczemas, which differ from ichthyosis both in their course and in the fact that they are accompanied by inflammatory symptoms.

Georges Thibièrge at one time demonstrated a case as ichthyosis in which there were immense irregular horny masses distributed symmetrically in various regions of the body, but principally on the face and on the palms. There was almost no hair on the scalp. The buccal and nasal mucous membranes were thickened and furrowed, and there was a grayish infiltration in the superficial layers of the centre of each cornea. Latterly he has concluded that this case was analogous to one in which Giovannini had found the epidermal alterations principally about the orifices of the sweat glands. As the affection was congenital he gave it the name congenital disseminated porokeratosic hyperkeratosis, instead of ichthyosis.

For the diagnosis between ichthyosis and ichthyosis fœtalis the reader may consult the article on this latter subject.

Those who are much reduced by some chronic disease or by old age often have a fluffy scaliness of the skin. This is distinguished in the former case from ichthyosis by the fact that it develops and disappears with the development and disappearance of the cachexia.

A number of diseases of the nervous system are accompanied by atrophy and desquamation of the skin similar to ichthyosis. These ichthyotic states are distinguished from ichthyosis by their occurrence only on the skin supplied by the affected nerves.

PATHOLOGIC ANATOMY.—The principal lesion found in ichthyosis is a hyperkeratosis of the superficial layers of the epidermis, with atrophy of the deeper layers. The papillary layer is less developed than normal. The muscle bundles are hypertrophied. The keratosis pilaris can be seen to be due to plugs of cornified epithelial cells in the pilo-sebaceous orifices. Thibièrge says the orifices of the sudoriparous glands are free, but the sweat glands themselves and the sebaceous glands are frequently atrophied and cystic. The hair follicles may disappear and the hairs may atrophy. The papillary layer and the superficial layers of the derma show evidences of inflammation, which, however, are nothing more than one would expect from the irritated condition of the skin.

There is a question whether the green color developed in the epithelium in ichthyosis hystrix is true pigment, or dirt caught in the interstices of the epithelium. In the child at present under treatment in the University Clinic the green color is quite vivid, but when the epithelium in peeled off, as it can be in masses, the color is seen to be very superficial. It must also be remembered that when dirt is allowed to accumulate under one's nails, it has the same dirty olive-green color as in ichthyosis hystrix.

TREATMENT.—As ichthyosis is a congenital disease and permanent, all treatment must be directed not toward a cure, but to an amelioration of the condition. Much can be done for these patients, and in many ways, but everything of course is temporary, as they relapse as soon as remedies are withdrawn. Residence in a hot climate would be beneficial, as a spontaneous amelioration takes place in warm weather; but, of course, for many patients this is impossible. Frequent hot baths bring about the same result by increasing the activity of the sweat and fat glands, and in fact hot baths are indispensable in any plan of treatment. If a quick temporary effect is desired, jaborandi or pilocarpine may be given on account of their action on the sweat glands, but of course their continued administration would not be advisable.

Besides pilocarpine and jaborandi the internal use of many remedies has been advised, but they have very little effect on the malady, with the exceptions perhaps, of cod-liver oil and arsenic. Sulphur, the balsams, mercury, and many other drugs have been recommended but have been found to be of no avail. In some instances it is rational to suppose, and is by many believed, that arsenic in small doses does good. Arsenic in the form of Fowler's solution may be given in cod-liver oil emulsion.

As some cases of ichthyosis have been reported in which the thyroid gland has been found much diminished in size, and as roughness and desquamation of the skin are symptoms of cachexia strumipriva, it naturally follows that thyroid extract may be given with some hope of success.

Ehrmann, following out the idea suggested by Tommasoli that ichthyosis is due to an autointoxication, gave menthol internally in one case. He reported that under its influence the desquamation ceased, but the criss-cross lines persisted.

External treatment is of course what one must rely on. Hot baths, soft soap, and a good nail brush to get rid of the superfluous epithelium, and after the bath the inunction of a lubricant well rubbed in to assist in maintaining the skin soft and supple, constitute the principles of treatment. The hot baths must not be given too frequently and their effect on the patient must be watched, as in some cases they are debilitating. The choice of the lubricant is also not a matter of indifference; for instance cod-liver oil is acknowledged to be one of the best softeners of epithelium we have, yet its odor makes the patient more disagreeable to a larger circle of his acquaintance than the disease itself.

The treatment advocated by Lailler is one of the most effective and pleasant, and deserves the praise that Georges Thibièrge has given it. This treatment consists in the giving of a hot bath with soft soap and plenty of friction three times a week in order to remove the epidermal masses, and morning and evening prolonged and light massage of all the affected parts with glycerole of starch made in the following way: ℞ Amyli pulv., 15.00; Glycerini, 150.00. Mix and heat in a porcelain dish over a slow fire, stirring all the time until the mass is about to jelly, when 15 gm. of cherry-laurel water is added.

One can add to this one or two per cent. of salicylic acid, which has the effect of still further softening the skin and aiding desquamation. After a time one inunction a day will be sufficient, and when the skin has assumed its normal appearance Lailler says that one hot bath with soft soap a week, followed immediately with an inunction of the above glycerole of starch, or even of pure glycerin, is enough to maintain a normal suppleness of the skin.

It is important in using the glycerole of starch or pure glycerin that only a moderate amount should be applied so that the skin on finishing is supple and unctuous, but not gluey to the hands. Neutral glycerin only should be used. The advantages of the glycerin treatment are: That the glycerin itself is favorable to maintaining the moistness of the skin through its affinity for water; that even the slightly flat odor that glycerin has can easily be overcome by the odor, say, of cherry-laurel water; that it does not soil the clothing as the greases do, and does not render the clothing difficult to wash; and that it does not become rancid. Instead of using glycerin in the form of glycerole of starch, pure glycerin may be added directly to the bath. About six or eight ounces of glycerin may be added to each bath, and two or three baths a week may be taken.

Instead of adding glycerin to the bath, bicarbonate or biborate of sodium may be added, say one or two tumblerfuls of the powder, to each bath. Vapor baths are enjoyed by some patients, and they are efficacious. Starch poultices with boracic acid added to them, a heaping teaspoonful of boracic acid to a small bowl of starch paste, are an excellent means of loosening up epithelial masses.

Prognosis.—Ichthyosis as a deformity is not dangerous to life. As, however, it represents an extensive developmental fault in an important organ, it indicates a corresponding lack of resistance. As a matter of fact people so afflicted are frequently puny and illy developed in many directions. Usually they have not the normal quantity of subcutaneous fat. They easily become chilled and catch cold, and many of them end with tuberculosis (Lewin). *Douglass W. Montgomery.*

ICHTHYOSIS FŒTALIS.—Definition.—Ichthyosis fœtalis is an independent anomaly of development of the skin in the fœtus, accompanied by consecutive malformation of certain parts of the face. Ichthyosis fœtalis must not be confounded with ichthyosis vulgaris, with which it has nothing whatever to do. It is for this reason that the word ichthyosis in the name of this disease is unfortunate and leads to confusion. Very probably a better name would be hyperkeratosis fœtalis.

The disease is very rare, and even of those children who are born with it, but few come under the observation of men interested in skin diseases, as they usually die shortly after birth, and are therefore seen only by the accoucheur. Only a few of these cases have been reported, and of those few, it has several times occurred that one mother has had more than one child afflicted with this malady, so that ichthyosis fœtalis, like ichthyosis vulgaris, is a family disease. Excepting this fact of its being in many instances a family disease, very little is known of its etiology. Bowen thinks the disease may be due to the persistence of the epitricial layer of epithelial cells. The epitricial layer of epithelial cells occurs in some animals, and Bowen's hypothesis is that it is present at one stage of human fœtal development, but is, under normal conditions, shed. He supposes that in ichthyosis fœtalis it is for some reason not shed, but grows and forms the hard resistant coating seen in these cases.

Symptoms.—The epidermis has a dirty yellow, leathery appearance, and is thickened, and the skin looks too small to contain the infant. In fact it looks as if the infant as a fœtus had been covered by a much thickened and inelastic epidermis, and that in growing it had burst this inelastic coating, forming cracks in it running into one another at all angles. These fissures or cracks are more or less red, and about a centimetre wide, and they may or may not be covered by a thin epidermic layer; when not so covered the raw surface lies exposed, and it soon suppurates abundantly.

In addition to the deformity of the skin there are other deformities present, such as congenital ectropion in which the lids look like red projections hiding the globes of the eyes completely. There are neither eyelashes nor eyebrows, and in fact the whole piliary system is very badly developed. The hair, however, though thin, grows very quickly, as do the nails (Thibièrge). The nose is flat to the face, and is represented by two rounded holes, and the cartilaginous septum is entirely lacking. The lips are thickened and are cut by radiating fissures, or they are entirely absent and the skin of the face may run over directly to the gums. The ear shell is represented by a flattened plateau with a central rounded hole, the external auditory meatus. There are no nipples on the breast, the anus may be imperforate, and the external genital organs are imperfectly developed. The fingers and toes are often bent and clawed, and give the impression of being hidebound. The fingers and toes may be more or less soldered to one another, or they may be entirely absent, the extremities terminating in rounded masses.

The reasons for thinking that the fœtus at one stage of its existence is completely covered with this inextensible horny envelope, which afterward is burst open, are that the direction of the fissures is in all cases about the same, and is such as would be occasioned by the growth of the enclosed fœtus; that the furrows at birth are partially or entirely covered with a thin epidermal layer, which represents the healing process after the bursting has taken place; that the hair follicles are entirely absent from the centre of the furrows, while on the sides the hair follicles are directed outward as would result from tearing the plastic fœtal skin asunder (Peukert); and that the deformities at the orifices of the body, the absence of the eyelids and of the lips, the flattening of the nose and of the ears, as well as the deformities of the hands and feet are such as would be occasioned by the fœtus being hidebound.

Infants with such severe lesions die inevitably, and usually in two or three days after birth. They may not be able to take food at all, because of the malformation of the lips, or they may die from the suppuration in the cracks of the skin, or from bronchitis or pneumonia. Attenuated forms of the disease have been reported, however, in which the patients have lived for years. The mouth seems to be the chief factor in determining the prognosis, as those having a badly formed mouth die of inanition.

Diagnosis.—Ichthyosis fœtalis differs from ichthyosis vulgaris in the time of its appearance, ichthyosis fœtalis being apparent in the fœtus and in the new-born babe, while ichthyosis vulgaris is rarely evident before the second or third year of life. Ichthyosis fœtalis is almost always associated with malformation of the ears, eyes, and lips, and frequently with other malformations. It is rare for ichthyosis vulgaris to be associated with any other malformation whatever. Ichthyosis vulgaris has its regions of greatest development, and it rarely affects the folds of the articulations, but if it does affect them the disease in such situations is very mild. In ichthyosis fœtalis, on the contrary, the disease is as severe in the articular folds as anywhere else. Furthermore, in ichthyosis fœtalis the epidermis is not alone thickened, but it is also abnormally resistant and inextensible. In ichthyosis vulgaris the absence of sweat is a marked characteristic, while in ichthyosis fœtalis the secretion of sweat takes place (Thibièrge). The diagnosis between hereditary syphilis and ichthyosis fœtalis has only to be remembered to be made. Ichthyosis sebacea is simply a temporary exaggeration of the normal physiological desquamation of the new-born, and has nothing whatever to do with ichthyosis fœtalis..

Treatment.—In a case observed by Sherwell, in which the infant lived an unusually long time, it was kept soaked in olive oil. *Douglass W. Montgomery.*

ICTERUS. See *Jaundice.*

IDAHO HOT SPRINGS.—Clear Creek County, Colorado.

Post-Office.—Idaho Hot Springs. Hotel.

Access.—Viâ Colorado Division of the Union Pacific Railroad, the route lying through the famous Clear Creek Canyon. These springs are situated in the Rocky Mountains at an elevation of 7,500 feet above the sea level. The location is exceedingly picturesque, and the climate of a wholesome and salubrious character. Invigorating mountain breezes prevail throughout the summer. The facilities for bathing form a special attraction at these springs. Three immense swimming pools have been constructed, besides numerous private baths, the water ranging in temperature from 85° to 115° F. A natural tunnel furnishes excellent conveniences for a ready-made vapor bath, and is largely resorted to. The following analysis of the Idaho Hot Springs water has been made by J. G. Pohle, analytical chemist:

One United States Gallon Contains:

Solids.	Grains.
Sodium carbonate	30.80
Calcium carbonate	9.52
Magnesium carbonate	2.88
Iron carbonate	4.12
Sodium sulphate	29.36

Solids.	Grains.
Calcium sulphate	3.44
Sodium chloride	4.16
Calcium and magnesium chlorides	Trace.
Sodium silicate	4.00
Magnesium sulphate	18.72
Total solids	107.00

Within five minutes' walk of the Hot Springs there is a cold spring of sparkling, effervescent water, excellent for drinking purposes. A good carriage road leads to the summit of Bellevue Mountain, less than three miles distant, which it is said to afford the most majestic mountain view in Colorado. *James K. Crook.*

IDAN-HA SPRING.—Bannock County, Idaho.

POST-OFFICE.—Soda Springs.

Hotels: Idan-ha, Carriboo, Stock Exchange, and Williams.

The Idan-ha Spring is located two miles from Soda Springs, from whence it is reached by a good roadway. The situation of the spring is 5,886 feet above the sea, and the surrounding mountain scenery is of a grand and impressive character. The climate is very salubrious, the weather being, as a rule, clear and bright. The town of Soda Springs has long been known as a health resort. Within the town limits are the following named springs: the "Horseshoe," "Octonagon," "Williams," "Soda," "Mount" and "Blanche" springs. In the outlying districts are the "Mammoth," "Steamboat," "Hooper," "Jews-harp," and "Fresh-Water" springs. The latter supplies the town with water by a pipe line. Close to the Idan-ha (which is known as the "90-per-cent.") are the "100-per-cent.," the "80-per-cent.," and the "Champagne" springs. An extensive bottling establishment has been built in connection with the Idan-ha Spring, and the waters are shipped and sold in all parts of the country. It is charged with carbonic-acid gas from the Mammoth Spring, two and one-half miles east of Idan-ha, which supplies an immense amount of this substance. The following analysis was made by Prof. Charles F. Chandler:

ONE UNITED STATES GALLON CONTAINS:

Solids.	Grains.
Sodium chloride	13.19
Sodium bromide	Trace.
Lithium bicarbonate	1.27
Sodium bicarbonate	7.34
Magnesium bicarbonate	62.40
Calcium bicarbonate	57.96
Strontium bicarbonate	Trace.
Barium bicarbonate	.08
Manganese bicarbonate	1.73
Iron bicarbonate	.12
Potassium sulphate	1.72
Sodium sulphate	1.96
Sodium phosphate	.68
Sodium biborate	Trace.
Alumina	.05
Silica	3.56
Organic matter	Trace.
Total solids	152.06

This water also contains an excess of free carbonic acid gas. The analysis shows an excellent alkaline-saline water, with ferruginous properties. It should possess valuable properties as a diuretic, mild aperient, and tonic. It is very pleasing to the taste, and possesses the desirable quality of blending with wines and liquors, without giving discoloration or precipitation.

James K. Crook.

IDIOCY AND IMBECILITY. See *Insanity: Idiocy and Imbecility.*

IDIOSYNCRASY.—This term (from ἴδιος, σύν, κρᾶσις, literally, a personal or individual commingling) is applied medically to those mental or constitutional peculiarities of an individual which separate him from the majority of men. To those peculiarities which are shared by *classes* of individuals, on the other hand, the term temperament is given.

One should not include under the term idiosyncrasy qualities due to pathological conditions, as, for instance, the absence of reflexes in tabetic subjects or sensory aberrations like color-blindness, lack of smell or taste perception. But while idiosyncrasies are usually congenital, they may be, as we shall see later in the case of drug and poison addiction, acquired.

The most important idiosyncrasies which fall under the attention of the physician are included under (*a*) sensations, (*b*) reflexes, (*c*) infections, (*d*) foods, (*e*) drugs and poisons.

(*a*) *Sensations.*—One of the most marked idiosyncrasies has to do with response of a given individual to pain. This is shown, for a common illustration, in the matter of vaccination. The actual insult to terminal sensory nerves in a series of patients submitting to this little operation is about the same; but while some of them will notice no hurt whatever, others will shrink and cry out in evident acute pain. Some few will faint. This varying personal factor of pain susceptibility must receive due consideration by the physician in interpreting the symptoms which a patient describes. Other minor discomforts, which yet from a nosological standpoint may be important, receive very varying attention from different people. For example, the writer has observed a large scrotal tumor in an elderly bookworm who said, on his attention being called to it, that he had never noticed its presence at all. Or, again, a woman is found with a completely procident uterus to which she had never given any thought; whereas most women with a far less pronounced degree of prolapsus would have early sought medical advice.

Auditory sensations have a peculiarly unwelcome effect on certain people. The squeak of a file, of a saw, or of a slate pencil are familiar examples. Shylock emphasizes these sensory idiosyncrasies when he says:

> "As there is no firm reason to be rendered
> Why he cannot abide a gaping pig,
> Why he, a harmless, necessary cat,
> Why he, a swollen bag-pipe . . .
> So can I give no reason, nor I will not
> More than a lodged hate and a certain loathing."

(*b*) *Reflexes.*—These are perhaps more important medically than the class just considered.

Sea-sickness deserves first mention here, from its wide prevalence. In fact it is perhaps the absence of this reflex susceptibility that constitutes the idiosyncrasy. Certainly there is no way of foretelling which individuals will prove able to resist it. Freedom from it is to some extent cultivable, though it is well known that some sea captains and naval officers even lose what they have gained in that direction after a short residence ashore.

Hay fever doubtless belongs in this category, for while a pathological lesion exists in a certain proportion of cases, a reflex idiosyncrasy to certain irritants is also a factor. Whatever this irritant may be, it is doubtless similar in its action to ipecac upon another sort of idiosyncrasy. The writer knows a druggist who is so susceptible to the reflex irritation of this drug that he not only cannot dispense it himself, but is obliged to leave his store when any of his assistants is doing so.

Asthma probably owes a part at least of its etiology to a similar reflex idiosyncrasy. For while we have a determining cause in some pathologic state of the respiratory tract, and an exciting cause in an acute inflammation of the bronchi, or elsewhere, we must assume in asthmatics a predisposing cause in a peculiar reflex irritability; for not all persons possessing the first two conditions have asthma.

Another reflex idiosyncrasy is that which enables the rigger and the steeple-climber to ascend to high places without giddiness or fear of falling.

It is a failure of natural reflex response to cold baths and cold affusions which explains the idiosyncrasy noted in some people at water-cure establishments. On the other hand, those untoward results of baths which include skin eruptions, eczema, furunculosis, etc., are, in so far as they are not due to uncleanly methods, to be classed in the following section among therapeutic idiosyncrasies.

(*c*) *Infections.*—The present article does not touch upon the subject of *Immunity* (which see). But there is in some persons a lack of susceptibility to various diseases which can be ascribed only to idiosyncrasy. This is well illustrated by vaccinia, there being a very few persons upon whom vaccination cannot be made to "take" no matter how often repeated. Some families of children escape in epidemics of the exanthemata, while others have these diseases several times, seeming to be unable to acquire the usual immunity from one attack. The universal exposure to the bacillus tuberculosis would indicate that the varying resistance of different individuals was largely a matter of idiosyncrasy.

(*d*) *Foods.*—There are many instances of idiosyncrasy as regards special articles of diet. One person, for instance, not only cannot eat cheese without violent gastro-intestinal irritation but cannot eat comfortably at a table where it is served. A special form in which these food idiosyncrasies assert themselves is in the production of urticaria from the use of them. Familiar examples are fish and shell-fish, especially lobsters; also strawberries and peaches. The latter fruit with some patients will cause an intense coryza apparently like a rose-cold. Herpes and angioneurotic œdema are similarly produced. Milk is an article of diet which many persons, generally mistakenly, think they cannot take. But there are really some who undoubtedly do have an idiosyncrasy against it. Regarding this as every other article of diet, a person should, often with medical supervision to guard against error, establish the fact of his own idiosyncrasy, and having once established it should thereafter respect it.

(*e*) *Drugs and Poisons.*—In this field idiosyncrasy may show itself either by an unusual susceptibility to a small dose, or, on the other hand, by a lack of susceptibility to the average physiological or even toxic dose. The former of these conditions is usually congenital; the latter may be either congenital or acquired. To it is given the technical name of "tolerance.".

A high degree of tolerance is usually an acquired condition. It is well known that in both man and the lower animals, increasing doses of a toxin can be given till doses are tolerated far in excess of what would be fatal without such a progressive increase in dosage. The use of the toxin of diphtheria in the preparation of antitoxin is a familiar example of this. The same tolerance is established in the case of non-bacterial poisons, as, for example, tobacco, alcohol, and arsenic. But while such tolerance may appear to be present in certain organs or systems of the body, it may be absent in others. For example, the nervous system may appear to be resisting tobacco or alcohol, while the cardiac or digestive may be in reality succumbing to its use, or vice versa.

Such an acquired tolerance, whether in the case of toxins or of drugs, ceases soon after the regular administration of the poison has been stopped. The term Mithridatism was applied to a supposed immunity against poison gained by King Mithridates through the systematic use of poisons employed for that end.

The Styrian peasants have long been noted for their acquired tolerance for arsenic. One sceptical traveller is recorded to have administered seven grains of arsenious acid to an apparently healthy Styrian without ill effect. The enormous doses of morphine taken by morphinomaniacs of course suggest themselves in this connection.

A tolerance for one drug sometimes develops a tolerance for others of similar nature. To this may perhaps be ascribed the large amount of ether required to anæsthetize a habitual alcoholic. The writer once saw a morphine habitué who after taking nearly a drachm of morphine with suicidal purpose added to the dose over one hundred grains of chloral, to which he was not specially addicted, but the conjoined dose had no serious effect. Insensibility to large doses of sedatives, as ether, chloroform, opium, hashish, and bromides, is found in some persons not habitués of any of these drugs. Such persons are apt to be of a hysterical or emotional character. A lack of response to large doses of cathartics may be dependent on the cathartic habit or may be met with independently of it. People of warm climates are said to require exceptionally large cathartic doses.

Many persons are aware of their own drug idiosyncrasies, and may properly acquaint a strange physician with them. It is unwise to disregard such information if given by a person of intelligence. In doing so one is liable to repeat the disastrous experience of a previous attendant, and even if the experiment has no other ill-effect than the temporary discomfort of the patient, the latter is likely to feel provoked that his warning was not regarded. But of course the patient may have drug idiosyncrasies which are unknown to him. It is therefore unwise for a physician in case of untoward symptoms arising, to say offhand that they could not possibly be due to the use of a given drug, even though in his experience such a result had never occurred.

It may be said in passing that sometimes a pathological condition of some organ, involving too slow or too rapid absorption or impaired elimination, is at the bottom of what is regarded as a congenital drug idiosyncrasy. Thus renal inadequacy has been found in some persons who could not take iodine.

Childhood appears to present some special features with regard to drug susceptibility. Especially opium should be used very cautiously at this period. There is a common belief, on the other hand, that arsenic and belladonna are especially well borne by children. I think it very doubtful if this be true of the latter. Jacobi thinks children tolerate relatively large doses of quinine, digitalis, potassium iodide, and mercury.

It remains to mention a few specific drugs and poisons in regard to which marked individual idiosyncrasy is most often met.

Ivy Poison. Here all degrees of susceptibility are met, from perfect immunity to the most intense dermatitis following the slightest contact.

Alcohol. Here we find not only quantitative but qualitative idiosyncrasies One man can drink down all his fellows, while the others with an equal quantity of liquor may show either amativeness, quarrelsomeness, hilarity, or gloom.

Quinine is a drug which occasionally produces ill effects in a dose much smaller than ordinarily given. Such effects are tinnitus, deafness, blindness, and erythema. The writer has seen an intense universal dermatitis follow its use, and has known a clergyman in whom a dose of two grains invariably produced a marked erythema of the scrotum. Fever and abortion have both been reported to follow the use of quinine.

Salicylic acid will cause at times an intense delirium. I have seen it simulate an acute mania and last nearly a fortnight.

Belladonna also, as is well known, causes delirium in certain patients. *Opium* has caused vomiting, wakefulness, convulsions, and delirium. Doubtless there are some persons who should never take the drug. In the first use of the hypodermic syringe upon strangers a considerable conservatism is wise.

Potassium Iodide. Perhaps no drug reveals more of personal idiosyncrasy than this. Two to five grains often cause coryza. Four ten-grain doses have produced an œdema of the glottis severe enough to require tracheotomy. Fifteen grains a day will often cause a good deal of acne. But, curiously, patients who cannot take the small doses often can take the large one, and the massive doses of four to six drachms three times a day are generally well borne. One cannot insist too firmly that the tolerance for this drug is *not* a diagnostic criterion of syphilis. *Charles F. Withington.*

IGAZOL is said to be a mixture of formaldehyde, paraformaldehyde, and an iodine compound of unstated nature. It is in the form of a powder and was introduced by Cervello as a remedy for tuberculosis. Norway used it by vaporizing over a lamp for two hours three times a day. He reports good results in asthma, laryngeal spasm, and phthisis. It has no specific action.

W. A. Bastedo.

IGNATIA.—Saint Ignatius' Bean. The seed of *Strychnos Ignatii* Berg. (fam. *Loganiaceæ*). This is a large, half-climbing shrub, with very long, slender branches, and rather large, oval, pointed, three-nerved leaves. The flowers resemble those of *S. Nux vomica,* and the fruit is a very large (10 to 20 cm.), solid, many-seeded, hard berry. The plant grows in the Philippine Islands, and has been introduced into Cochin-China. The fruit appears to be not uncommon in some Asiatic markets. The seed has been known to Europeans since 1699 (Flückiger).

Saint Ignatius' Beans are hard, oblong, but irregularly faceted seeds, 2 or 3 cm. in length, of a dull yellowish-gray or blackish color, and corneous texture; they are normally covered with short, coarse, appressed, glistening hairs, but these are usually rubbed off before they reach this country, probably by the friction of the long voyage or carriage. The seed consists mostly of perisperm, but contains an oblong embryo, 6 or 8 mm. in length, in a cavity near the centre. The seeds have but little odor, and a very bitter taste.

Composition.—*Strychnine,* to the extent of from one to one and a half per cent.; *brucine* from one-half to three-fourths per cent.; considerable albuminoid matters; no starch. These seeds, from chemical, structural, and physiological points of view, are qualitatively so exactly duplicates of nux vomica that the reader is referred to that article for further information. Because it was supposed to be more uniform in its alkaloidal percentage, and in the relative percentages of strychnine and brucine, this drug was made official in 1880, but it was found impossible to induce physicians to substitute it for the familiar nux vomica, and it was dropped at the 1890 revision. An abstract, of fifty-per-cent. strength, dose 0.06 to 0.3 gm. (gr. i.–v.), and a tincture of the same strength and dose as that of nux vomica, were supplied.

W. P. Bolles.

IMMUNITY.—The past few years have added a great deal to our knowledge concerning the nature of immunity, but there is still much to be learned. Care must therefore be taken, while discussing the many plausible theories advanced, to remember always that they are but theories and may be, however interesting, still untrue.

Experience and observation have taught us that various races of animals and men, and various individuals among these, differ in their susceptibility to certain diseases; and, further, that the same individual is at one time more resistant to such diseases than at another. This inborn or spontaneous refractory condition is termed natural immunity, in contradistinction to that acquired during an attack of disease.

As in bacteria we distinguish between the ability to produce poison and the power to multiply, so in animals and man we may distinguish between immunity to poison and immunity to the invasion of bacteria.

With regard to variations in susceptibility, certain facts have been ascertained. Thus, cold-blooded animals are generally insusceptible to infection from those bacteria which produce disease in warm-blooded animals, and *vice versa.* This is explained in a measure by the inability of the bacteria which grow at the temperature of warm-blooded animals to thrive at the temperature existing in cold-blooded animals. But differences are observed not only between warm-blooded and cold-blooded animals, but also between the several races of warm-blooded animals. The anthrax bacillus is very infectious for the mouse and guinea-pig, while the rat is not susceptible to it unless its body resistance is reduced by disease and the amount of infection is great. The inability of a micro-organism to grow in the body of an animal does not necessarily indicate, however, an insusceptibility to its poison; thus, for instance, rabbits are said to be less susceptible than dogs to the effects of the poison elaborated by pneumococci, but these bacteria develop much better in the former than in the latter. Differences in susceptibility are sometimes very marked among different varieties of the same race of animals, as, for instance, between different kinds of rats and pigeons to anthrax. In animals, as a whole, experiments have shown that the young of all species are on the average less resistant to infection than the older and larger ones.

The difficulty experienced by many micro-organisms in developing in the tissues of the healthy body can be to a great extent removed by any cause which lowers the general or local vitality of the tissues. Among the causes which bring about such lessened resistance of the body are hunger and starvation, bad hygienic surroundings, exhaustion from overexertion, exposure to cold, the deleterious effects of poisons, bacterial or other, acute and chronic diseases, vicious habits, drunkenness, etc. Purely local injuries, such as wounds, contusions, etc., give a point of entrance for infection, and also through tissue injury one of less resistance, where the bacteria may develop and produce local inflammation. Local disease processes, such as endocarditis, may also afford a weak spot for the bacteria to seize upon. The presence of foreign bodies in the tissues in like manner predisposes them to bacterial invasion. Interference with free circulation of blood and retention in the body of substances which should be eliminated also tend to lessen the vitality. In these and other similar ways animals which are otherwise refractory may acquire a susceptibility to bacterial invasion.

Just as all conditions which are deleterious to the body lessen its power of resistance to bacterial invasion, so all conditions which are favorable to it increase its resistance, and thus aid in preventing and overcoming infection. The internal use of antiseptics against bacteria has not proved successful, for the reason that of all known non-specific bactericidal substances an amount sufficient to inhibit bacterial growth is found to be poisonous to the tissue cells. The efficacy of quinine in malaria and of mercury in syphilis is, possibly, an exception to the rule, but in both cases we are dealing probably with animal parasites, not bacteria. Such substances as nuclein and others contained in blood serum, when introduced into the body in considerable quantity, aid somewhat in inhibiting the growth of many bacteria. Even bouillon, salt solution, and small amounts of urine have a slight inhibitory action. The hastening of elimination of the bacterial poisons by free intestinal evacuation and encouragement of the functions of the skin and kidneys are also of some avail. The enzymes formed by certain bacteria have been found to exert a slight bactericidal action, not only on the germs which have directly or indirectly produced them in the body, but also on other varieties. None of these enzymes is sufficiently protective, however, to be of practical value nor equal in power to the protective substances formed in the body after infection with many micro-organisms.

The tissues of the animal body under the normal conditions of life are unsuitable for the growth of the great majority of bacteria, and are only fairly favorable to the development of the few remaining. Indeed, only a very small number of varieties of bacteria find the conditions really satisfactory, and even these must gain a point of entrance.

In seeking for a reason for the difficulty experienced by the bacteria in growing in the tissues, we cannot expect to find it in either the lack of or concentration of the nutritive substances, in the temperature, or in the reaction; for although these conditions may be unsuitable for some bacteria they are suitable for many, and thus cannot constitute the fundamental explanation of immunity. A possible reason for the inability of the bacteria to invade living tissues may be in the fact that the nutritious material in the living cells is in a form which the bacteria cannot readily assimilate; but if this be true it does not adequately explain why the bacteria do not develop in the nutritious fluids so abundant about and in the body tissues. We are thus driven to the conclusion that the body fluids themselves contain substances which are directly deleterious to the bacteria. As to the origin of these substances, it is conceivable that they may be either regularly produced in the cells or that they may be produced only when the body is invaded by micro-organisms. They may then remain unaltered in the fluids or be quickly eliminated. More than one of these things may actually occur.

The bactericidal effect of sera upon most bacteria is shown by the fact that when injected into the blood they begin to die at once, and this often continues until in a few hours all have died. Even when bacteria produce infection there is usually for a time a decrease in the number of bacteria living, but this is soon followed by a progressive increase. This fact can be observed not only in the blood and peritoneal cavity, but also when the bacteria are enclosed in animal or vegetable capsules, where the serum passing into them destroys the bacteria. The bacteria are killed even if they have previously grown in blood serum. Bacteria have also been injected into a vein carefully ligated above and below, and here without coagulation the blood exerts bactericidal properties. Even spores are killed in a few days. The effect of the fresh unheated blood serum can also be watched outside of the body. Here some species of bacteria die quickly, some slowly, and some lose only a portion of their number, and here the remaining portion after a time rapidly increases. The number of bacteria introduced is of great importance, for the serum seems capable of destroying only a certain number and after that loses its bactericidal properties.

If the bactericidal effect of the serum outside the body always went hand-in-hand with the immunity of the individual from which it was taken, the problem of immunity would be more easily solved, but this is not wholly the case. We must therefore add to the serum the activity of the cells which constantly produce the antiseptic substances which are given up largely to the blood and fluids of the body. This deleterious action of the blood on bacteria can be increased or diminished by infection, thus indicating living-cell influence.

Concerning the nature of these protective substances, named *alexins* by Buchner, we have as yet little positive knowledge, but certain properties of them are known. They are precipitated by a forty-per-cent. solution of sodium sulphate. A bactericidal serum affects in a deleterious manner the red blood cells of a different species of animals. These substances would seem to belong to the proteids and resemble certain of the globulins in their properties, but they are evidently extremely complex in their nature.

Their source is generally attributed to the cells, but probably certain cells only produce them. The red blood cells, for instance, seem rather to destroy than to increase them. The nuclein derived from the cells, although it has a general bactericidal action, does not belong to the specific alexins. The cells which have abundant nuclear substance, such as the leucocytes and lymph cells, seem especially to be a source of the alexins. Buchner and others have found that, through the irritation of bacterial filtrates, the leucocytes were attracted in great numbers to the region of injection, and that the fluid here, which was rich in leucocytes, was more bactericidal than the blood serum elsewhere. The same fluid acted also more perfectly when it contained numbers of leucocytes than when they were filtered out. Substances similar to the alexins are apparently derived from the leucocytes and their attraction to the injected areas gives to that location greater protective power. Still it has not yet been positively established that the specific alexins are derived from the leucocytes. The attraction between the leucocytes and the bacteria is rather due to the chemical attraction of the bacterial cell products and the bacterial body substance. Some chemical substances not derived from bacteria have also this quality, called positive chemotaxis, while others repel the leucocytes—negative chemotaxis. The theory of Metchnikoff that the leucocytes are the only actual protective bodies which ward off disease, and that they do this by attacking and devouring the bacteria, has been somewhat modified by more recent knowledge, and it is now believed that the bacterial substances attract the cells and that when these are brought together the general, and perhaps the specific, bactericidal property of the blood is thereby increased. The death of the bacteria liberates this positive chemotactic substance, and the death of the leucocytes gives rise to an increase of the non-specific bactericidal bodies. Thus we find that phagocytosis is most marked when the disease is on the decline or the infection mild, but that in rapidly increasing progressive infection it is usually absent. This would seem to indicate that the course of the infection is already determined before the leucocytes become massed at the point of its entrance. The first determining influence is given by the condition of the tissues and the bactericidal substances contained in them, and then later, in cases in which the infection is checked, comes the additional bactericidal substance given off by the attracted leucocytes. In so far as the tissues themselves are unsuitable for the development of bacteria they are sufficient to ward off infection, but in proportion as they are incapable of doing this they are assisted by the substances contained in the leucocytes. If the tissues are wholly adapted for the growth of the bacteria, neither they nor the leucocytes, nor both combined, can furnish sufficient protective substances to prevent the bacterial increase. The entrance of bacteria into the leucocytes, which is not infrequent, may mean the destruction of the former, but, on the other hand, the bacteria may increase in the white blood cells and destroy them, and they may be killed without entering the cells. The simple absorption by the cells is not necessarily a destructive process.

No explanation can as yet be given of natural immunity to bacterial poisons, except that it may be connected with some general property of the protoplasm of the cells which renders a combination between certain molecules of the cell and the poison impossible; thus, if tetanus toxin is injected into a susceptible animal it has been found that it will disappear from the blood in a few minutes. If the cells are subjected to suitable processes the tetanus poison will be found present in all the cells except those of the nervous system. In these it has apparently disappeared. As these are the cells that received injury from the toxin it is fair to assume that some chemical combination has occurred between them and the toxin. There is far less variation among different species in their resistance to the bacterial poisons than in their suitability for the growth of the living bacteria which produce them. Possibly certain organs, such as the lymph glands, the liver, etc.—may have some destructive power with regard to poisons.

By what means are virulent bacteria enabled to increase in the body, notwithstanding its protective powers, when non-virulent organisms of the same species are incapable of so doing? This is but little understood, but experiment shows in the first place that both virulent and non-virulent forms are equally resistant to general destructive agencies; and, secondly, that the bacteria are capable of producing substances (*lysins*) which neutralize in some way the protective substances (alexins). The virulence of bacteria would, therefore, depend partly upon their ability to produce these lysins, which act perhaps as the ferments upon the alexins, or perhaps combine with them. That bacteria under certain conditions form specific poisons, and under others, even when they grow luxuriantly, do not, is clearly shown by our experiments on the production of diphtheria toxin. Here it was found that when the bouillon was either a little too alkaline or too acid, though the bacilli grew rapidly, they did not produce specific toxins. When the bacilli were grown for a time in such bouillon they eventually became able to develop toxin in a soil in which they previously failed to do so. Similar cultivation in the body may be assumed to increase their ability to produce specific poison after a while under what would at first be adverse conditions.

With regard to the increase and decrease of general, and perhaps also of specific immunity, we have reason to believe that as the protective substances are produced through the action of the living cells, anything which lowers the general vitality must lessen the vitality of the cells, and thus their ability to produce protective substances in the amount possible in a normal condition.

Specific Immunity.—The following theories have been advanced concerning the nature of specific immunity: The theory that a second infection is impossible because the first used up substances which were necessary to the growth of the bacteria is untenable for many reasons. Thus it can be demonstrated that the injection of a small amount of specific serum, which robs the tissues of nothing, produces the same immunity. Again, the injection into the body of a sufficient number of bacteria pathogenic for the animal selected gives rise to an infection in all cases.

The original theory of Metchnikoff, that the leucocytes or wandering cells of the body, after an infection with a certain variety of bacteria, become influenced in some way, so that they attack especially that form of infection again and destroy the bacteria (phagocytosis), can no longer be regarded as more than a very partial explanation, and can be accepted only by assuming as proven a number of hypotheses.

The retention theory of Wernich and Chaveau, somewhat modified, has most to support it. They have shown that the chemical changes in the blood serum of animals recovering from an infection are of such an extent as to be capable of being demonstrated experimentally, and these changes have been shown to persist for a number of weeks or months or even years. Similarly the serum of immunized animals retains for a long time its immunizing substances. We are therefore compelled to accept the fact that when an infection is passed through there are more or less protective chemical substances left in the blood which remain there for a considerable time. Kruse believes that these substances have the power of neutralizing the poisons which are given off by the bacteria upon their entrance into the body, and of thus robbing these poisons of their deleterious effects on the alexins; the body fluids in this way remaining antagonists to the growth of the bacteria, the alexins being bactericidal. If only a small amount of antilysins are present some of the alexins are destroyed and the bacteria are not all killed or weakened. Those remaining active are then further acted upon by the alexins in the tissues and by the substances given off by the leucocytes. If these protective substances are insufficient the infection is established.

According to Ehrlich the production of antitoxins and of the specific portion of bactericidal sera is due to overproduction of molecules in cells sensitive to the toxins or bacterial cell products. Ehrlich considers that toxin molecules have what he calls haptophore atom groups which find in sensitive animals cells and atom groups having for them an affinity. The groups unite and later the poison or toxophore atom group of the toxin molecule having been assimilated acts upon the vital part of the protoplasm of the cell, and injury results. This injured cell substance is replaced by the cell in excess, and this excess is thrown off free in the blood. This free cell substance has affinities similar to what it had in the cells and so unites with the toxin molecules, and satisfying them, neutralizes their poisonous properties.

When the substance of bacterial cells is injected into a susceptible animal body, there results in the same way as with toxins an injury of certain cell molecules, and an attempt at repair, with usually an overproduction. The specific substances produced cannot alone attack living bacterial cells similar to those whose protoplasm has previously caused the injury. To destroy the bacterial cell, besides the specific "antibody" there is needed a complementary body. This is the substance normally present in all healthy sera. The two substances together, uniting with the bacterial cell, destroy it.

According to Ehrlich these specific substances are present in minute amount in all living animals. After an injection or a series of injections, that one which has affinity for the poison or bacterial protoplasm is enormously increased. These atom groups of the large molecules of certain body cells are "side chains" as it were, which stand in the same relation as the side chains of the aromatic attachment to the benzol nucleus. On the ability of these groups to unite lies their tendency to be poisoned or to protect.

The agglutins seem to have a close resemblance to, if they are not identical with, the antibodies, which together with the complementary bodies destroy the bacteri

Ehrlich's "side-chain" theories are most interesting; whether they have in them a foundation of truth, or not, only further investigation can reveal. They have, however, helped greatly to establish that the protection given by antitoxic and bactericidal serums is due, for the most part at least, to purely chemical action, the antitoxins uniting with the toxins, and the bactericidal antibodies and complementary bodies combining with the bacterial cells.

An important fact recently established is that while we may accumulate antitoxin to almost any extent in the blood of infected animals, we cannot so increase the bactericidal substances in the serum, for the complementary body which is essential can never be increased in the blood much beyond the extent to which it is normally present in the blood. We can neutralize any amount of toxin by sufficient antitoxin, but we cannot protect an animal from death from a septicæmic germ, if we give an excessive quantity of bacteria. At the present time, therefore, we cannot be hopeful of having protective sera which will be of much value in the treatment of disease, when an extensive invasion of the body by bacteria has taken place.

With antitoxins we seem limited also to those cases in which we can give the antitoxin before sufficient toxin has united with the body cells to produce fatal injury. If even seven minutes have elapsed after an excessive amount of tetanus poison has been injected into a sensitive animal, no amount of antitoxin will protect it from death, while if previous to the injection of the toxin, the same amount of antitoxin has been mixed with it, no harm results.

The injection of toxins and bacterial poisons is followed after forty-eight to ninety-six hours by the development of protective substances. The immunity reaches its height a week or ten days after the injection, and then continues for a week or two, when it slowly declines again. When protective sera are injected the immunity is greatest at the time of the injection and then gradually lessens. The immunity following serum injections is frequently called passive immunity and that due to bacterial or toxin injections active immunity.

If a greater quantity of protective substance is desired in the blood than occurs after one infection, repeated injections of living or dead bacteria or their products are given, the doses being administered at short intervals and in sufficient amount to produce a slight elevation of temperature and malaise. Then, as soon as the animal returns to a normal condition, another injection of slightly greater quantity is given. After several months of such treatment the blood is withdrawn, allowed to clot, and the serum then siphoned off aseptically and stored either with or without the addition of preservatives. The serum is tested by mixing it with a certain number of times the fatal dose of a culture or its toxins whose virulence or toxicity is known, and then injecting this under the skin, in the vein, or into the peritoneum, according to the nature of the bacteria to be tested. The main point is that some definite method be carried out by which the relative value of the serum can be judged in comparison with other serums. As a rule, the value is stated in the number of fatal doses of culture or of toxin which a fraction of a cubic centimetre of serum will prevent from destroying the animal. It is well to remember that with a living germ a multiple of a fatal dose is not as much more severe than a single dose as the figure would suggest. One thousand times a fatal dose of a very virulent micro-organism will be neutralized by several times the amount of serum which a single fatal dose requires, since in the case of very virulent living bacteria whose virulence is due to their ability to increase, it is not the organisms which are introduced that kill but the millions that develop from them. As a rule, the serum has to be given before the bacteria introduced into the body have multiplied greatly. After that period has elapsed the serum usually fails to act. The immunity conferred on a person from serum lasts from a few days to several months, according to the amount of serum injected. As in animals, it is strongest immediately after absorption. An injection of bacterial poisons or the contraction of actual disease usually confers immunity in from one to three weeks after the infection, which lasts, according to the nature of the infection, from one month to a year or more. The serum loses all appreciable protective value as measured in test animals in the usual doses before the person is liable to infection. Repeated injections of serum continue this condition of immunity indefinitely.

The use of sera having specific protective properties has been tried in both animals and man as a preventive of infection. In susceptible animals injections of some of the very virulent bacteria, as pneumococci, streptococci, typhoid bacilli, and cholera spirilla, can be robbed of all danger if small doses of their respective sera are given before the bacteria have increased to any great extent in the body. If given later they are ineffective. For some bacteria, such as tubercle bacilli, no serum has been obtained of sufficient power to prevent infection. Through sera, therefore, we can immunize against an infection, and even stop one just commencing; but as yet we cannot cure an infection which is already fully developed, though even here there is reason to believe that we may possibly prevent an invasion of the general system from a diseased organ as by the pneumococcus from an infected lung in pneumonia. On the whole, the sera which simply inhibit the growth of bacteria have not given, as observed in practice, conclusive evidence of great value in already developed disease. This is partly due to the difficulty of determining early enough the exact nature of the bacteria causing the infection. Although the serum of animals which have been infected with any one of many varieties of bacteria is usually both antitoxic and bactericidal, still one of these protective substances may be present almost alone; thus antitoxic substances are present almost exclusively in animals injected with two species of bacteria which produce powerful specific poisons—the bacilli, namely, of diphtheria and of tetanus. When the toxins of either of these are injected in small amounts the animals after complete recovery are able to bear a larger dose without deleterious effects, and these doses in the more suitable animals can be gradually increased until a thousand times a previously fatal dose may be administered without any serious results whatever. To Behring and Kitasato we owe the discovery that this protecting substance accumulates to such an extent in the blood that very small amounts of serum are sufficient to protect other animals from the effects of the toxin.

Some other important parasitic bacteria produce toxins and in the body antitoxins, but all to a far less extent than those of tetanus and diphtheria. Following them is the plague bacillus, and then, but far behind, the cholera spirilla, the typhoid bacilli, the streptococci, etc. These latter bacteria produce more of the substances which inhibit bacterial growth than of those which neutralize their toxins.

Inherited Immunity.—Natural immunity pertains more to species than individuals, and such immunity is handed down by the parents to their offspring. If the immunity of one or both parents has been acquired by them during their lifetime previous to the birth of the offspring the immunity conferred is slight or none at all. This is especially true of the male side. In the case of the female parent another factor comes into play after the fructification of the ovum,—viz., the absorption of products from the fluids of the mother, for the placenta is no barrier to soluble substances. Thus, sheep which have been immunized to anthrax have moderately immune young. On the other hand, animals vaccinated with cowpox have not been found to have immune offspring. Antitoxins injected into the parents apparently pass the placenta, giving thus a slight transitory passive immunity. A slight immunity is also given by immune mothers through their milk, a small amount of antitoxic substance being absorbed. *William H. Park.*

IMPETIGO.—This is an acute specific inflammatory affection of the skin, spontaneously and experimentally inoculable, contagious, and epidemic; characterized by the formation of superficial flaccid vesicles which soon rupture and give place to crusts formed by the drying of the effused serum. These crusts are without inflammatory areola and look as if stuck on the sound skin, the underlying epidermic erosions healing in a few days without leaving cicatrices.

Impetigo is a disease peculiar to infants and young children, not that there is with them any special underlying predisposing cause in the soil, so to speak, such as a strumous or lymphatic condition as is often alleged, but that simply their skins are more delicate, particularly that of the face, where the corneal epidermis is less thick and where impetigo occurs most frequently.

Given an erosion of the skin—and the thinner the skin the more easily does erosion occur—and the introduction of the special germ, a characteristic lesion of impetigo will result. The *accidental* causes which lead to this inoculation are those that conduce to scratching by which the skin is broken, such as phthiriasis, especially of the scalp, and scabies. Eczema may lead to impetigo. The contagiousness of impetigo was clinically established by Devergie and experimentally proven later by Tilbury Fox, of London, and others. Fox prefixed the term contagious, which would make it appear that his "contagious impetigo" was a different affection from the impetigo of the French school, which is not the case. Impetigo and "contagious impetigo" are one and the same disease and "contagious" is an entirely unnecessary and confusing qualification. Through the more or less intimate association with the greater opportunity for contagion that takes place in schools and families, impetigo may become epidemic solely through the inoculation of one by the other of the members of such bodies. The direct and efficient cause of impetigo is a microorganism—one of the streptococci.

The elementary lesion of impetigo is an erythematous spot but slightly if at all elevated, varying in size from the head of a large pin to that of a split pea. This lesion is very transitory and gives place in a few hours to a superficial flaccid vesicle containing a clear limpid serum. The thin corneal covering of this blister-like lesion is easily ruptured, spontaneously or by scratching, allowing to exude a limpid serum which quickly coagulates and forms the characteristic honey-like crusts that appear as if stuck on the sound skin. An accumulation of these friable amber-yellow crusts, without surrounding inflammatory areola, over the cheeks, forehead, and chin, and around the lips, presents a classical picture of the disease known as impetigo. It may occur on any part of the body, but the face is the familiar location. At times, after the breaking of the imperfect vesicle, little or no exudation will take place, so that no crusts are formed, there being merely a thin glaze over the underlying superficial erosion which heals quickly, leaving an erythematous spot that slowly disappears. This abortive attempt is noticed more frequently in grown persons. Ordinarily through successive reinoculations an attack of impetigo will last for from three to four weeks. The burning and itching, though slight, are sufficient in a child to cause it to scratch the lesions, thereby infecting the finger nails, and thus transference to other parts is effected with the establishment of new lesions. When uncomplicated, the lesion of impetigo never suppurates and terminates, after falling of the crust and the gradual disappearance of the underlying reddened, area without cicatrix.

Impetigo may be diagnosed from varicella by the more widespread distribution of the latter, impetigo being essentially regional; the vesicle of varicella is smaller and more prominent, is surrounded by a wide area of erythema, and dries up into smaller and far less bulky crusts.

From ecthyma the diagnosis is made by the distribution of the lesions of the latter on the covered portions of the body, and by the greater intensity of the inflammatory process in ecthyma with accompanying indurated base, wide inflamed areola around the crust-covered pustule, and deeper erosive action upon the skin.

A bullous impetigo—a rare form—has at times been erroneously reported as "acute pemphigus in children."

A crusted impetigo lesion may simulate a syphilide, especially when situated around the mouth and chin in adults; if the lesion is one of syphilis the crust on being removed will be found to have surmounted a papule or a sanious ulcer.

Treatment is simple and effective. Removal of the crusts by soaking in olive oil until they are easily detached is the first step, after which an application, renewed twice daily, of a five- to ten-per-cent. ointment of ammoniated mercury will complete the healing in a few days, leaving only the after-redness which in turn gradually disappears. This treatment is all-sufficient, and while there are many other remedies that will perhaps cure as well, there is none better than this.

Charles Townshend Dade.

IMPOTENCE. See *Sexual Organs, Male, Affections of.*

IMPREGNATION is the union of two germ cells, to form a single new cell, capable of initiating by its own division a rapid succession of generations of descendent cells. This process is more frequently called *fertilization* or *fecundation.* The new cell is called the impregnated, or fertilized, ovum; also, especially in botany, it is called *oöspore* or *zygote.* The production of cells from it is called its segmentation, or cleavage. For the theory of the relation of the elements to one another and to other cells, see *Sex;* for accounts of the sexual bodies, see *Ovum* and *Spermatozoon.*

In all multicellular animals, impregnation is effected by three successive steps: 1, The bringing together of the egg and spermatozoon; 2, the entrance of the spermatozoon into the ovum, and formation of the sperm nucleus; 3, fusion of the sperm nucleus with that of the egg to form the segmentation nucleus. We proceed to consider these steps in their order.

1. The Bringing Together of the Germ Cells.—This is effected among animals in a great variety of ways, which, however, fall into two groups, according as the impregnation is effected, (*a*) outside the body of the mother, or (*b*) inside. The simplest manner is the discharge of the eggs and spermatozoa at the same time into the water, leaving their actual contact to chance, the method of the osseous fishes for the most part, and of many invertebrates. An advance is the copulation of the Anura (frogs, etc.), the male embraces the female, and as the latter discharges the ova, ejects the sperm upon them. In the higher vertebrates the seminal fluid is transferred from the male to the female passages during coitus. The physiology of this complicated function does not fall within the scope of this article.

For a long time it was not known how the semen fertilized the ova; the problem was long fruitful of fruitless speculation. The first step toward gaining actual knowledge was the discovery of the possibility of artificial fecundation by Jacobi, in 1764. Spallanzani was the first to take advantage of this, and to show that fecundation implied a material contact of the semen with the ova, and thus to set aside De Graaf's notion of the *aura seminalis.* But not until fifty years later did the memorable experiments of Prévost and Dumas (*Annales des Sciences Naturelles,* 1824) establish the fact that the spermatozoa are the essential factors of fertilization. Again, a little over fifty years later, Hertwig and Fol showed that one spermatozoon suffices to impregnate an ovum.

We have then to consider how the spermatozoa, after the semen has been transferred to the female, attain the ovum. They are found in mammals after copulation in the vagina and even in the uterus, but it is not clearly ascertained how they get beyond the vagina. It is probable that they travel through the female passages partly by the movements thereof, partly by their own locomotion, and enter the Fallopian tubes, though why or how is really unknown, and pass upward to meet the ovum. They are found in considerable numbers in the Fallopian tubes. The ovum meanwhile travels down the oviduct, it probably being impelled by peristaltic movements of the duct.

The meeting point or site of impregnation in placental mammals is about one-third, perhaps one-half way down from the fimbria to the uterus. It is remarkably constant for each species. Nothing positive is known as to the site of impregnation in man, but there is no reason to suppose, as is unfortunately often done, that the site is variable or different from that in other mammalia.

In the sexual reproduction of plants the germ cells are brought together in a great variety of ways; and in the higher forms the process is complicated by an alternation of generations. It will suffice for our present purpose to note that in many of the lower plants the male germ cell is an actively motile *spermatozoid,* homologous with the spermatozoon of animals, on the one hand, and with the germ cell of the pollen grain in higher plants, on the other hand.

2. The Entrance of the Spermatozoon into the Ovum and Formation of the Sperm Nucleus.—With our present knowledge, the assumption appears unavoidable that the ovum exerts a specific attraction upon spermatozoa of the same species. We observe, in fact, when artificial fecundation is employed, the spermatozoa swarming around the ova as if held by an irresistible impulse. This phenomenon occurs with every class of animals, even in mammals, whose freshly removed ova were examined on a warm stage under the microscope (Rein). Stassano has maintained that the eggs of echinoderms do exert such an attraction and also a similar but less strong attraction upon the spermatozoa of allied species. Since the brothers Hertwig have found by their experiments with sea urchins that hybrid impregnation takes place more readily after the ova have been kept awhile, Stassano's view involves the further assumption that the specific nature of the attraction fades away during a few hours. Very suggestive in this connection is Pfeffer's discovery that certain chemical substances may attract moving spores, etc., to definite spots. It is conceivable that the ovum may draw the spermatozoa toward itself by chemical influence, acting as an attracting stimulus. That this attraction may be exerted by the cytoplasm of the egg alone, is shown by the experiments of Boveri, Hertwig, Bresi, and Morgan, who found that spermatoza will enter enucleated fragments of eggs.

There may be mechanical devices to facilitate the entrance of the spermatozoon; this is, perhaps, generally true of all ova with micropyles serving for the passage of the spermatozoa. A careful study of such devices in the cockroach has been made by Dewitz, who found that the motions of the spermatozoa of this insect are peculiar, and adapted to increase the probability of their passing through one of the micropyles of the ovum. In ova without micropyles, among which those of mammals are included, the spermatozoa may, so far as we know, penetrate any part of the envelopes.

In the rabbit (Rein) about ten hours after coitus the ovum is found nearly half-way through the oviduct, and surrounded by many spermatozoa, perhaps a hundred, more or less. These are all, or nearly all, in active motion, for the most part pressing their heads against the zona radiata. Several of them make their way through into the interior of the zona. According to Hensen, only those spermatozoa which enter the zona along radial lines can make their way through; those which take oblique courses remain caught in the zona, and may still be seen there during segmentation. As the ovum at this time is already fully matured (see *Ovum*), there is a space between the contracted ovum and the zona. In this space, as well as in the zona itself, several spermatozoa may be observed at scattered points (Fig. 2787). The egg nucleus (see *Ovum*) is present, having been reformed since the expulsion of the second polar globule from the ovum, while in the ovary. One spermatozoon gets into the egg proper, and its entrance apparently prevents the penetration of other spermatozoa—*how* is undetermined. The tail of the spermatozoon soon disappears; while the head, which consists almost entirely of nuclear material, chromatin, enlarges, probably by the imbibition of fluid from the cytoplasm of the egg, and becomes the sperm nucleus. This was formerly called the *male pronucleus*, in distinction from the egg nucleus, which was called the *female pronucleus*; but they differ in no respect from other nuclei, except in the number of chromozomes which they contain.

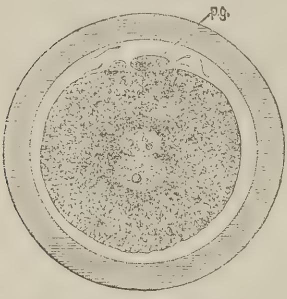

FIG. 2787.—Ovum of a Rabbit (in Optical Section) taken from the Middle of the Oviduct about Seventeen Hours after Coitus. The sperm and egg nuclei are close together at the centre of the egg; the polar globules, *p.g.*, are shown; numerous spermatozoa lie within the zona, *z*. (After Rein.)

The passage of the spermatozoa through the zona was first discovered by Martin Barry, in 1843, and although his statement was received with considerable hesitation by his contemporaries, it has since had competent confirmation repeatedly. Warneck is said to have been the first (1850) to see the *two* pronuclei, but their significance was not perceived. The nature of the male pronucleus was first recognized by Oscar Hertwig, who traced its genesis in the ova of echinoderms from the spermatozoon. The fact that the male pronucleus is the metamorphosed head of the spermatozoon has since been confirmed by Selenka, Ed. van Beneden, Nussbaum, Eberth, Platner, and others.

Although a number of the spermatozoa make their way into the perivitelline space, probably always one alone normally enters the ovum there to form a pronucleus. The best observers are agreed upon this point, and in all species, the observations upon which have covered the whole series of steps in the impregnation, there has been found in normal cases always a single sperm nucleus. Schneider's statements to the contrary have been definitely corrected. Bambeke, Kupffer, and Kupffer and Benecke have observed that several spermatozoa actually enter the yolk in batrachians and Petromyzon. Hertwig, however, found only one sperm nucleus in the frog, and there has as yet been no evidence adduced that several spermatozoa are concerned in the final phases of impregnation. Fol observed that star-fish eggs are normally impregnated by one spermatozoon; but if they are exposed to the action of carbonic acid they may, while so poisoned, be impregnated by several spermatozoa, but the subsequent development in this case is abnormal.

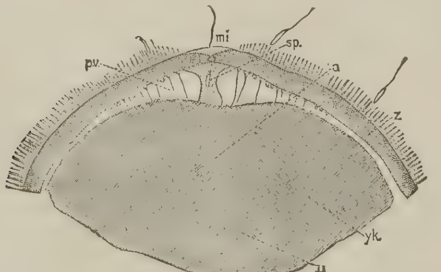

FIG. 2788.—Anterior Pole of the Ovum of Petromyzon, with a Spermatozoon (*sp*)., entering the Micropyle (*mi*). (After Calberla.) *p.v.*, Perivitelline space; *z*, zona pellucida; *a*, pathway to egg nucleus, *n*; *yk*, yolk.

The term micropyle is applied to various structures, and does not in all cases designate a passage through which spermatozoa enter—thus the micropyle of holothurians is merely a structure left in the envelopes in consequence of the way the egg is developed. A micropyle has been observed in the ova of teleosts and the lamprey, but it is doubtful whether it is, like the micropyles in the hard-shelled eggs of insects, intended for the passage of spermatozoa. Calberla saw the micropyle thus used in the lamprey, and it is possible that the fructifying spermatozoon enters that way, although Kupffer and Benecke state that spermatozoa may also pass directly through the zona. A good synopsis of the observations on the lamprey is given by Hensen (Hermann's "Handbuch," vi., ii., 120). We have only to notice that there is a special band of non-granular protoplasm leading from the micropyle to the egg nucleus (Fig. 2788), and serving as a path for the spermatozoon; a similar band has been observed in amphibian eggs by Hertwig and Bambeke; it serves perhaps as a mechanism to guide the sperm nucleus to the egg nucleus.

The manner in which additional spermatozoa are excluded, after the first has entered, is still under discussion. In cases in which there is a single micropyle, which is used for entry, it is possible that a portion of the first spermatozoon may remain to close the passage, or that in going through it sets in action some mechanism by which the opening is automatically shut. Where there are several or many micropyles, as in some insects, or where the envelopes may be pierced at any point, as in mammals, there must of course be some other device. Fol has maintained that this is found in the starfish in the rapid formation of a membrane around the yolk, immediately after the entrance of the first spermatoon. This is confirmed by the observations of Wilson and others on other echinoderm eggs. The egg is at first perfectly naked and the membrane is formed very quickly after the entrance of the head and middle piece, leaving the tail outside. Selenka (*Biolog. Centralbl.*, v., 8) describes the fertilization of the ovum of a nemertean worm —several spermatozoa enter within the vitelline membrane; the yolk contracts slowly; after a time the two polar globules are expelled, and before they separate from the yolk one spermatozoon passes into the yolk between them; the globules then break off and are knocked about by the spermatozoa in the perivitelline space. In this case there seems to be a portal opened just long enough for one spermatozoon to enter. As the phenomenon to be explained is common to all ova, its causation is presumably fundamentally identical in all cases. Beyond this surmise our present knowledge does not permit us to go. The hypothesis may be suggested that the attractive power of the ovum is annulled or weakened by the entrance of the first spermatozoon.

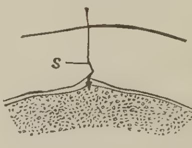

FIG. 2789.—Egg of Toxopneustes, with entering Spermatozoon (*s*), and a Protuberance of the Cytoplasm rising toward it. (After Selenka.)

The fate of the tail of the spermatozoon differs in different species. In some the whole spermatozoon enters the egg, while in others, as the echinoderms, only the head and the middle piece enter. In either case it is a well-established fact that the tail is simply a locomotor organ and takes no part in fertilization proper.

While the spermatozoon is passing through the ovic envelopes active changes occur in the cytoplasm. Of these, the most constant, as well as the most obvious, is the formation of a slight protuberance on the surface of the cytoplasm of the egg, rising up toward the spermatozoon. This protuberance (Fig. 2789) may remain, as in echinoderms, until the spermatozoon meets it, and by penetrating it enters the ovum; or it may retract before the spermatozoon passes through the envelopes, and even withdraw, as in Petromyzon, so far from the advancing spermatozoon as to change into a depression (Fig. 2788). The protuberance lasts only a few minutes. In Bufo, according to Kupffer, several spermatozoa enter the egg and a protuberance rises toward each one, as if the cytoplasm were actively striving to reach the male element.

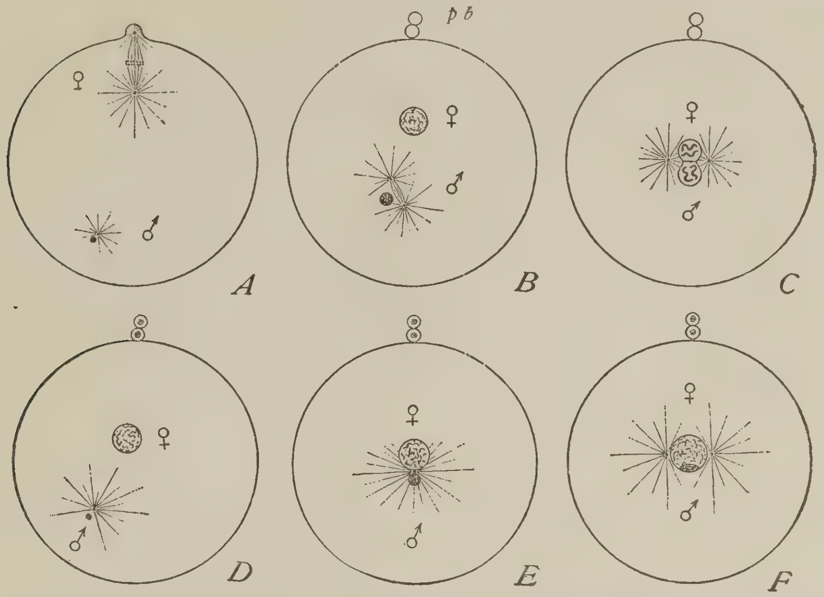

FIG. 2790.—Diagrams of Two Principal Types of Fertilization. *A*, *B*, and *C*, Polar bodies formed after the entrance of the spermatozoon, as in Nematodes, Annelids, and Mollusks; *D*, *E*, and *F*, polar bodies formed before entrance of spermatozoon, as in Echinoderms. Egg nucleus at ♀, sperm-nucleus at ♂. (From Wilson.)

3. FUSION OF THE GERM NUCLEI, FERTILIZATION PROPER.—For many centuries the process of fecundation was wrapped in the deepest mystery, and while the keen observers of the latter half of the eighteenth century and the first half of the nineteenth did much necessary preliminary work in this direction, they so far failed to clear up the mystery that, although spermatozoa had been discovered by Hamm and Leeuwenhoek in 1677, and Spallanzani had shown in 1786 that spermatic fluid deprived of spermatozoa by filtration is sterile, Johannes Müller wrote in his "Physiology" in 1840 that it was uncertain whether the spermatozoa were parasites or not; and, although Schwann had declared the egg to be a cell as early as 1838, it was still possible in 1875 for a distinguished zoologist, Alexander Goette, to write "that the egg was a mass of non-living yolk which, under the influence of the spermatozoon, gradually came into a living condition." While the process is still sufficiently wonderful and mysterious, a great deal has been done during the past twenty-five years to render it intelligible.

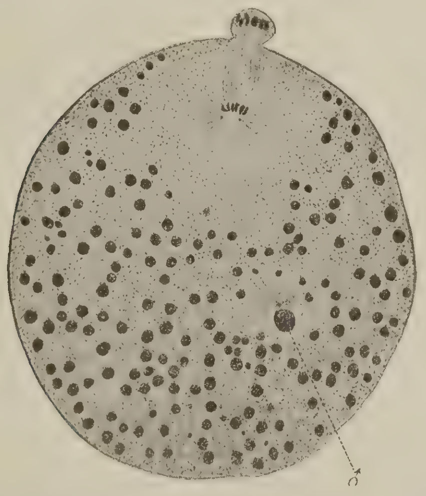

FIG. 2791.—Fertilization of the Egg of *Thalassema melitta*. The head of the spermatozoon preceded by the sperm aster is shown at ♂. The formation of the first polar body is nearly completed and the inner centrosome of the polar spindle has divided preparatory to the formation of the second polar amphiaster. Highly magnified. (After Griffin.)

The first great discovery was made by Oscar Hertwig, who observed in 1875 that the egg of a sea-urchin, *Toxopneustes lividus*, is normally fertilized by the entrance of a single spermatozoon, and that the spermatozoon gives rise to a nucleus which unites with the nucleus of the egg, forming by this union the segmentation, or cleavage, nucleus. We know now, as the result of numerous observations, that both the egg and the spermatozoon are living cells, and that they are morphologically equivalent, except in so far as they are altered in form in adaptation to a physiological division of labor, the principal difference being that the egg is provided with a large amount of cytoplasm, often heavily laden with food yolk for the nourishment of the embryo, and has no power of locomotion; while the spermatozoon is totally devoid of

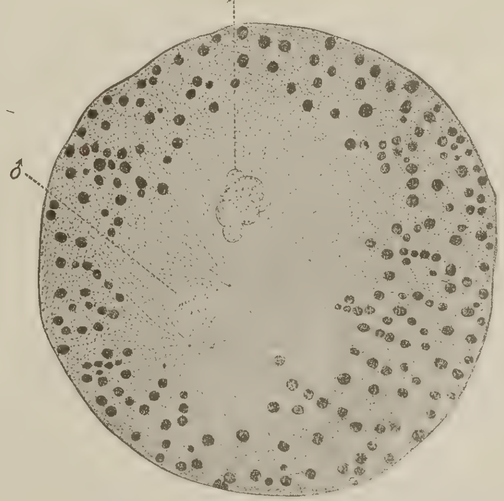

FIG. 2792.—Later Stage of the Same. The egg nucleus is shown at ♀ and the sperm nucleus at ♂. The two nuclei are approaching one another. The egg centrosome has vanished, while the persistant sperm centrosome has divided forming two centrosomes with asters. (After Griffin.)

food material and has but little cytoplasm, most of which is usually modified to form a flagellum or other organ by which the spermatozoon may move actively and seek the egg. There is possibly another physiological difference which will be noticed in connection with the function of the centrosome. The terms male and female cannot be applied properly to these cells, and should be used only as descriptive of the organisms that produce them or their equivalents.

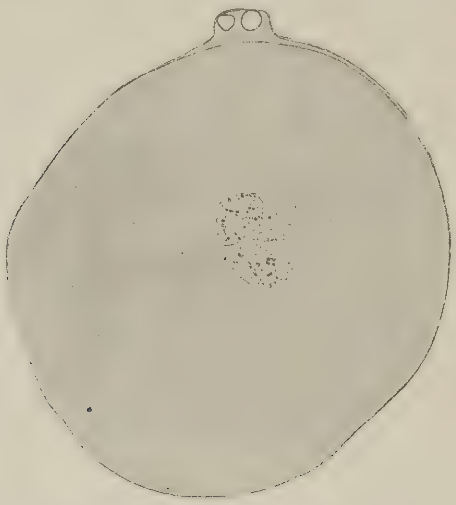

Fig. 2793.—Thalassema. Copulation of the germ nuclei. The sperm centrosomes are seen in the plane separating the two nuclei. (After Griffin.)

There are two types of fertilization in animals, depending, as was first suggested by Hertwig, upon the time of entrance of the spermatozoon.

The eggs of echinoderms (Fig. 2790, *D*, *E*, *F*) pass through the whole process of maturation (see *Reduction Division*) before the entrance of the spermatozoon, the egg nucleus has resumed the form of a spherical vesicle, and the aster and centrosome of the last polar spindle have disappeared. The spermatozoon may enter the egg at any point. Soon after entrance the head of the spermatozoon revolves end for end and begins to enlarge, while a series of lines appear in the cytoplasm radiating from the position of the middle piece. These radiations form the *sperm aster*, and at their centre there is a small darkly staining spot, the *sperm centrosome*. The head of the spermatozoon, now called the *sperm nucleus*, moves rapidly toward the *egg nucleus*, preceded by the aster. The latter touches the egg nucleus and divides into two, and shortly after this the sperm nucleus unites with the egg nucleus, the two becoming completely fused in a single segmentation, or *cleavage, nucleus*. In the mean time the two asters formed by division of the sperm aster have taken up positions at opposite poles of the nucleus. Soon the nuclear membrane disappears, chromosomes and spindle are formed, and the first cleavage begins. In this type of fertilization the two nuclei are of unequal size, the sperm nucleus being much the smaller.

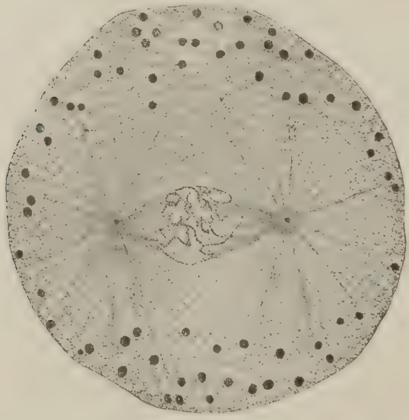

Fig. 2794.—Thalassema. The first cleavage amphiaster. Germ nuclei completely fused, with the chromatin in the spireme stage. (After Griffin.)

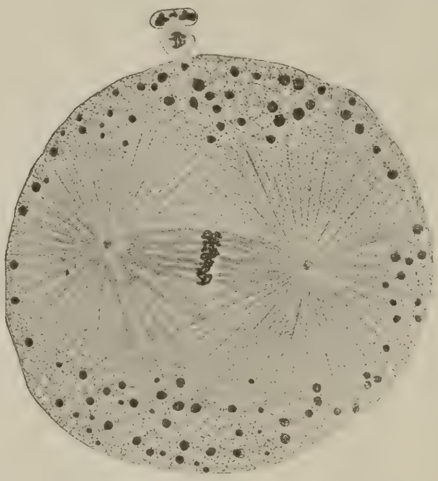

Fig. 2795.—The Same. First cleavage spindle in the late prophase. Chromosomes forming at the equator. The centrosomes have begun to divide preparatory to the second cleavage. This section passes through the plane of the two polar bodies, which are seen at the upper pole of the egg. (After Griffin.)

The second type is seen in the eggs of flat worms, annelids, and mollusks (Fig. 2790, *A*, *B*, *C*). In these groups the whole process of maturation of the egg takes place after the entrance of the spermatozoon, that act being apparently the stimulus necessary to set the process in motion. While the two polar bodies are being formed, the sperm nucleus advances to the centre of the egg and becomes greatly enlarged, and at the same time the sperm

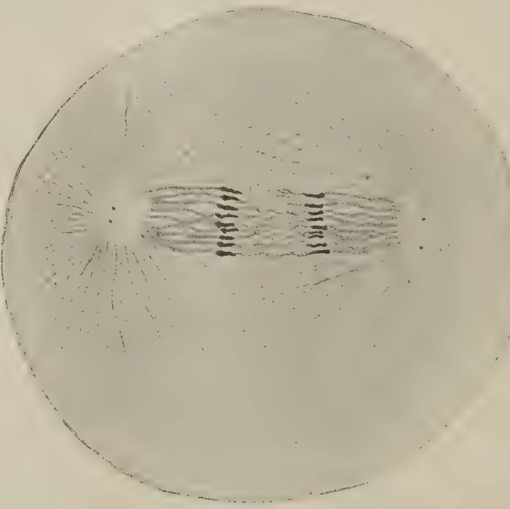

Fig. 2796.—The Same. Cleavage spindle in the anaphase. The chromosomes have divided and are separating to opposite poles. (After Griffin.)

aster divides to form an amphiaster (Fig. 2791). At the completion of the second polar division the egg nucleus is reformed and moves toward the sperm nucleus (Fig. 2792). As a rule the egg aster and centrosome disappear. Finally the two nuclei, now of equal size, lie side by side, but without fusing, with the two asters derived from the sperm aster lying in the plane between them (Fig. 2793). Soon after this the chromosomes reappear in each nucleus, the nuclear membrane fades away, and the first cleavage spindle is formed as before (Figs. 2794, 2795, and 2796).

Between these two types there are various intermediate forms in which the entrance of the spermatozoon occurs either after the extrusion of the first polar body or during some other phase of the process of maturation.

The account given in the preceding paragraphs should be taken as merely a general statement of the main facts of fertilization. The details of the process vary to a greater or less degree in different species. In the slipper shell, Crepidula, for example, the protoplasm flows toward the upper pole of the egg, while the yolk becomes more concentrated in the lower part. This is true probably, more or less, in all eggs that divide unequally. In such cases the union of the germ nuclei takes place near the centre of the protoplasmic mass.

In the first type of fertilization it is impossible to trace the history of the chromosomes of the cleavage nucleus. But in many cases of the second type it is possible to do this very clearly. The eggs of Ascaris are known to be especially favorable objects as the result of the brilliant researches of Boveri, Van Beneden, and Herla. In such cases it has been shown beyond a doubt that of the chromosomes in the cleavage spindle, one-half are derived from the egg nucleus of maternal origin and the other half are in like manner derived from the sperm nucleus of paternal origin (Fig. 2797). Now during the mitosis preparatory to the first cleavage, each chromosome is divided into two and the halves separate to opposite poles of the spindle, so that each daughter nucleus receives an equal number of chromosomes of maternal and of paternal origin (Fig. 2796). The same thing occurs in all subsequent mitoses. Therefore if the chromosomes maintain their individuality during the resting stage, as there is reason to suppose they do (see *Chromosome*), each somatic cell is provided with chromatin derived in equal measure from the two parents. This is a fact of the greatest importance for our theory of heredity (see *Heredity*).

The origin and fate of the centrosomes of the cleavage spindle have been fruitful of much discussion, and the results of investigation are still somewhat contradictory. The majority of observers are agreed now that the centrosome accompanying the egg nucleus after the separation of the second polar body usually disintegrates and disappears before the union of the two nuclei (as seen in Fig. 2792). But Conklin maintains that in Crepidula this centrosome persists, unites with the sperm centrosome, and that the product of this union divides to form the centrosomes of the first cleavage amphiaster. If true, this is certainly exceptional. The sperm centrosome which appears near the sperm nucleus soon after the entrance of the spermatozoon appears to be derived from the middle piece, which in turn was formed from the centrosome of the spermatid (see *Spermatozoon*). At any rate, it appears in the position of the middle piece, or near it. But because of its minute size it cannot, as a rule, be supposed to represent more than a part of the middle piece. Some observers have asserted that it is a new structure that arises in the cytoplasm of the egg as a result of a stimulus from the spermatozoon, with which it has no morphological connection. But the view that it is derived from the middle piece seems to agree best with the observations in most cases. The fate of this centrosome is also a matter of doubt. At least in most cases it has been impossible to show conclusively that this centrosome gives rise to the centrosomes of the cleavage amphiaster. It may disintegrate, and a new centrosome may arise in the cytoplasm close by the united nuclei. But Griffin has asserted positively that in the gepherian worm, Thalassema, he has been able to trace the history of the sperm centrosome continuously to the formation of the cleavage amphiaster. The centrosomes of this amphiaster pass one into each daughter cell during cleavage, and frequently each one divides into two before the first cleavage is complete, in anticipation of the second cleavage (Fig. 2796). This process is continued during subsequent cleavages; so it appears that the centrosomes of the first cleavage amphiaster give rise by division to the centrosomes of all the cells of the embryo, at least for a number of cell generations.

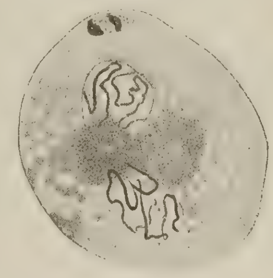

FIG. 2797.—Fertilized Egg of *Ascaris megalocephala* var. *bivalens* just previous to the formation of the cleavage spindle. Two elongated chromosomes have appeared in each germ nucleus. The two large centrosomes are surrounded by extensive masses of granular archoplasm, and the second polar body is visible in the upper part of the section. Highly magnified. (After Boveri.)

As to the function of the centrosome, Boveri maintains that it is a permanent cell organ and that it is the dynamical centre of the cell. The egg centrosome having been absorbed, he regards the sperm centrosome as the especial fertilizing agent introduced into the egg by the spermatozoon. That is, while the sperm nucleus introduces the physical basis for heredity of the paternal characteristics, it is the centrosome that furnishes the stimulus necessary to start the segmentation of the egg and development of the embryo. Boveri finds evidence for this view in certain abnormal phenomena called partial fertilization. He observed that in sea urchin eggs it sometimes happens that the sperm centrosome gets so far ahead of the sperm nucleus that it conjugates with the egg nucleus and causes the egg to divide before the union of the two nuclei. The sperm nucleus, however, subsequently unites with one of the nuclei of maternal origin in the two-cell stage.

Of great interest in this connection are the observations of Hertwig, Morgan, Loeb, and Wilson upon the production of artificial parthenogenesis in unfertilized eggs. Hertwig, using solutions of strychnine, and Morgan, using chiefly solutions of sodium and magnesium chlorides, found that unfertilized echinoderm eggs when treated with these substances might undergo cleavage; and Morgan discovered, moreover, that as a result of this treatment there might appear in the cytoplasm of the egg a large number of asters, each having at its centre an accumulation of material like a centrosome. This last observation would seem to raise a serious objection to the idea that the centrosome is a peculiar and permanent cell organ. Loeb subsequently made the remarkable discovery that by careful treatment with various inorganic salts, and even with sugar and urea, unfertilized eggs of two species of echinoderms and of one annelid could be induced, not only to segment, but to give rise to swimming larvæ. These results have been fully confirmed by Wilson, who has shown that in the case of the sea urchin, Toxopneustes, the eggs, which begin development under the influence of a twelve-per-cent. solution of $MgCl_2$ without fertilization, do not develop a vitelline membrane and contain only the number of chromosomes normally present in the egg nucleus. So there can be no question of accidental fertilization. Wilson has worked out the cytological changes occurring in such eggs. He finds much variation and many abnormalities, which result in the death of the embryo. Where nearly normal development takes place, he finds that always a *new* centrosome with its surrounding aster forms close to one side of the nucleus. It then divides, the two halves passing to opposite poles of the nucleus to form an amphiaster, and then cleavage proceeds very much as usual. If the primary centrosome fails to divide, it may go through certain periodic changes, increasing and decreasing in size, and these changes are accompanied by division of chromosomes in the nucleus, but no cell division takes place. The cleavage of the egg then appears to depend upon the normal behavior of a centrosome closely associated with the nucleus, but this centrosome may be caused to arise *de novo* by appropriate chemical stimuli. It, however, acts much more slowly than the centrosome introduced with the spermatozoon. But the centrosome is not capable of producing cleavage of the cytoplasm unless accompanied by a nucleus. For example, Wilson has found that asters containing centrosomes may be produced by chemical stimulus in enucleated fragments of eggs obtained by shaking unfertilized eggs to pieces. Such asters may multiply by division, but the cytoplasm does not divide. And Boveri has observed that sometimes during cleavage of fertilized eggs all of the chromatin will go to one daughter cell, the other receiving only an aster. In such a case the aster in the enucleated cell will continue to divide, but the cell will not.

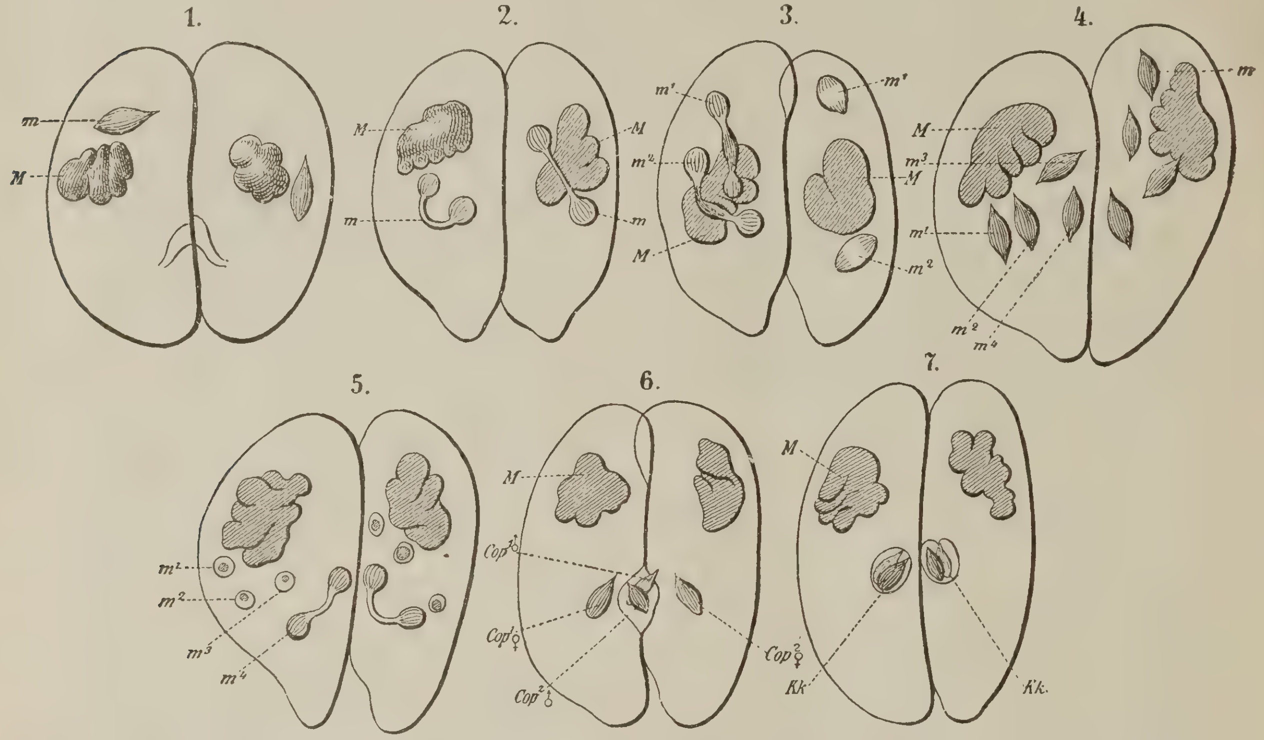

FIG. 2798.—The Conjugation of Infusoria. (From Weismann, after Maupas.) 1, Two infusoria copulating; *M*, meganucleus; *m*, micronucleus; 2–5, successive divisions of micronuclei; 6, fertilization by the migration of one of the persisting micronuclei from each infusorian into the other; 7, union of the interchanged micronuclei.

Hertwig, Boveri, and others have found that if enucleated fragments of unfertilized eggs be mixed with spermatozoa of the same or closely related species, the spermatozoa will enter the fragments, the nucleus will undergo regular mitotic division, the cytoplasm will divide, and larvæ will be produced that are indistinguishable from normally produced larvæ, except for their smaller size. The sperm nucleus is, then, perfectly equivalent to the egg nucleus and only needs to be supplied with the necessary envelope of cytoplasm in order to undergo the same series of changes; and under certain conditions the normal cycle of life may be inaugurated by either the sperm or the egg nucleus without union with the other, even in species in which normal parthenogenesis is unknown.

The process of fertilization in plants has not been studied so extensively as in animals. But enough has been learned to show that, so far as the nucleus is concerned, the process is essentially the same. In the sexual reproduction of all plants that have been examined, it has been found that fertilization is effected by the union of a single germ nucleus of paternal origin with the egg nucleus. This was described for the first time by Strasburger in 1884, and his results have been confirmed by Guignard and a number of other investigators in a variety of plants of various orders. In some plants the paternal gamete is an actively motile spermatozoid, in others it is an immobile cell that reaches the egg cell by a process of growth, as is the case with the pollen tube of the higher plants. But in all essential features the process is the same in both cases.

Although Guignard, in 1891, described with much detail a conjugation of centrosomes in connection with fertilization in the lily, his results have not been confirmed; and most observers have failed to find any evidence of a centrosome in any way connected with either of the conjugating nuclei of plants. This would seem to indicate that the presence of a centrosome is not essential to fertilization. But Strasburger has found that a centrosome appears in Fucus on the side of the cleavage nucleus that is derived from the sperm nucleus, and Wilson approves of his suggestion that in plants "the sperm nucleus may import into the egg either a formed centrosome (probably thus in Fucus) or a certain quantity of 'kinoplasm' which excites the mitotic phenomena in the absence of individualized centrosomes."

The pollen tube of angiosperms contains two sperm nuclei, of which only one unites with the egg nucleus. In 1898 Nawaschin published the interesting discovery that in *Lilium martagon* and *Fritillaria tenella* the other sperm nucleus conjugates with the two "polar nuclei" to form the embryo sac nucleus, the division of which gives rise to the endosperm of the seed. The same phenomenon was described more in detail by Guignard in 1899, and confirmed by Miss Sargent. It immediately occurred to De Vries, and independently to Webber, that this might explain a phenomenon called *xenia* by Focke (1881). For a long time it has been known that if the pollen of one variety of maize be allowed to fall upon the silk of a different variety, the kernels in the ear may show the characters of the male parent. Until this process of double fertilization was discovered, the embryo was the only part known to have a double origin, and the appearance of the paternal characters in a part of the seed supposed to be purely of maternal origin seemed very mysterious.

From a careful study of the phenomena of xenia in maize, in which the only undoubted cases occur, Webber has reached the conclusion that they are perfectly consistent with the theory of double fertilization, no xenia appearing in characters not connected with the endosperm. But the actual double fertilization has not yet been observed in this plant.

Xenia has been supposed to be a similar phenomenon to *telegony* in animals. But it seems impossible for any such process of double fertilization to occur in animals, and Ewart has found that in the mare "the spermatozoa lodged in the upper dilated part of the oviduct are dead, and in process of disintegrating, eight days after insemination." Moreover, the supposed existence of telegony has been entirely discredited by Ewart on experimental evidence, and by Pearson on evidence from statistics.

In the conjugation of the unicellular animals and plants, we find a process clearly analogous to the fertilization of the higher groups. The two conjugating cells may be similar or diverse in form. In many motile Infusoria (Fig. 2798) two similar individuals come together, exchange nuclei, each one giving off a "male pronucleus," which enters the body of the other and unites with its "female pronucleus," and then the two separate. In other cases there is a motile "microgamete" that forms a permanent union with a sessile "macrogamete," comparable to spermatozoon and egg respectively. In each case the essential feature of the process is a union of two equivalent nuclei, preceded and followed by a complicated series of divisions that we need not discuss here.

Summing up the subject of fertilization, Wilson says ("The Cell," ed. 2, p. 230): "We thus find the essential fact of fertilization and sexual reproduction to be a union of equivalent nuclei; and to this all other processes are tributary." The almost universal occurrence of this process in animals and plants of all grades, from the protozoa to man, indicates that it has some profound significance, but what this is is unknown. According to Weismann, fertilization has for its object the mingling of ancestral germ plasms and the consequent production of variability in the offspring. But Pearson, as the result of statistical investigations, holds that variability is not produced by fertilization. According to Maupas, fertilization has for its object a rejuvenescence of protoplasm, which thus wards off the senescence and "natural death" that must inevitably overtake it if fertilization does not take place; and Minot finds evidence for this view in the results of his investigations of the law of growth (see *Growth*). But when we consider the innumerable generations of domestic plants that have been produced with unimpaired vigor by cuttings, grafts, and other purely asexual methods of reproduction, the existence of any such "natural death" appears to be extremely doubtful. So while our knowledge of the details of fertilization has advanced enormously during the past quarter century, the origin and object of the process remain as mysterious as ever.

INCOMPATIBILITY, MEDICINAL.—The word *incompatible*, used in connection with the mutual relations of medicines, is one of very loose application. Thus, in a sweeping way, a medicine is said to be *chemically* "incompatible" with anything that will produce a chemical or physical change in its condition, and *physiologically* "incompatible" with anything that produces the reverse of its so-called physiological effects. Under these definitions, however, it is evident that in many cases so-called "incompatibility" may yet not interfere at all with full medicinal power or purpose. Practically, the subject of medicinal incompatibility deals with those chemical, physical, and physiological mutual relations of medicines that require consideration in the prescription of different medicinal substances in conjunction, and such topic it is that will here be considered.

As regards *chemical* and *physical* reactions there are many which are special, between special medicines. Such must be learned in connection with the individual medicines concerned. But, also, there are certain reactions that affect broad categories of medicines, and which, therefore, admit of general consideration. Such reactions and the practical bearings thereof in prescribing are as follows:

1. *Acids and bases tend directly to combine, to form salts.* This reaction may be utilized, if it be the object of the prescriber to obtain the salt that will result from the bringing together of an acid and base; but if the purpose of the prescription be to retain free acidity or alkalinity, acids and bases must not be conjoined in prescription.

2. *Stronger acids or bases tend to displace, in the case of salts in solution, weaker bodies of their own respective kinds.* Thus, if sodium carbonate in solution be treated with nitric acid, the nitric acid will displace the carbonic to the formation of sodium nitrate in solution and the evolution of carbon-dioxide gas. Strictly speaking, the statement of this reaction is a *circulus in definiendo*, since one acid is known to be "stronger" than another only by

the fact of its supplanting such other acid in saline combination, in solution. The statement, however, is a convenient reminder, to the prescriber, of a set of reactions which are of common occurrence, and whose bearing upon prescribing is as important as it is obvious.

3. *Salts in solution tend to exchange radicals; or acids, or bases, to displace their respective brethren in saline combination, if thereby an insoluble compound will form.* If, as the cant phrase runs, nature "abhors a vacuum," she also *delights in precipitates;* for reactions, determined evidently by the fact that a precipitate will result, are among the commonest occurrences of chemistry. Concerning this reaction it is to be noted that while precipitation may affect potency profoundly in the case of some medicines, in other cases it may make no difference or may be of distinct advantage. Thus in the case of the so-called black and yellow washes of mercury, it is a precipitate which is wanted, and which therefore is intentionally the subject of prescription. Generally, however, the occurrence of a precipitate in a medicinal mixture is objectionable; for, even if medicinal virtue be not affected, the turbidity is unsightly, and, by the settling of the precipitate as the bottle stands, doses drawn, on the one hand, from the full or, on the other, from the nearly empty vial will vary enormously in strength of the precipitated ingredient, unless the bottle be thoroughly shaken at the taking of each dose. The table of *notable* mutually precipitant solutions, taken from the writer's "Manual of Medicinal Technology" (see at the foot of page 853), is convenient for reference. The reactions therein broadly stated as occurring with solutions of salts of the *alkaloids*, and of the *metals*, are true in the *generality* of instances only.

4. *Things in solution precipitate on addition of an excess of a fluid in which they are respectively insoluble.* Here, as in the former instance, precipitation may not affect medicinal potency, but yet is generally to be avoided because of the intrinsic objections to precipitates in medicinal mixtures, as set forth above. The two medicinal solvents most concerned in the present relation are *water* and *alcohol*, and the commonest instances of the reaction in question are as follows: *albuminous, gelatinous, gummy, saccharine*, and certain *saline* bodies dissolve in water but are insoluble in alcohol, and accordingly precipitate on addition of an excess of alcohol to their aqueous solution; while, *vice versa, alcoholic* solutions of *volatile oils, balsams, camphor*, and *resins* precipitate on treatment with excess of water.

5. *Powerfully oxidizing agents may determine explosions on concentrated admixture with readily oxidizable substances.* The exact conditions determining explosions with individual mixtures of this category will vary with the substances concerned, and must accordingly be learned with each medicine. All that is appropriate to state in this place is that the powerful oxidizers used in medicine are *chromic* and strong *nitric* or *nitrohydrochloric acids, potassium chlorate*, and *potassium permanganate;* while the medicinal substances of easy combustibility are *oils, alcohols*, and *ethers* (including in the latter categories *glycerin* and *sugars*, bodies chemically belonging to the alcohols), dry *organic* substances generally, and the elementary bodies, *sulphur* and *phosphorus*.

Physiological incompatibility, as already stated, is alleged between medicines whose respective so-called "physiological" effects are mutually antagonistic. Such antagonisms are individual and peculiar, and are best discussed in connection with the individual medicines concerned. Two points alone are proper subject for mention in this place. The first is that *exact* antagonism in *all directions* of physiological action of drugs is very rare, and the second, that in practical prescribing the fact of an antagonism need not preclude the proper conjunction of two antagonistic medicines in the same mixture. On the contrary, many of the happiest of medicinal combinations are of remedies more or less antagonistic in operation; this either because the antagonism is itself serviceable in mellowing a too intense action of the dominant antagonist, or because the drugs, though antagonistic in some lines, are synergic in others, and so together yield a resultant effect better for certain remedial purposes than the unmodified effect of either medicine used singly. An example of the former instance is the common combination of castor oil and laudanum; and of the latter, the association of atropine with morphine.

INDIAN MINERAL SPRINGS.—Kendall County, Texas.

Post-Office.—Boerne. Boarding-houses.

The town of Boerne is located about thirty miles northwest of the city of San Antonio, on the line of the San Antonio and Arransas Pass Railroad. The country has a general elevation of about 1,670 feet above the sea. The general aspect of the country is very pleasing, being quite hilly, even rugged in places. There are many beautiful drives and fine views. The town of Boerne has a population of about 800. It contains a telegraph and express office, very good hotels and boarding-houses. Four trains daily reach the place. From data furnished by the National Climatological Reports it is found that the average number of sunny days in each year is 277, and that invalids can enjoy more or less outdoor life 350 days yearly. The average summer temperature of the place is 85° F.; winter temperature, 62° F. It is said that a cooling southeast breeze from the gulf prevails all the year and greatly tempers the heat of the summer sun, making the evenings and nights cool and pleasant. The location is beginning to attract the attention of Northern visitors, who visit the place in constantly increasing numbers during the winter months. The Indian Mineral Spring is located three miles from Boerne, from which it is reached by stage and private conveyances. The water is said to be efficacious in a variety of debilitated states, besides being a valuable table water. A partial examination was made by Prof. Charles F. Chandler, of New York. It showed the presence of 138.38 grains of solids per United States gallon, consisting principally of calcium, magnesium, and sulphuric acid in the form of sulphates. A more detailed analysis will be required to classify the water properly. *James K. Crook.*

INDIAN SPRINGS, BUTTS COUNTY, GEORGIA.—

Post-Office.—Indian Springs. Several hotels in village.

Access.—Viâ Macon and Western Railroad to Forsyth, thence by stage line to spring. This celebrated spring received its name on account of its great reputation as a medicine spring among the Indians. In the treaty of 1821, when all this portion of Georgia was ceded to the whites, a special reservation of one-thousand acres, including Indian Spring, was made by the Creek nation. This, however, was given up to the whites a few years later. In 1823 General McIntosh erected a small hotel, which is still used for its original purpose (Duggan). A village of three hundred or more inhabitants has sprung up in the neighborhood. The following analysis was made by Prof. A. A. Hayes a number of years ago:

One United States gallon contains 648.03 grains of solid matter consisting chiefly of the following ingredients.

Magnesium sulphate.
Magnesium carbonate.
Calcium sulphate.
Potassium sulphate.

Gases { Carbonic acid .... 2.61 cubic inches per gallon.
Gases { Hydrogen sulphide...... 1.05 " "

The water contains an exceedingly large amount of sulphate of magnesia or Epsom salts. When to this is added the considerable quantity of other sulphates we have a very valuable mineral water. There is sufficient calcium sulphate to exert a useful influence in diseases of the urinary apparatus and also to modify the purgative effects of the sulphate of magnesia. Among the numerous affections in which the water has been found useful may be mentioned dropsical affections when not due to heart disease, rheumatism, and tertiary syphilis.

James K. Crook.

INDIAN SPRINGS, MARTIN COUNTY, INDIANA.—Post-Office.—Indian Springs. Hotel for 500 guests. Hacks meet all trains during the season. The resort is located eight miles north of Shoals, the county seat of Martin County.

The therapeutic value of the waters of these springs has been known for years, and they were in great repute among the aborigines. The springs were first opened to the public as a health resort in 1814, and they have maintained their reputation ever since. They have their source along the course of Sulphur Creek, which wends its way through the surrounding valley and empties into the Indian Creek one mile distant from the hotel. The surrounding country is hilly and quite picturesque. The following analysis was made by Prof. E. T. Cox, State Geologist:

One United States Gallon Contains:

Solids.	Grains.
Sodium carbonate	3.65
Magnesium carbonate	18.95
Calcium carbonate	33.10
Potassium carbonate	2.40
Sodium sulphate	11.83
Potassium sulphate	2.40
Magnesium sulphate	30.40
Aluminum sulphate	.82
Iron sulphate	20.23
Sodium chloride	39.38
Magnesium chloride	.06
Bromides	Trace.
Iodides	Trace.
Iron oxide	Trace.
Silica	.45
Total	163.67
Gases.	**Cu. in.**
Carbonic acid	9.58
Sulphureted hydrogen	3.33
Oxygen	3.95
Nitrogen	6.45

This water is a powerful chalybeate, also a fairly strong alkaline-saline water. *James K. Crook.*

INDIANA MINERAL SPRINGS AND MUD BATHS.—Warren County, Indiana.

Post-Office.—Indiana Mineral Springs. Hotel. This new resort is located four miles from Attica, at the junction of the Wabash and the Chicago and Eastern Illinois railroads. Stages from the springs meet all trains. Although but recently improved, this resort is rapidly coming into popular favor. A first-class hotel, with all modern improvements, has been constructed, and an elegant and commodious bath-house is ready for the requirements of visitors. The naturally picturesque location has already been much beautified by the landscape gardener and architect. The water of the springs is said to be pure and sparkling and pleasant to the palate. A recent qualitative analysis (May, 1893) under the direction of the manufacturing chemists, Messrs. Parke, Davis & Co., Detroit, showed the following ingredients: Total solid residue from one gallon, 20.21 grains, made up of the salts of magnesium, sodium, lithium, calcium, potassium, and silicon. The chemist also reports the presence of sulphuric and hydrochloric acids (probably in combination). There was no organic matter, and the water was highly carbonated. A special feature of the place is a deposit of inky black mud surrounding the springs, and said to be strongly impregnated with the mineral ingredients of the water. This mud is warmed to the proper degree and applied by an attendant to the affected parts—the whole body, if required—in the form of a poultice. About one hour is required for a mud bath, when the patient passes under a shower bath and remains until all traces of the mud are removed. He is then placed in a porcelain-lined tub filled with lithia water for a soaking; then comes a refreshing rubbing by the attendant, and the bath for the day is ended. These baths are said to be very beneficial in cases of obstinate rheumatism, in hemiplegia, and in eczema and gout. The internal use of the water is indicated in renal and bladder affections.

James K. Crook.

INDIANAPOLIS, INDIANA.—The largest city and capital of Indiana is situated near the centre of the State, 195 miles southeast of Chicago. An index of its climate is here given for the sake of reference and comparison.

Climate of Indianapolis, Ind.—Latitude, 39° 46′; Longitude, 86° 10′. Period of Observation, Eleven Years Nine Months.

	January.	March.	May.	August.	November.	Year.
Temperature—						
Average or normal	20.9°	40.3°	64.3°	74.3°	40.7°	53.2°
Average range	15.1	16.3	18.9	18.4	14.0	
Mean of warmest	36.5	49.9	73.8	82.9	49.1	
Mean of coldest	21.4	33.6	54.9	64.5	35.1	
Highest or maximum	69.0	77.0	89.0	101.0	75.0	
Lowest or minimum	−22.0	9.0	31.0	48.0	− 5.0	
Humidity—						
Average relative	73.6%	67.0%	60.3%	68.5%	69.9%	67.7%
Wind—						
Prevailing direction	W.	N. W.	S. E.	S.	N. W.	N. W.
Average hourly velocity in miles	6.4	7.3	5.7	4.5	5.8	5.7
Weather—						
Average number clear days	5.3	6.5	9.5	11.0	6.1	94.8
Average number fair days	10.5	10.6	12.5	14.1	10.2	142.4
Average number clear and fair days	15.8	17.1	22.0	25.1	16.3	237.2

As will be seen, it is a temperate climate, with considerable seasonal extremes and diurnal fluctuations of temperature. The humidity is not high, and the rainfall is moderate. More than a quarter of the days in the year are clear, more than a third fair, and about two-thirds clear and fair.

Such a climate is well-situated for a residence for those in ordinary health. For the delicate or sick, a change might be advised to escape the cold of the winter and the heat of the summer, and in order to obtain purer air than a city affords. As the elevation is low, a change also to a high altitude might be beneficial for various morbid conditions. *Edward O. Otis.*

INDIGO, WILD.—Baptisia. *Dyers' Green Weed.* Under these names, the herb, and more particularly the root, of *Baptisia tinctoria* (L.) R. Br. (fam. *Leguminosæ*) has been more or less used in domestic, and to a slight extent in professional medicine. Its common names come from the fact that it has been used as a poor substitute for indigo.

The plant is a large, much-branched perennial herb, very abundant in sandy soil, especially in the borders of woods, throughout the Eastern United States. It is said to contain two glucosides, *baptin* and *baptisin*, and the poisonous alkaloid *baptitoxine*, which is believed to be identical with *cytisine*. According to the dose, the properties vary from stimulant, increasing peristalsis and acting as a laxative, to irritant, producing purging and vomiting. Upon the nerve centres, it is primarily stimulant, secondarily depressant or paralyzant, and causing death by paralysis of respiration. Its use has been chiefly, both systemically and locally, in diphtheria, scarlet fever, and sore throat. The dose of the fluid extract is 1 to 4 c.c. (♏ xv. to lx.). *Henry H. Rusby.*

INEBRIETY. See *Insanity: Alcoholic and Drug Intoxication and Habituation.*

INFANCY.—Under the term *infancy* (inability to speak) we include that early period of life which extends from birth to the close of the first dentition. Its first few weeks represent a period of great feebleness during which there exists a liability to special forms of disease consequent upon the great change which takes place in the circulation at birth, and upon the assumption by the several organs of their special work in the economy. To the infant at this period the name of "the new-born" (neonatus) is frequently applied. From the end of the first month to the close of lactation between the ninth and twelfth months is sometimes referred to as the period of early infancy and corresponds to the term "Säuglingsalter" of German writers.

Compared with childhood and adult life, infancy is characterized by rapid growth and development. It is a period specially liable to disease, some of the manifestations of which are peculiar to it; others, though similar to what we meet with in adult life, are more or less modified by the peculiarities of the infant constitution. Its mortality is much greater than that of adult life.

Anatomical and Physiological Characteristics.—The first act of the new-born is to inspire. With the separation of the placenta from the maternal connection and the tying of the cord, the whole circulation of the infant is profoundly altered; for the first time a full current of blood distends the pulmonary arteries to meet air in the newly opened vesicles of the expanding lungs. The thorax is enlarged and the diaphragm and abdominal viscera are depressed, all conspiring to favor the associated changes which take place in the heart. With the sudden deflection of blood to the pulmonary circulation and the greatly increased intrathoracic pressure, the flow of blood through the foramen ovale and the ductus arteriosus comes almost to a standstill, and both these passages become gradually obliterated. Within thirty-six hours Vogel found the ductus arteriosus scarcely large enough to admit a probe; the foramen ovale closes more slowly, the border of the valve usually remaining free for some months, but the foramen is so completely covered that no detriment to the circulation ensues. The left ventricle now takes on the burden of the systemic circulation, rapidly increasing in muscular power so that at the end of the second year its walls are double the thickness of those of the right side.

With the establishment of respiration the livid hue of the skin, due to the interference by parturition with the fœtal circulation, is rapidly exchanged for the deep red of the new-born infant. This hue fades in a few days and the skin not infrequently then assumes a more or less yellow tinge unaccompanied by any symptoms of systemic disorder. This condition is known as *icterus neonatorum;* its true cause is still uncertain, but it is supposed to be associated with the disturbance of the hepatic circulation due to the alteration in its blood supply. This yellow tinge gradually disappears of itself, and by the third week of life the skin assumes the rosy tint of healthy infancy. The fine soft hairs which at birth frequently cover almost the whole body generally fall out by this time and are not renewed, though feeble infants may retain them for some time. The long strong hairs on the scalp with which many infants are born fall out at a later period and are generally replaced by finer and, as a rule, lighter-colored hair. At birth the lachrymal and sudoriferous glands are inactive. It is almost impossible to produce sensible perspiration in an infant a few weeks old; not until after the third month does the activity of the sweat glands commence, but after this age in rachitic infants, perspiration is often very profuse. The sebaceous glands, on the other hand, are very active in the new-born. In the third month the secretion of those in the scalp frequently gives the vertex the appearance of having been smeared with wax, and later on forms a distinct crust of a yellowish-brown color (seborrhœa capillitii) portions of which can be easily removed by the finger nail, when the subjacent skin will be found in a healthy state, not even congested. This excessive secretion ceases spontaneously about the end of the first year, and the scabs, if still remaining, dry and crumble away.

Fat is abundant in the subcutaneous tissues of the healthy infant but is generally absent from the interior of the body. The muscles in the first months are small and soft; not till after the sixth month can they be felt firm and resisting. The bones are still in great part cartilaginous and possess, therefore, much greater flexibility than in the adult.

With the introduction of air the compact tissue of the fœtal lung is converted into a spongy alveolar structure of a rose-pink color and expands so as to cover in great part the pericardium and to come into contact with almost the whole extent of the thoracic wall. The approximation anteriorly of the two pleural cavities, however, is not so close as it becomes in later life, the anterior aspect of the heart and thymus gland remaining comparatively uncovered. The thymus gland, situated partly in the thorax and partly in the lower region of the neck, is in the new-born of large size and increases till about the close of the second year when it ceases to develop; it presents much variation, however, in size and shape. After the eighth year it rapidly decreases in size. Its functions have not yet been ascertained, but it would appear to be connected with the formation of the blood cells. The thyroid gland in the infant is relatively larger than in the adult.

The liver at birth is large and its lower margin is easily felt from 1 to 2 cm. below the ribs. The stomach occupies a more vertical position than in the adult owing to the slight development of its fundus. Its capacity at birth is somewhat less than one ounce.

In the infant the shape of the duodenum is not unlike its form in adult life; its folds are less developed, and more than in the adult does it act as a digestive reservoir where the food from the stomach is mingled with the secretions of the liver and the pancreas. Below the duodenum the several portions of the intestines show considerable difference in their relative lengths as compared with those which they attain in the adult. Both small and large intestines are relatively long; Treves states that the average length of the small intestine at birth is nine feet five inches and of the large, one foot ten inches, and says there is remarkably little deviation from these figures. He estimates that the small intestine grows about two feet per month for the first few months, but after this period development proceeds irregularly, depending upon the nature of the food, the vigor of the digestive process, and the activity of the abdominal nervous centres; it bears no relation to the general growth of the body nor to the weight of the child. The position of both small and large bowel is much less fixed than in the adult; the upper part of the small bowel may frequently be found occupying the lower part of the right iliac fossa, and the caput coli may be found near the umbilicus from which position the colon ascends toward the left hypochondrium. Both ascending and transverse colons are generally very short, while the descending colon and sigmoid flexure are of great comparative length. For the first four months the growth of the large bowel is relatively slight, but a certain amount of readjustment of its position appears to take place by which the ascending and transverse portions increase at the expense of the sigmoid flexure. After the age of four months, however, growth generally goes on steadily. Occasionally this undue length of the sigmoid flexure persists during infancy, seriously impeding the passage of the fæces and leading to constipation.

At birth the kidneys are of comparatively large size and distinctly lobulated. This peculiarity in form gradually passes away, and by the close of infancy they have the same shape as in adult life, though still relatively large. Anomalies are occasionally found. The suprarenals at birth are as large as in the adult. The bladder in the new-born has a capacity of from two to four drachms and lies partly in the pelvis, and partly above it in the abdominal cavity. Renal secretion commences early, and at birth urine is normally present in the bladder and should be voided during the first twelve hours of life. During the first few weeks of life crystals of uric acid and urates, occasionally hyaline casts and epithelial cells with a minute amount of albumin, may be found in the urine, a result of the prenatal condition known as uric-acid infarction. During infancy the urine is of a light color, low specific gravity (1.004–1.010), faintly acid in reaction, and contains a low percentage of urea and of the inorganic salts. The amount of urine passed for the first few days is very variable and has been estimated at from two to three ounces, increasing in the second week to five or ten ounces. Throughout infancy the amount of urine passed is relatively larger than in adult life, but is dependent partly upon the amount of liquid taken by the infant; micturition is very frequent.

The urethra in the male is 6 cm. long, delicate and distensible and generally presents a marked constriction at the meatus. The glans penis is closely invested by the prepuce; cohesion is frequently very firm between the membrane covering the glans and that covering the prepuce. Congenital deformities due to arrested development are not infrequent. In the female infant the urethra and vagina are relatively large and distensible; the uterus is from an inch to an inch and a quarter long, but its fundus is quite undeveloped. Deformities occasionally arise from the non-absorption of the septum formed by the infolding of the cloaca. The mammary gland is well developed, possessing secreting structure in both sexes.

Although the brain of the new-born is of relatively large size, the anterior lobes and the cerebellum are comparatively small, and the fissure of Rolando is much less vertical than in later life. The brain tissue is of a nearly uniform whitish color and of soft pulpy consistence, and contains a large percentage of water. Not till after the close of the first month does gray matter make its appearance on the convolutions. The centres in the medulla and in the spinal cord are in a much more forward state of development than those in the cerebrum, and throughout infancy maintain their functional superiority; of those in the spinal cord the motor centres in the anterior cornua are more developed than those of sensation in the posterior; to this forward state of development of the spinal centres is due the great reflex excitability of the nervous system in infants. So much is this the case that the infant at birth has been termed "a spinal system man."

Circulation.—The blood of the new-born contains a large amount of hæmoglobin, twenty-two per cent. of its solid constituents, but the amount of fibrin is small and the total amount of blood in the body is less than it is in the adult; for this reason infants bear loss of blood badly. The blood cells also for the first few weeks show much variation in size and shape. These conditions, however, soon change; the amount of hæmoglobin at once begins to decrease, reaching its minimum about the sixth month when it remains stationary until after the first year and then begins to increase again; the fibrin rapidly increases in amount. After the first few months the infant has more blood in proportion to its weight than the adult, but the blood is of low specific gravity, has less fibrin, less salts, less hæmoglobin, less soluble albumin and more white blood corpuscles than that of more adult life.

Although at birth the heart as a whole is relatively larger than in the adult, it has to be remembered that in intra-uterine life the auricular half is unduly developed, and that after birth the walls of the left ventricle only slowly acquire that increase of power demanded by their newly assumed burden of the systemic circulation. The arterial system of the infant has also a large relative capacity as compared with the size of the heart, which, associated with a comparatively weak ventricle, renders arterial tension low. This condition persists in some degree till puberty, when it ceases owing to the rapid development of the heart at that age. It would appear that in the young growth and physiologically low blood pressure go hand-in-hand (Jacobi). It is also to be noted that the growth of the large arterial trunks in the infant is not uniform: the subclavian and carotid at birth are relatively large, corresponding with the greater development of the head and upper extremities; after birth the descending aorta and the femoral and renal arteries increase more rapidly in size, corresponding with the rapid growth of the lower extremities.

The pulse rate during infancy is much more rapid than during childhood or adult age, and is easily disturbed and quickened by slight causes; irregularity of rhythm may not infrequently be noted. A girl's pulse is almost always a few beats more rapid than that of a boy. The following table furnishes approximately the pulse rate at various periods:

TABLE SHOWING PULSE RATE AT DIFFERENT PERIODS OF INFANCY.

At birth	From	120-140
At six months	"	110-120
At twelve months	"	105-115
At two years	"	90-105
At five years	"	80-90

Muscular exercise or excitement will increase this rate by from twenty to fifty beats.

The lymphatic system in the infant is well developed; its glands are numerous and large in size, and the intercommunication between them and the general system is more marked than at any other period of life.

Respiration in the infant, as a consequence of the circular shape of the chest, is chiefly carried on by the diaphragm. Owing to the compressibility of the chest wall, to the lack of development in the respiratory muscles, and the yielding character of their points of origin and insertion, and also to the narrowness of the upper air passages, respiration is easily disturbed and in young infants may not infrequently be observed to be irregular. The rate and rhythm of the respiratory movement are very variable; Eustace Smith gives 40 or perhaps more as the number of respirations in the new-born, but adds that they soon become less rapid. Rotch places them at about 45 for the first weeks of life, and in infants under two years at between 20 and 40 per minute. The ratio between the rapidity of the respiration and that of the pulse for the first few months of life is inconstant and easily disturbed. During infancy more oxygen is inhaled and more carbonic dioxide exhaled than in adult life, as the result of the more rapid tissue change. Infants, however, stand complete deprivation of air for a longer period than will adults. Attention is drawn by Jacobi to the greater labor required by the organs of both circulation and respiration in the infant as compared with those of the adult, while at the same time their own development must go on. Hence fatigue is more easily experienced and rest and sleep are much more urgently demanded.

The Digestive Tract.—The mouth is early moistened by secretion from the buccal and labial glands, though in the first days of life often imperfectly so. Saliva is secreted at this date only by the parotid glands; its amount for the first two or three weeks is but one-tenth of what it becomes after the sixth month; not until after the fourth month do the submaxillary glands assume activity. Even in the first days of life, pepsin is secreted by the gastric follicles in small amount. For the first few weeks the stomach is small in size, somewhat tubular in shape, and plays a comparatively unimportant part in the process of digestion, acting chiefly as a receptacle in which the milk is coagulated by the rennet ferment, and from which it passes in a comparatively undigested state into the duodenum where digestion is completed by the pancreatic ferments. While in a breast-fed infant two months old the stomach empties itself in an hour and a half, in an infant four months old the average time is about two hours. Infants fed on cow's milk require half an hour longer. At birth the average capacity of the stomach is under an ounce; the organ, however, increases rapidly in size, and by the end of the fourth week its capacity in an infant of average size is about two and a half ounces, at three months four and a half ounces, at six months six ounces, and at twelve months nine ounces. In estimating the size of the stomach of an infant, not only is its age to be considered, but also its weight; the greater the weight of the infant the greater will be its gastric capacity. After the first six months of life the secretion of gastric juice becomes distinctly more abundant, but during the entire period of infancy free hydrochloric acid is either absent altogether or exists in only very small amounts in the contents of an infant's stomach. In the intestines the villi are numerous and large, even surpassing in size the corresponding structures in the adult, and contain large capillaries. The glands of Lieberkühn are present, but only in small numbers and they are poorly developed. The same is true of Peyer's glands, which do not reach their proper development till the second year of infancy. In a healthy infant the greater part of the food is absorbed from the small intestine. The mucous glands of both stomach and small intestine are more numerous in the infant than in later life, and if unduly stimulated pour forth a copious secretion which readily undergoes acid fermentation and becomes an irritant. The secretion of the pancreas is for the first few months very deficient; three of its ferments are present at birth, viz., trypsin, steapsin, and the milk-curdling ferment, but the amylolytic ferment is quite absent till after the sixth month. Bile is early secreted in considerable quantity, but compared with that of the adult it is defective in organic salts, in cholesterin, in lecithin, and in fat.

The fæces of an infant after the first few days should be of an orange-yellow color, of soft homogeneous consistence, distinctly acid in reaction and not offensive in odor. They are chiefly composed of fats, of fatty and lactic acids in combination with lime, of cholesterin, of intestinal epithelium and mucus, with about three per cent. of the milk ingested which has remained unabsorbed. Meconium is no longer considered to be simply an admixture of bile with intestinal mucus, but is found to contain flat epithelial cells which cannot have originated in the intestinal canal, along with fine hairs and fat globules which have evidently had a cutaneous origin.

GROWTH.—The average weight of the new-born babe is a little over seven pounds, males as a rule weighing a few ounces more than females, but occasionally this average is very much exceeded. During the first two or three days of life a loss in weight of from eight to twelve ounces almost invariably takes place, due partly to the passage of urine and meconium, partly to the disturbance of nutritive processes necessarily associated with its entrance on a new life, and partly to the fact that during these days the infant is not generally able to obtain sufficient nourishment. Townsend, at the Boston Lying-in Hospital, has shown that the infants of primiparæ lose more and are slower to recover their loss than those of multiparæ; large children, however, suffer less loss of weight and recover more quickly than small ones; children which have to be fed artificially do not as a rule regain their original weight before the tenth day. That the loss is to some extent avoidable is indicated by the fact that in the young of mammals which commence to take the dug immediately after birth, increase of weight is immediate and uninterrupted. Any failure of the infant fully to regain this loss by the end of the second week should be regarded as an indication that its nutrition is at fault and special measures should be taken to increase its vitality (Rotch). After the second week there should be a weekly gain in weight of from five to seven ounces for the first five months. After this age growth gradually becomes less rapid. It is generally considered that the initial weight of the infant at birth should be doubled at five months and trebled between thirteen and fourteen months of age. The weight at one year should be doubled at six years and this weight doubled again when the child reaches fourteen years. Weighed from day to day the amount of increase in an infant may be found to vary considerably, even a uniform weekly increase is exceptional. Slight disturbances such as dentition, weaning, improper feeding, or undue excitement may interfere with or even interrupt the regular increment. The weight of an infant carefully and systematically taken is to be regarded as an excellent index of the infant's nutrition, and our most exact guide in determining the suitability and sufficiency of the food supplied. Bowditch has also insisted that actual loss in weight, and sometimes even a failure to gain, is often an early premonitory indication of the onset of constitutional disease.

The average length of the infant at birth is nineteen and three-quarter inches. During the first six months it grows from four to five inches and in the second from three to four. In the second year the gain is from three to five inches, and by the end of the fifth year the child should have doubled its original length. Insufficient nourishment and improper food, especially in rachitic children, retard growth in length. Chronic disease of the brain (idiocy) is apt to give rise to more or less dwarfing. Cretinism, also, in a very marked degree stunts growth. On the other hand an attack of one of the exanthemata appears in some children to accelerate growth.

At birth the circumference of the head much exceeds the circumference of the thorax, but with the rapid development of the lungs the difference is notably diminished during the first few months, and at the end of the first year, notwithstanding the rapid development of the head, the thorax exceeds it. Between six and eight weeks old, the child begins to raise its head and turn it voluntarily toward a bright object and a few weeks later is able to hold it up without support. Not till about the seventh month does it acquire the power of sitting alone, and not till the close of the first year are the lower extremities sufficiently developed to enable the infant to make some effort to stand. Two or three months later it should walk alone. Growth does not always take place uniformly; the head often increases the most rapidly in size, but sometimes the extremities. When growth is too rapid, failure of strength, with anæmia and more or less emaciation, ensues.

About the sixth month dentition generally commences with the eruption of the two lower central incisors and these are followed at varying intervals by the other teeth in successive groups. Every kind of variation may be met with as to the order in which the several groups of teeth appear without any evidence being found either at the time or later of the existence of any pathological condition, mental or otherwise (Rotch). Nevertheless delayed dentition is generally regarded as to some extent an evidence of imperfect nutrition. Merei and Whitehead state that in seventy-nine per cent. of the well-developed, the first teeth appear before the eighth month has passed, while in sixty per cent. of those with imperfect development the first teeth are cut after the eighth month. The following is the formula for their usual appearance as given by Rotch:

Groups.	Time of appearance.
Two central lower incisors	6th to 8th month.
Four upper incisors	8th to 10th month.
Two lateral lower incisors and four first molars	12th to 14th month.
Four canines	18th to 20th month.
Four second molars	28th to 32d month.

During the earlier months of infancy the anterior fontanel remains open, and affords a fair indication by its size of the state of development in the cranial bones, and to some extent of the state of ossification in the body generally; and by the presence or otherwise of any distention in the membrane covering it, of the condition of the brain, whether congested or anæmic. This fontanel is of small size in the new-born, but gradually increases up to the ninth month when its size remains stationary for two or three months, and then it rapidly begins to close (Vogel). Between the fifteenth and eighteenth months in healthy, well-developed children it should become completely ossified.

The Development of the Senses and Mental Faculties in the infant is an interesting study to which in recent years considerable attention has been directed. The first movements of the new-born infant are either purely reflex, like its crying, or impulsive, and due to the unloading, in an objectless manner, of its "inherited provision of motor impulses." Tactile sensation at birth appears to be developed in lips, tongue, eyes, and hands; numerous reflexes of prenatal development also manifest themselves, *e.g.*, respiration, swallowing, winking, coughing, sneezing, etc. With these exceptions sensation, both general and special, is in the early weeks of life very defective. The senses of taste and smell appear to be the first to make distinct and clear impressions on the mind. The new-born can distinguish between bitter and sweet, and the taste and smell of the milk first received makes a permanent impression, so that another is often tried only to be put away. Thus memory and judgment appear to arise first in the domain of these senses.

Hearing and sight are very defective at first, but become afterward of much importance to development. All children are born deaf. Even the strongest do not notice a sharp sound earlier than six hours after birth. More frequently it is some days before we notice the infant starting at a sudden noise. This deafness is due to the fact that the Eustachian tube is closed at birth and is only gradually opened by the acts of breathing and swallowing. Until it is opened the middle ear contains no air, and the tympanum stands too obliquely. After hearing becomes active no organ of sense contributes so much toward mental development. Deaf children are much more backward than are the blind. Toward the end of the third month a child should recognize the direction of a noise and turn toward it. It requires more time, however, before children can distinguish between different sounds. Demme found only two per cent. able to recognize their mother's voice at three and a half months. At six months most babies enjoy being sung to, and are amused by the jingle of rattles.

The infant appears to be able to distinguish light from darkness almost immediately after birth, but that is all, for the movements of the lids and balls are not at first symmetrical. About the sixth week a bright light, if moved slowly, is followed by the eyes, and after the third month we may observe the quick closing of the lids on the approach of an object. By this time also the child should recognize its mother's face. After the sixth month the estimation of size, distance, and color becomes gradually developed, but not till after the third year are all the colors distinguished.

Voluntary grasping is generally noticed very shortly after the third month and with it comes the knowledge of things apart from itself.

Speech is not inborn, but the tendency to it is inherited. At first only vowels are uttered, but after the first few weeks the mental state of the child may be determined to some extent from the different sounds that it makes and its voice gradually becomes modulated to suit its mood. Toward the end of the first year the child begins its first imitation of sound. The progress is more rapid after this, but for a long time expression and gestures are the most important means of communication, and sounds are merely accompaniments. Then one word is used to signify several thoughts, showing the growth of reasoning power. Two or three words are next joined together, and finally complete sentences are formulated. All the disturbances of speech noted in the adult may have their counterpart in the child. In the one the functions are disturbed by disease, in the other the defect is due to insufficient development.

INFANT MORTALITY.—The high rate of mortality in infancy has been referred to and deplored by all writers on the subject. In England, out of 1,000 infants under one year there die annually 141.8; in France, 223.2; in Italy, 273.3 (Farr). These are the mean rates for rural and urban districts; in large cities the rates are higher. In Paris during the four years, 1863–66, the mean annual death rate of infants under one year was 290 per 1,000 living. Eross in a recent article based on statistics obtained from sixteen large European cities, states that about nine per cent. of all children born alive die before the end of the fourth week. In small towns and in the country the rates are much lower than in the cities, but even in these the percentage of deaths occurring in infancy is very large. In this country statistics are not sufficiently defined to enable us to state the exact mortality of the several months and years of infancy. In Boston, with a general death rate not exceeding 24.5 per 1,000, the mean death rate of infants under one year, determined in the four census years 1855, 1865, 1870, and 1875, was 272.7 per 1,000 infants living, while for children under five it was 95.6. These rates are still true for many of our large cities, but in others it is probable that a great diminution in them would be found to have taken place in recent years. Wende (*Pediatrics*, vol. ix., 1900, p. 103) states that in 1890 out of a total of 5,024 deaths in Buffalo, N. Y., 2,305 were under five years of age; but in 1898, owing to a careful inspection of the milk supplied to infants, and to greater care in the feeding of it, out of a total of 4,533 deaths, only 1,570 deaths of infants under five years were recorded.

The high mortality rate in early infancy demands an earnest consideration of the causes that may give rise to it and an effort on the part of every physician to reduce it. Unfortunately some of the causes contributing to it appear at present to be unavoidable. The great and important changes which take place in the organism with the completion of birth, and the rapid development which afterward ensues, are both fraught with special dangers, even to those naturally healthy. In many instances, however, we have the added weakness involved in hereditary disease; syphilis and tuberculosis in the parent necessarily entail an enfeebled offspring unless active preventive measures be taken. Even when we have no distinct diathetic disease to deal with, general debility and many chronic affections in the mother affect the vitality of the offspring unfavorably and render it more liable to succumb to disease. Dr. Curtis estimated that from ten to fifteen per cent. of all deaths under five years must be assigned to this class of hereditary causes. Ashby, in an analysis of the causes of death in two thousand infants under two years of age, estimates that congenital syphilis was the active agent in ten per cent. Acute zymotic disease also plays an important rôle; pertussis has its maximum fatality during the first year of life and measles in the second, while scarlet fever does not reach its maximum fatality till the third and fourth years. Ashby in the analysis above quoted states that pertussis was the cause of death in twelve per cent. and measles in nine per cent. of his cases. Unfavorable hygienic surroundings may increase largely the mortality of this class of diseases by weakening the vitality of the infant and perhaps by increasing the virulence of the poison itself, while strict isolation and thorough disinfection will undoubtedly lessen the frequency and diminish the mortality from this source.

Diseases of the alimentary tract contribute largely to this high death rate. Jacobi has estimated that the deaths from this cause alone in the first year of life amount to nearly forty-one per cent. of the total number which occur at this period of life. In the second year the mortality, although large, is not quite so great. This class of disease must be regarded as resulting almost entirely from defective knowledge and care in the feeding and hygienic surroundings of the infant, and therefore in great part preventible. Inflammation of the respiratory organs, principally bronchitis and pneumonia, is also another important cause of this high rate of mortality. Dr. Farr states that in England this class of diseases is the cause of nearly one-sixth of all the deaths under five. According to Jacobi twenty-one per cent. of all the deaths in the first year of life are due to this cause, and about thirty-six per cent. of the deaths in the second year. In the majority of the cases in this class, imperfect ventilation of living rooms, and undue exposure to wet and cold with insufficient covering to chest and extremities, conduce greatly to this result. It is surely not too much to hope that with the rapid diffusion of more exact knowledge of the important principles of hygiene and infant feeding, this excessive mortality in infancy may be greatly reduced.

INFANT HYGIENE.—*Feeding.*—As soon as the mother has to some extent recovered from the exhaustion of labor, the infant should be applied to the breast. Although the full supply of milk is not established until the second or third day, yet, as a rule, sufficient will be obtained to satisfy the infant; when it is very feeble, however, artificial feeding with a weak sterile cream mixture may be advisable. At this early period the infant does not require much and a frequent application to the breast is unnecessary. Should the influx of milk be delayed and the infant be fretful, feeding with some substitute milk may be deemed advisable. For the first month it is difficult to obtain regularity in nursing, but the importance of regular feeding should be impressed on the mother, and she should be told that crying and fretting during the intervals are in general due not to hunger, but to colic, which may be aggravated by irregular nursing. After the second month an interval of at least two hours between two successive nursings should be insisted on for the day; during the night this should be lengthened to three or four. As the child grows older its stomach becomes capable of taking larger quantities at a time, and the intervals should accordingly be gradually lengthened to four hours. In some cases the breast milk of the mother does not agree with the infant and gives rise to more or less pronounced symptoms of indigestion associated with much fretfulness, sleeplessness, and either an actual loss of, or a failure to gain in weight. This condition of the milk is sometimes due to over-anxiety, insufficient sleep, an improper dietary, or irregular habits on the part of the mother, and may be remedied by securing for her a correct dietary, regular outdoor exercise, sufficient sleep and freedom from undue worry and excitement. In a few instances, however, the fault appears to be irremediable, and artificial feeding with a properly constituted food must be attempted. (See article *Infants, Artificial Feeding of.*)

In estimating the suitability of any food to an infant's requirements the important test is the weekly increase in weight. If the food is digestible, and sufficient in amount for its wants, the infant should be free from colic, happy in disposition, should sleep quietly, and gain regularly in weight. No fixed rule can be stated as to the proper time to allow artificial food in connection with breast milk. While robust mothers, with an abundant supply of milk, can easily satisfy their infants up to the age of twelve or fifteen months, many begin to feel the drain upon them by the second or third. In others, the milk, though abundant, fails to satisfy and sufficiently nourish the child, and must be early supplemented by artificial food.

Bathing.—The first bath of the infant should be given in a warm room, free from draughts, and in water of a temperature of 96° F. The infant should be dried beneath some warm flannel covering. In general, nurses are not sufficiently alive to the necessity of preventing undue chilling of the surface. From the fifth to the ninth day the navel string becomes detached, and not till that occurs is a second general bath advisable. After that the bath should be given daily in water at a temperature of about 92° F. This temperature, after the age of eight or nine months, may be lowered carefully to 90° or 85°, according to the strength of the infant and the vigor of its reaction. Too prolonged chilling of the surface during bathing and dressing is the frequent beginning of catarrhs of all sorts.

Clothing.—In the dressing of the new-born care should be taken that there is no injurious dragging on the navel, that the usual abdominal band is not applied so tightly as to interfere with respiration or digestion, and that sufficient warmth be secured for the extremities. Later on, caution should be enjoined that none of the clothing press unduly on either chest or abdomen—all should hang loosely from the shoulders; neck bands should not be tight, and the extremities should always be efficiently and warmly covered. No sudden change in the amount or character of the clothing is, on any account, to be permitted. Special care is also to be given to the shoes. The leather should be pliable, and the shoes made broad and loose about the toes, so as to allow freedom for movement and growth.

Sleeping.—For the first few weeks of its life an infant should sleep eighteen hours out of the twenty-four. As it grows older, it gradually requires less. A fretful and wakeful baby is ailing in some way, and the cause of its fretfulness should be found out and remedied. When possible, the nursery should be large and well ventilated. For the first few days of infant life it may be desirable that the room in which it is kept should be somewhat darkened, but after that fresh air and sunlight should never be excluded. At the same time draughts and rapid changes of temperature are fraught with much danger.

Exercise is important, but the manner of it is equally so. No infant should be carried about upright until it is able to raise its head and rotate it easily; nor should it be encouraged to walk or stand till nearly a year old, and if there be any tendency to rachitis this must be postponed still later. After an infant is three months old—a little later, in the winter season—it should be "short-coated," and the fullest liberty given to its arms and legs. It should be encouraged to lie on its back in its crib with loose clothes and enjoy, as it will do, the liberty of kicking. Every day it should be taken out regularly during the more suitable portion of the day, unless the weather be blustery. When it is sufficiently old, walking forms a pleasant exercise, but it should never be carried to the extent of much fatigue.

Weaning should, if possible, be effected gradually, and the digestive organs should be accustomed to some suitable artificial food before lactation is altogether stopped. Abrupt changes in its food try an infant's digestion, and frequently upset it. In selecting the time to make the alteration, attention should be given to the following points: 1. An interval between the eruption of the several sets of teeth should, if possible, be chosen, as we sometimes notice at these times irritation of the nervous system with hyperæmia and increased peristalsis of the alimentary canal. 2. It is never desirable to take the breast from an infant while it is sick or recovering from sickness, unless it is manifest that the milk of the mother is injurious. Even an inadequate supply will often be all-important for the nourishment of such an one (Busey). 3. Regard must be paid to the season of the year. Any change during the hot months is very undesirable.

In the EXAMINATION of infants much tact and observation are necessary. All appearance of abruptness is to be avoided; no harshness in voice or manner is allowable; the physician's hands must be warm; and a full supply of patience must ever be ready to be exercised if demanded. If the infant be asleep on the physician's arrival, it should on no account be awakened until he has seen its decubitus, counted its pulse and respirations, and noted their character, and made such other superficial examinations as are possible without disturbing it. The pulse and respirations in an infant just awakened are always extremely rapid. With regard to its decubitus, a healthy young infant in sleeping generally assumes the position he is supposed to have had *in utero.* An older infant, even if lying on its back, should incline its head to one side or the other, so that its cheek comes in contact with the pillow. If it be found with closed eyes and face directed straight upward, it is probably suffering from serious disease. If it be lying with its head retracted, cranial disease should be thought of. If it sleep on its belly, or resting on elbows and knees, it is probably suffering from abdominal discomfort. Healthy children should sleep quietly. Much tossing, any twitching of the muscles, or screaming and talking in sleep, indicate feverishness or digestive derangement.

Much may be learned from the character of the child's cry. Unappeasable screaming, without any other symptom, often results from earache. The temperature should always be taken with a sensitive thermometer, preferably in the rectum; if not convenient there, in the groin. The armpit is not so good, as infants object to the necessary restraint of the arm. In many abdominal troubles the skin and extremities may be quite cool, yet the thermometer in the rectum show a temperature of 104° or 105°. The respirations, if practicable, should always be counted. At the first examination we should always insist on having the infant stripped, otherwise no thorough examination can be made. Care should at the same time be taken that the infant be not chilled by a too prolonged examination. Passing downward, we note: (1) shape of child's head and state of fontanel; (2)

shape of chest, character of the breathing, whether there be any retraction of chest walls or intercostal spaces. With warm hands palpation should be made, and the expansion, and also the presence, if any, of rhonchal fremitus should be noted; (3) shape of abdomen, whether protuberant or retracted, whether the walls are tense or lax. Gentle pressure may be made by the hand, and any tenderness of the abdomen or enlargement of liver or spleen detected; (4) condition of the lymphatic glands.

In addition, the color and elasticity of the skin and the general nourishment of the tissues should be observed at this time. In auscultating the chest, the infant should be placed on the left arm of the nurse, leaning over her left shoulder, with its arms around her neck. In this way only are the muscles of the back equally relaxed and correct results obtained. Percussion should always be gentle. Immediate auscultation never gives the exact results obtained by the use of the stethoscope, but any painful pressure by the instrument must be carefully avoided. In infants, symptoms of disease are more frequently found at the back than at the front, and at the base rather than at the apex. Nevertheless, no part should be omitted in the examination. Inspection of the mouth and fauces should always be left to the last, as giving rise to more or less resistance. To effect this the infant should be seated on the nurse's lap before a bright window. Sometimes with a little gentle pressure on the chin the mouth is opened and the tongue seen. To examine the fauces requires the use of a depressor, for which nothing is better than the smooth handle of a spoon. This can always be slipped in behind the teeth and over the tongue to its base. When the pharynx is reached the mouth involuntarily opens, and, if the physician be on the alert, a good view of the fauces is obtained. Lastly, the secretions should be examined, if in any way at fault. Trouble is sometimes experienced in obtaining the urine. If necessary, a small silver catheter may be passed and a sample drawn off.

In making our diagnosis and prognosis in infancy, the following points must always be remembered as modifying disease at this period:

1. The wide diffusion of symptoms met with at the onset of an acute attack.
2. The severity of the initial symptoms often bear no proportion to the gravity of the local lesion.
3. The extremely rapid rise and fall in the temperature of the body frequently observed.
4. The rapidity with which functional mischief may pass into organic.
5. The extent to which local disease is modified by certain diatheses.

For an account of the special diseases to which the infant and new-born are liable, the reader is referred to the separate articles on these diseases.

INFANTS, ARTIFICIAL FEEDING OF.—When for any reason the infant is deprived of its mother's milk, its natural and most perfect food, the necessity of supplying it with nourishment from some other source is forced upon us. This may best be done by means of a healthy, efficient wet-nurse, if such can be obtained; but this is always a difficult matter. Very seldom can one be found who fulfils all the requirements demanded by the physician, and who is willing to submit to the careful dietary and regular mode of life necessary to insure a wholesome and even supply of breast milk to the foster child. In the great majority of cases, therefore, we have to find some artificial nutriment which shall fulfil the important conditions of being easily digested by the infant and at the same time of supplying in due amounts all the elements required for nutrition.

Nitrogenous material it must have to provide for the wants of the growing tissues; without a sufficient quantity of this element in the food, growth and development will be defective. Carbohydrates must also be present. Not only are they essential to nutrition, but they are also necessary for the production of heat in a being whose muscular activity is comparatively slight, yet in whom the activity of the vital processes would be much impaired were the body heat lowered in any degree. These carbohydrates must be in a condition easily assimilated, and it is to be remembered that during the early months of life no provision is made by nature for the digestion of starch; they must, therefore, be supplied in the form of some sugar, and of the various sugars milk-sugar appears for the infant to be the most assimilable. Fats appear to be closely associated with new cellular growth, and must be supplied in a state of fine emulsion. The food must also contain a due amount of mineral matter, calcium phosphate for the hardening bone, and sodium chloride and iron for the blood, daily increasing in amount. Salines are also undoubtedly of much service in the vital processes of digestion, absorption and nutrition; processes for which water is demanded in larger amounts than required by the more adult constitution.

To supply a food suitable in all these respects to the wants of the infant organism, and yet easily digested and assimilated by the imperfectly developed alimentary tract of the infant, is a problem demanding much thought and care. Its importance will be appreciated when we consider the disastrous results which frequently follow attempts made in thoughtlessness and ignorance to hand-feed infants. The enormous death rate which in all countries occurs among those deprived in early days of maternal milk is appalling, while among those that survive, poor health, defective nutrition, and stunted growth plainly attest the defective nourishment supplied. As a recent writer says, it is proper or improper nutriment which makes or mars the perfection of the coming generations.

The problem, although at all times demanding careful thought, is one of very varying difficulty. If the powers of digestion are naturally strong, and especially if the infant has received the advantage of maternal nursing until the gastric and intestinal secretions have become to some degree developed. the task of supplying a suitable food may be a comparatively easy one. But if the infant inherit a weak constitution with feeble powers of digestion and assimilation, still worse, if it must be bottle-fed from its birth, much difficulty will be experienced; our difficulties are still further increased during the hot season and under the unsanitary influences associated with city life. It is only within the last few years that advancing knowledge has enabled us to cope, for the most part successfully, with these various difficulties, and it must be acknowledged that for the greater part of this advance we are indebted to American physicians.

In the preparation of a substitute food for infants, it must be our aim to copy as closely as possible in all particulars the food which nature supplies. The substitute food must resemble maternal milk in the elements entering into its composition, in the percentage of them present in the food, in its freedom from the presence of noxious micro-organisms, and in the fact that it is an animal food. To enable us to attain this result, many careful analyses have been made to find out the exact composition of mother's milk.

Rotch gives us the following as a summary of several of the more recent analyses of human milk:

AVERAGE HUMAN MILK. (Rotch.)

Reaction	Amphoteric or slightly alkaline.
Specific gravity	1.028 to 1.034.
Water	87 to 88 per cent.
Total solids	12 to 13 per cent.
Fats	3 to 4 per cent.
Milk-sugar	6 to 7 per cent.
Proteids	1 to 2 per cent.
Total mineral matter	.1 to .2 per cent.

As an indication of the differences which may exist in the breast milk of different women, the following analyses, made by Harrington and quoted by Rotch, are interesting:

HUMAN BREAST-MILK ANALYSES.

(Mothers Healthy and Infants Digesting Well and Gaining Weight.)

	I.	II.	III.	IV.
Fat	5.16	4.37	3.28	3.16
Milk-sugar	5.68	6.30	5.70	7.20
Proteids	4.14	3.27	1.08	1.65
Mineral matter	.17	.16	.20	.21
Total solids	15.15	14.10	10.80	12.22
Water	84.85	85.90	89.20	87.78

In connection with these analyses it is to be noted that, although the several infants digested and throve well on their own mother's milk, when supplied with milk from another mother colic and disturbed digestion frequently resulted. Breast milk may also vary according to the period of lactation at which it is drawn. Baginsky quotes the following as the result of numerous analyses made by Pfeiffer:

Period of lactation.	8th day.	65th day.	371st day.
Water	89.62	89.72	87.72
Total albuminoids	2.365	1.496	1.552
Casein	1.665	.844	.718
Albumen	.108	.228	.183
Undetermined albuminoids	.592	.424	.651
Fat	3.345	1.827	3.984
Sugar	3.274	6.22	6.088
Salts	.446	.180	.126

It is evident from these analyses that we have to deal with a fluid which, while containing all the elements necessary for the perfect nutrition of the growing infant, contains them in quantities which may vary considerably in each individual case, and to some extent from time to time. Of its several constituents the proteids and the fats are the most variable in their amounts, while the sugar in all is comparatively constant. This perhaps is only what we should expect from what we know of the secretion of milk, and considering how liable mothers are to the influences of worry, overexcitement, and disturbed sleep. In the majority of cases infants digest and assimilate their own mother's milk easily, but in a few instances, in which the mother's milk has contained a high percentage of proteids with a low percentage of fats, it has proved indigestible and has given rise to colic and much disturbance of the digestive tract. We may, therefore, infer that more or less variation in the composition of our substitute food will be necessary in many cases to secure a product that will suit the digestive idiosyncrasies of the infant as an individual and yet be efficient as a source of nutriment to its growing tissues.

ANALYSES OF THE MILK OF VARIOUS ANIMALS. (After König.)

	Cow.	Goat.	Ewe.	Mare.	Ass.
Water	87.41	86.91	81.63	90.71	91.40
Caseinogen	3.01	2.87	4.09	1.24	1.23
Lactalbumin	.75	1.19	1.42	.75	
Fat	3.66	4.09	5.83	1.17	3.01
Sugar	4.92	4.45	4.86	5.70	6.93
Mineral matter	.70	.96	.73	.37	.45

At the outset of our endeavors to prepare such a food we naturally turn to the milk of other mammals, and of these the milk of the cow, goat, ewe, ass, and mare have been by various writers recommended for this purpose. Careful analyses have been made of these various milks, with the results shown in the last preceding table.

It is evident that the milk of the ass and mare approaches more nearly that of the human being than does that of the cow, but as it is impossible to obtain from these animals a supply in any way adequate to our wants, they may be dismissed from our present consideration. Goats' milk, although more frequently available, possesses no advantage over cows' milk. The quantity of casein in it is large, and its peculiar odor is often very objectionable. Cows' milk, on the other hand, has many advantages; it is plentiful and cheap, and can with due care be obtained fresh and pure. The following analyses of the two milks, as given by Rotch, shows us how closely they resemble one another in composition:

	Cows' Per cent.	Woman's (directly from breast). Per cent.
Reaction	Slightly acid.	Amphoteric, generally alkaline.
Water	86–87	87–88
Mineral matter	.70	.20
Total solids	14–13	13–12
Fats	4.00	4.00
Milk-sugar	4.50	7.00
Proteids	4.00	1.5–2
Caseinogen	2.88	.59
Lactalbumin	.53	1.23

Although on comparing these two tables we see much similarity between the two fluids, nevertheless important points of difference may be noted. While human milk is almost always alkaline and remains so for many hours, the reaction of cows' milk is acid, owing partly to the presence in it of potassium biphosphate, and partly to the formation of small quantities of lactic acid; especially is this the case when the cow is stall-fed or the milk a few hours old. Our knowledge does not as yet permit us to recognize any difference between the fats in the two milks. The milk-sugar is notably deficient in cows' as compared with human milk. The mineral matter is more abundant in cows' milk. An analysis of the saline ingredients in the two milks shows that the potassium salts are in larger proportion in breast milk, while the lime salts are more abundant in cows' milk. Cows' milk also contains more phosphoric acid, less chlorine, less iron, and less sulphur. These differences, however, may be regarded as comparatively unimportant. The most important practical difference exists in the proteids, of which we notice that in cows' milk the greater part may be readily coagulated, forming tough and dense curds, while in human milk the coagulable proteids exist only in small amount. König's analysis shows that, while in human milk the caseinogen forms one-third and the lactalbumin two-thirds of the proteids, in cows' milk the caseinogen forms four-fifths and the lactalbumin only one-fifth. As a result of this difference, it is noticed that on coagulation of the proteids of human milk by acids or rennet the curds form slowly and are small and flocculent, whereas in cows' milk they form comparatively rapidly and are large and tenacious. Similar results are observed when the two milks are acted upon by artificial gastric juice in a test tube; the proteids in woman's milk are precipitated slowly and imperfectly and are easily redissolved in excess of the juice, while the proteids of cows' milk are precipitated in large masses which are redissolved only with difficulty.

Another important difference between the two milks still remains. While breast milk is always practically sterile, commercial cows' milk invariably contains many bacteria, from one hundred thousand to several million in each cubic centimetre, and if old it also contains the toxins evolved by their actions. It is therefore extremely important that milk to be employed in the feeding of infants should be obtained from healthy, vigorous animals, cleanly kept under the best hygienic conditions, and carefully fed and watered. The milking should be done with careful precautions to avoid contamination by impurities (see article *Milk*). The milk should at once be cooled and aërated and delivered to the consumer with as little delay as possible; prolonged transportation is to be avoided. Milk may acquire noxious properties and be rendered dangerous as a food, especially for infants, by (1) poisonous weeds taken with the food; (2) by diseased conditions in the cow; (3) by contamination with pathogenic organisms communicated during either milking, or storing, or transportation. Whenever the temperature of milk is allowed to rise above 7° C. (45° F.), it becomes an excellent culture medium for the growth and development of the many forms of bacteria which, even with our most careful precautions, are always present to a greater or less extent. Milk containing micro-organisms in excess of ten thousand per cubic centimetre must be regarded as unfit for infant feeding.

Cows' milk also varies considerably in its percentages according to the special breed supplying it, according to the character of the food on which they are fed, and the amount of exercise permitted. It is therefore desirable that before employing cows' milk for the feeding of delicate infants, for whom fine adjustments may be necessary, an analysis of the milk supplied by the herd should be obtained. Afterward an effort should be made to maintain uniformity by careful regulation of the food.

Obtained with the above precautions, we have in pure cows' milk a food which, compared with breast milk, contains an equal amount of fat, an excess of indigestible proteids, an insufficiency of sugar, and an excess of saline matter; our efforts must therefore be directed so to modify its composition and the character of its proteids as to render it suitable and digestible by the young infant.

Many plans have at various times been recommended. Simple dilution lessens the amount of the proteids, and to a slight extent renders the curd formed by them less dense. It reduces, however, the fats and sugars much below the amount demanded by the infant organism. Keller has also shown us that with a low percentage of carbohydrates in the food there is a very low retention percentage of nitrogen in the system, and general nutrition is defective. Mere dilution, therefore, is not to be commended.

Lehmann many years ago pointed out the effect of the addition of an alkali in rendering the curd less dense. He writes that human milk when acid yields a much thicker coagulum than when alkaline, and cows' milk when alkaline a much looser coagulum than when acid. We also know that casein is precipitated from its solutions by acids, while its precipitation is retarded by the presence of neutral salts. It is, therefore, always desirable to have the acidity of cows' milk well neutralized by an alkali, and for this purpose either lime water or sodium bicarbonate may be employed. It is to be remembered, however, that milk, when recently drawn from pasture-fed cows, is much less acid than the milk of cows stall-fed on dry fodder and grain. Milk also increases in its acidity on standing, owing to the conversion of some of the milk-sugar into lactic acid by the numerous lactic-acid-producing bacteria always present in milk. Harrington ascertained by experiment that ordinary milk, twenty-four hours old, required the addition of one-sixteenth of its volume of lime water to make its alkalinity correspond with that of breast milk. The addition of one-eighth of its volume of lime water rendered it strongly alkaline. Fresh milk from cows on pasture required a much smaller quantity. When constipation is present in the infant, sodium bicarbonate may be used in place of lime water to the extent of from five to ten grains to the pint of milk.

Another plan, frequently recommended as preventing the formation of firm, tough curds is to dilute the milk with a thin gruel, which by its physical consistence is able to diminish the density of the coagulum. This method is an old one, as we read that Van Swieten, in the fifteenth century, used decoctions of wheat or barley for this purpose; but its utility has of late years been very strongly urged by Dr. Jacobi and Dr. Chapin. That it has a distinct value has also been proved by Professor Leeds, who, in a series of careful experiments, showed that the coagulum which forms in a thin gruel encloses much material which, by honeycombing the curd, acts as an attenuant. Coagulation also takes place more slowly—a very positive advantage, as it affords the digestive fluids a better opportunity for action. Many substances have been used for this purpose. Dr. Jacobi recommends well-boiled decoctions of barley or oatmeal. He says: "I have always preferred barley when an article for steady diet was to be recommended, for the reason that oatmeal, on account of its containing fat and mucin, tends to relax the intestines more than barley meal. Otherwise the chemical composition of both is so nearly alike that it would make but little difference upon which the choice would fall. . . . In the case of very small children, the whole barley corns ground for the purpose should be employed, on account of the proteins being mostly contained just inside and very near to the husk." When the smaller pearl-barley is used, Dr. Jacobi thinks that much of the gluten is lost with the husk. Gum arabic and gelatin may also be employed in the case of very young infants.

Dr. S. C. Busey urged the advantage occasionally obtained by substituting rice water, prepared in a similar way, for the barley gruel, and says that he has often witnessed its beneficial effects in cases of diarrhœa and vomiting.

The disadvantage of all such diluents, however, for young infants, is that they introduce a material quite foreign to milk, and one with which their digestive powers are unfit to grapple until their salivary and pancreatic secretions become somewhat developed. For such, therefore, the addition of a gruel to milk has no nutritive value, but serves only as an attenuant of the casein. Dr. Jacobi, however, considers that a small amount of starch may be digested at the very earliest age. It is nevertheless important that in all cases the percentage of starchy matter should be small, and that it should be very thoroughly cooked. Recently Chapin has strongly advocated the use of a gruel made from wheat, barley, or oatmeal, the starch of which has been predigested or dextrinized by the addition of some form of diastase. His directions are as follows: "A heaping tablespoonful of flour made from one of these cereals is boiled with a pint and a half of water for fifteen minutes. It is then removed from the stove and set in cold water till cooled to about 120° F., when a teaspoonful of some good preparation of diastase is added; this dextrinizes the starches and renders the gruel thin, watery, and easily assimilated by the infant, though it still remains an efficient attenuant of the curd."

In addition to these methods of preventing the firm coagulation of the casein, it is always practicable to predigest the proteids of the milk by means of one of the numerous preparations of pancreas, and thus to do away more or less completely with the formation of the curd. A peptogenic milk powder has also been prepared, containing pancreatin and bicarbonate of soda, along with milk-sugar. When the food is wanted the powder is added to a mixture of milk, cream, and water, and the whole is kept at blood heat for some minutes. When properly prepared the resulting milk should closely resemble mother's milk in the reaction of its proteids and its composition.

In practical use, however, predigestion of milk does not appear to have given as excellent results as was at first anticipated. It is a method that may be employed occasionally with benefit in cases of severe exhaustion accompanying or following acute disease, and in some forms of gastric disorder associated with a temporary inability to digest the proteids in milk. The degree to which the predigestion must be carried at first will depend on the power of proteid digestion present in the infant, but in all cases as soon as possible the time of predigesting the milk and therefore the amount of peptonization it undergoes should gradually be lessened; predigestion of food for any lengthened period appears to be quite opposed to the teachings of physiology.

In all these methods, however, with the necessary dilution of the milk, the quantity of fats and sugar falls far below the requirements of the growing infant organism and requires to be increased. In reference to the deficiency in the fat, Dr. Jacobi puts in a strong plea against allowing any excess to be present in our mixtures. He says that the infant does not digest all the fat contained even in its mother's milk, and we ought not therefore to increase the amount of the indigestible ingesta by adding to them. In opposition to this, Dr. Rotch very pertinently remarks: "We have no right to conclude from the fact that a certain amount of surplus fat is found in the napkins, that only a small per cent. is sufficient for nutrition. It is more probable that nature introduces a certain percentage of fat in human milk with a purpose which can only be accomplished by that percentage,and it will be an error on our part not to conform to our standard." My own experience confirms that of many others, that average infants can digest from two to four and one-half per cent. of fat; more than this is liable to give rise to gastric disturbance, and may induce vomiting or diarrhœa; a deficiency in the fat, however, will interfere very distinctly with the infant's nutrition. Biedert also says that while remarkably small amounts of proteid may be sufficient for the good development of infants during the first few weeks of life, an increase in the amount of fat considerably above what is contained in dilute cows' milk spares albumin, renders digestion easier, and increases the growth of the child.

To make good the deficiency in the fat, we have to rely on creams of known strength. The only serious drawback to its employment is the difficulty of obtaining it fresh and sterile. Freeman has told us that when milk is set the great majority of the bacteria rise with the cream, leaving the separated milk comparatively free. In the food of infants cream more than twelve hours old should not be employed.

In correcting the deficiency of the sugar the majority of pediatrists prefer to use milk-sugar, the form found in the milk of all mammals. Jacobi, however, prefers cane sugar, considering that the identity of the lactose in human and cows' milk is very doubtful and that the commercial milk-sugar is often very impure. He also thinks that as milk-sugar readily undergoes the lactic-acid fermentation, any excess of it tends to increase the elimination of calcium phosphate and may thus favor the development of rickets. On the other hand, Vaughan considers that milk sugar is more readily assimilated by infants, and Escherich states that milk-sugar when acted on by the Bacillus lactis aerogenes develops lactic acid, which tends to prevent the development of many noxious forms of bacteria. In general, milk-sugar would appear the preferable form to employ, but should it at any time give rise to symptoms of indigestion, or should pure milk-sugar be difficult to obtain, cane sugar may be employed, but in smaller quantities, owing to its greater sweetness.

Until very recently, in our attempts to modify cows' milk by any of the above methods, we spoke and thought in measures of milk, cream, and sugar, without a very clear idea of the exact percentages in which the elemental constituents of the milk—the fat, the caseinogen, the lactalbumin, and the sugar—were present in our mixtures. A few years ago Dr. Rotch introduced the method and emphasized the value of thinking, working, and speaking entirely on the percentage plan, and of making our modifications from a cream containing a known and definite percentage of fat, and from a milk containing a known and definite percentage of proteids, fat, and sugar. By this plan scientific accuracy was substituted in our modifications for much indefiniteness, and we were not only enabled to prepare a food which we could feel sure exactly resembled breast milk in its physical characters and chemical composition, but also to vary the percentage of the several constituents so as to render it suitable to the varying wants of the different individual infants. On this subject Dr. Rotch says: "While in quite a number of cases rather gross changes in the percentages of the different elements of the milk may be sufficient for the range of the individual digestion and for the nutrition of the special case, yet in a large number of infants whose vitality is low and digestive powers feeble, good results can only be obtained by gradual and minute changes in the percentage combinations of the milk elements."

For such we must have the power of making use of modifications as precise as our knowledge at the present time renders possible. Even slight changes in the percentages of the fat, the sugar, and the proteids are of real value in the management of the digestion and nutrition of the infant.

The substitute food must be adapted, not only to the infant's stage of development, but also to its individual capability of digesting the several elements of its food. To enable us to obtain these varying combinations of the milk elements and to have them regularly and exactly supplied to our patients, Dr. Rotch originated *milk laboratories*, which have been established in many of our large cities, equipped with special machinery and placed under the management of men specially trained for the work. The milk employed in these laboratories is obtained with the strictest precautions to insure its absolute cleanliness, from vigorous cows of a carefully selected breed. The feeding and housing of these cows are under careful supervision, and are so arranged that milk of a known and almost uniform composition is obtained. From this milk, by means of the centrifugal separator, the fat is separated and a cream of uniform percentage obtained. The milk remaining is almost fat-free, and is found by frequent analysis to contain a fairly uniform percentage of proteids, milk-sugar, and mineral matter. It is now a simple matter to dilute, with distilled water, either the cream or fat-free milk, so as to obtain the requisite amount of proteid; milk-sugar is added to make up the defective percentage in that element, and cream supplies the exact quantity of fat. With a knowledge of the exact percentages in the cream and fat-free milk, a simple calculation suffices to obtain the formula within certain limits for dispensing whatever percentage of the elements the physician may prescribe. These limits are as follows:

Fat from	.03 to 36.00
Sugar	.87 to 20.00
Proteids	.22 to 4.00

The amount of mineral matter may be disregarded, as the dilution required by the proteid practically makes a sufficient reduction in its amount.

The milk thus modified may be sterilized, at the temperature deemed necessary by the physician, and is then placed in bottles, each containing the amount ordered for one feeding of the infant; the total number of feedings for the day, securely packed in a small basket, are delivered each morning to the consumer.

The following is an illustration of the method in which this modified milk may be ordered by the physician:

Fat	3.00	No. of feedings	9
Milk-sugar	7.00	Amount at each feeding	75 c.c. (2½ oz.)
Albuminoids—			
Caseinogen	.25	Infant's age	3 weeks.
Lactalbumin	.75	Infant's weight.	9 pounds.
Mineral matter	...	Alkalinity	5 per cent.
		Pasteurize at	155° F.

Although this is a very great advance on our previous crude methods of modifying cows' milk, nevertheless many instances occur in which even the small amount of casein present in the diluted milk overtaxes the feeble digestive powers of the infant. In these Rotch has recommended that the amount of proteids be reduced at the first to a minimum, and then gradually, as the infant's digestion becomes stronger, their amount may be increased until the quantity necessary for perfect nutrition is attained. Thus, beginning with a proteid percentage of 0.25, he advises that it be slowly increased up to 1 and afterward 1.50. Many physicians, however, experience much difficulty in making this increase as rapidly as the demands of nutrition appear to require, and a recourse has been had to the addition of one of the cereal gruels, which in many instances appear to render the casein more digestible.

Very recently Dr. Rotch has proposed to get rid of the caseinogen, in young infants such a frequent source of trouble, by the use of a whey obtained from fresh cow's milk by the use of rennet. Thus prepared, whey contains all the lactalbumin, sugar, and mineral matter, but none of the caseinogen and almost none of the fat. Its average composition, as compared with that of whole milk, is as follows:

	Whole milk.	Whey.
Fat	4.00	0.32
Sugar	4.50	4.79
Proteids	4.00	.85

Many years ago a similar plan was recommended by Professor Frankland, who employed fresh calf's rennet. Dr. Rotch's directions for its preparation are as follows: For each pint of whey required take one quart of whole fresh milk, or fat-free milk, heated to 37.7° C., and add 8 c.c. of essence of pepsin or an equivalent of one of the liquid preparations of rennet. This will precipitate the casein in the form of curds, which are afterward to be broken up with a fork; the fluid remaining is then strained through several thicknesses of boiled cheese cloth and slowly cooled to a temperature of 10° C. It must be kept on ice till required. If the whey is to be mixed with cream, it must first be heated to 65.5° C., in order to kill the rennet enzyme. Whey mixtures should not be heated above 68.3° C., if one wishes to keep safely under the coagulation point of the lactalbumin. With whey as a basis to which cream and milk-sugar in requisite amounts may be added, a modified milk may be prepared which will exactly correspond in its percentages and reactions to that of breast milk. This modification will be found of great value during the early months of infancy, while the digestive powers of the infant are still feeble.

Should whey not be employed, the amount of the proteid element must for some weeks be kept at a minimum and only gradually increased. A slight increase should be arranged for, however, every week or fortnight. Northrup insists that by the ninth month infants should be able to digest full milk, and considers that the slow dentition, anæmia, and loss of weight frequently observed in the later months of lactation are attributable to an insufficient amount of the proteids.

While milk laboratories are not only a great convenience to the physician in the preparation of these various combinations of percentages, but also of value in permitting such combinations to be made with greater exactness than by any method of home modification, nevertheless the advantages of a milk laboratory are not everywhere to be obtained, and in the opinion of many physicians modifications of milk can be carried out at home with sufficient exactness to fulfil the wants of the great majority of infants. To succeed, however, the physician must be capable of giving exact instructions as to the details of the process.

In undertaking home modification it is extremely important to secure a supply of good fresh milk, and one in which the percentage of the fat is known and maintained by careful feeding at a fairly uniform amount. It is to be remembered that the amounts of fat will vary very much according to the particular breed of cows supplying the milk. In an average mixed herd the fat generally amounts to about 4 per cent.; in a herd of Jersey or Alderney cattle it may amount to 5 or 6 per cent. On the other hand, if during the winter season the cows be poorly fed and housed, the fat may not much exceed 2 per cent. Cream obtained by a centrifugal separator contains from 20 to 30 per cent. of fat, together with a slightly lessened percentage of proteids and milk-sugar, and may be employed with advantage in the preparation of mixtures in which a very small amount of proteid is required. For general use, however, the most convenient way of obtaining a cream or superfatted milk, from which to prepare our percentages, is to take advantage of the deep-setting process, *i.e.*, to allow fresh milk to stand in a tall glass jar on ice for some hours. After standing for twelve hours the cream will have almost all separated and will contain about 16 per cent. of fat. If it stand only six hours, the upper fourth will contain about 12 per cent. of fat; if only three hours, the upper third will contain about 8 per cent. of fat. In this top milk when removed the sugar may be regarded as amounting to 4 per cent., and the proteids to very nearly the same.

Chapin recommends that top milk, obtained from milk as ordinarily delivered in quart bottles, be employed, and gives the following assays of various amounts of top milk taken in this way after standing twelve hours:

	Per cent.	Per cent.	Per cent.
Fat in whole milk	3.1	4.3	5.0
Fat in the top 6 ounces	13.4	19.0	23.0
Fat in the top 9 ounces	9.2	12.4	14.6
Fat in the top 12 ounces	7.0	9.6	11.1
Fat in the top 16 ounces	5.8	7.9	9.0

One may in this way obtain a superfatted milk which on dilution will give us the desired percentages of both proteids and fats. Thus if we take a 12 per cent. cream and add to it three parts of water, we shall obtain a milk containing 3 per cent. fat, 1 per cent. proteids, and 1 per cent. milk-sugar. If to each twenty ounces we add one ounce of sugar of milk, we shall then have a milk formula: fat, 3; sugar, 6; proteids, 1—a formula which will agree with most vigorous infants between the second and third months of life. By the use of creams of different strength one may modify the percentage of any of the ingredients and obtain milk of almost any desired strength.

To prevent any impurity arising from the sugar of milk, it is generally deemed advisable that it should be previously dissolved in boiling water and afterward filtered through absorbent cotton. The following table shows the amounts of milk-sugar and water required to make solutions of various strengths:

1 oz. milk-sugar added to	25	oz. water represents	4	per cent.
1 " " " "	20	" " "	5	"
1 " " " "	16⅔	" " "	6	"
1 " " " "	14	" " "	7	"
1 " " " "	12½	" " "	8	"
1 " " " "	10	" " "	10	"

Baner has prepared a series of simple formulæ for determining the amount of cream, milk, water, and milk sugar required to make any desired quantity of modified milk containing certain given percentages. His formulæ are based on the understanding that good average milk contains fat 4, sugar 4, and proteids 4, and that cream is simply a superfatted milk containing practically the same amount of proteids as milk itself. In the formulæ given:

Q represents the total quantity desired in ounces;
F, the desired percentage of fat;
S, the desired percentage of sugar; and
P, the desired percentage of proteids.

To find in ounces the required amount of:

$$\text{Cream} = \frac{Q}{12} \times (F - P);$$

$$\text{Milk} = \frac{Q \times P}{4} - C;$$

$$\text{Water} = Q - (C + M);$$

$$\text{Milk-sugar} = \frac{(S - P) \times Q}{100}.$$

The above formulæ are calculated for use with a 16-per-cent. cream. If 20-per-cent. centrifugal cream is used, the denominator of the cream formula will be 16 instead of 12, and if a 12-per-cent. cream is used it will be 8 instead of 12. It must, of course, be remembered that a milk with a very high fat and a very low proteid percentage cannot be made from cream with only a moderate percentage of fat. From a 16-per-cent. cream it is possible to make the fat percentage only four times the proteid, and with a 12-per-cent. three times the proteid. The great advantage of these equations is their simplicity and the ease with which odd amounts of milk mixtures can be calculated.

Sterilization.—In the infant the digestion of milk is for the most part accomplished in the small intestine. There is no long delay in the stomach with prolonged exposure to an acid and therefore antiseptic medium, as in the adult, but the milk after an imperfect curdling is quickly passed on to the duodenum. Gastric digestion, the safeguard in older children and in adults against the entrance of disturbing micro-organisms into the alimentary tract, affords in infants but a feeble barrier. For this reason one of the more important conditions in the infant's food is that it be sterile. This is the more necessary should the infant's food involve a longer time in its digestion than breast milk.

It is, therefore, extremely desirable that the milk employed in infant feeding be obtained with such careful precautions as to render it practically free from extraneous bacteria. It is not always our good fortune, however, to be able to obtain such with the regularity necessary for the daily preparation of an infant's food, and when our supply cannot be depended upon it appears the lesser of two evils to have the milk pasteurized at the lowest efficient temperature—that is, 60°–68° C. (140°–155° F.). Milk sterilized at over 70° C. is altered to an extent varying according to the elevation of the temperature employed and the duration of the exposure in the following respects: (1st) its proteids are modified and rendered less digestible; our knowledge on this subject, however, is still indefinite and dependent chiefly on clinical experience; (2d) the combination of its saline ingredients with the proteids is to some extent broken up and the salts assume a condition in which they are less readily absorbed; (3d) natural ferments, whose presence in milk may with much probability be inferred and which may materially assist its digestion in the infant's stomach, are destroyed; and (4th) an alteration takes place in the emulsion normal to milk, which may also have distinct effect in lessening its digestibility by the infant. For these reasons, it is important that the milk for infant feeding should not be sterilized at too high a temperature. After pasteurization it should be kept at a continuously low temperature; and it is to be remembered that the employment of sterilized milk which has been kept for many days is not free from danger.

Gärtner's Fettmilch.—In Germany during the last few years a modification of cows' milk has been prepared by Gärtner, as follows: Into the drum of a large centrifuge a mixture of milk and sterile water, at a temperature of from 10°–15° C., is allowed to run, care being taken that the milk used is obtained in the most cleanly manner from healthy cows properly fed. The drum of the centrifuge is made to revolve rapidly, driving the fat, as it is only in suspension, toward the centre of the drum, while the sugar, casein, and salts, which are in solution, remain uniformly distributed. Two tubes which carry off the milk enter the drum, one near the centre and one at the periphery. By arranging how near to the centre the inner tube opens, and the speed at which the drum revolves, milk containing fat in various percentages may be drawn off. As ordinarily set the milk drawn off near the centre has the same amount of fat as mother's milk, and is only deficient in sugar. Its composition, which is fairly constant, is fat 3, sugar 2.5, proteids 1.76. By adding a certain proportion of milk-sugar, milk closely resembling breast milk in composition is obtained.

This plan has also the advantage that any dirt present in milk and most of the bacteria are thrown off toward the periphery, thus leaving the central portion free. It is also claimed that the cream is not so completely separated from the milk as in Rotch's plan, but remains in a more perfect emulsion. Thus prepared the Fettmilch resembles ordinary milk in appearance and has an agreeable taste. Before using it as an infant's food it is recommended that it should be sterilized. Escherich has laid down the following rules for the amount and frequency with which this food may be given:

During each 24 hours children of 2 weeks require 16 ounces in 9 meals; from 2 to 4 weeks, 25 ounces in 8 meals; from 4 to 8 weeks, 33 ounces in 8 meals; from 3 to 4 months, 42 ounces in 8 meals; from 5 to 6 months, 50 ounces in 7 meals.

The employment of this milk is strongly recommended by many eminent German authorities.

Condensed Milk.—When pure fresh milk cannot be obtained, several writers have recommended the use of condensed milk. In the form of fresh evaporated milk (milk condensed without the addition of cane sugar), it may be of much service when pure fresh milk is impossible to obtain. The heat employed during the earlier stages of its preparation has rendered it sterile, and it will therefore keep well for a few days. For ordinary use it should be diluted with from seven to ten parts of water, and fresh cream, if this is obtainable, and sugar of milk added. Keating advised the following as making a useful preparation closely resembling breast milk: Preserved milk, 1 ounce; boiled water, 8 ounces; fresh cream, 1 ounce; sugar of milk, 3 drachms.

The ordinary canned condensed milk has the disadvantage of containing a large amount of cane sugar and a very small amount of fat. When diluted with six parts of water the resulting product on analysis yields fat 1, proteids 1.2, and sugar 8, the latter being chiefly cane sugar. This dilution is generally too strong for the majority of infants, and produces colic and indigestion. When diluted with twelve parts of water, its composition is fat 0.05, proteids 0.06, and sugar 4—a fluid altogether too weak to be efficient as a permanent diet. Holt states that he has not yet seen an infant who was reared exclusively on condensed milk which did not show on careful examination more or less evidence of rickets. During the summer season its use may be permissible for those who are unable to obtain fresh milk. In these cases Kerley advises that a weak meat broth or an albumin water be used as a diluent instead of boiled water, thus increasing the amount of the proteid and rendering it more valuable as a food. The deficiency in the fat may in many cases be supplemented by an emulsion of cod-liver oil.

Patented Food.—When for any reason failure has attended the attempt to feed an infant on cows' milk more or less modified, there is with many parents a strong inclination to resort to one of the numerous patent artificial foods placed before the public by interested agents who loudly vaunt their own special preparations as the exact analogue of mother's milk and the only food calculated to help the infant in its dire distress. We cannot deny that many of these foods have met with much popular favor and that some of them have proved of occasional service. It seems desirable, therefore, that the physician should have a knowledge of their physical properties and their composition further than the meagre and often incorrect statements contained in their advertisements. In almost all these foods dependence is put, for the greater part of the nourishment supplied, on milk which is either added by the user or previously introduced by the manufacturer. They are therefore to be regarded as modifications of cows' milk; a fact which may explain the apparently successful results which sometimes attend their employment.

With the exception of those which contain the milk in a condensed form, all, if administered alone, show a great deficiency in many of the most important ingredients of an infant food, and especially in the element of fat. It is to be noted also that they are secret preparations, over which we as physicians can exercise no supervision or control in regard to the quality of the material or to the amount of care used in their manufacture; that analyses made by many able chemists have given very variable results, often differing widely from the manufacturer's published composition; that they are liable to be old and musty; and that for the poorer classes they are an expensive food. To the analyses of Dr. Leeds we are principally indebted for a knowledge of their more exact composition. He grouped them into three classes. The first class contains the farinaceous foods prepared from the flour of one or more of the cereals, with the starch to some extent modified by baking. All of them, therefore, add a large proportion of starch to the milk dilution, and for this reason are not suitable for infants under six months. They are all liable to deterioration through long keeping. Among the best known of this class are the following: Imperial Granum, Blair's Wheat, Hubbell's Wheat, Hard's Food, Ridge's Food, and Robinson's Patent Barley.

In a second class are placed all those in which the starch is almost entirely converted into a mixture of dextrin, dextrose, and maltose, with a small amount of cane sugar. These foods have in some instances a distinctly laxative action, and may sometimes be of service when the infant is of a constipated habit. The principal foods of this class are Mellin's, Horlick's, and Malted Milk.

A third class comprises those foods to which the milk has already been added during the process of manufacture. All of them contain starch in considerable quantities, to a small extent only converted into dextrose. Their mode of preparation insures more or less complete sterilization of the milk, an important advantage during the summer season. Nestlé's Food, American Swiss, and Gerber's are examples of this class.

An additional class may be made of miscellaneous foods recently introduced, which do not conveniently fall under any one of these divisions, but which may be regarded as to some extent a combination of them. Carnrick's Soluble Food and Allen & Hanbury's Infant Food are examples of this class.

The following table of analyses, copied from Holt, represents the composition of several of these foods when prepared as directed for the infant's use:

INFANT FOODS DILUTED WITH WATER TO COMPARE WITH MILK.

	Breast milk. Per cent.	Condensed milk diluted 6 times. Per cent.	Mellin's food. Per cent.	Malted milk. Per cent.	Nestlé's food. Per cent.	Ridge's food. Per cent.	Imperial Granum. Per cent.	Carnrick's soluble food. Per cent.
Fat	4.00	0.99	0.04	0.39	0.76	0.16	0.14	1.12
Proteids	1.50	1.20	1.50	2.28	1.54	1.67	1.98	1.35
Soluble carbohydrates (sugar)	7.00	7.23	11.56	10.18	6.38	.41	.25	4.06
Insoluble carbohydrates (starch)	.....	......	.....	.....	4.19	10.91	10.65	5.61
Inorganic salts	.20	.17	.45	.50	.24	.07	.06	.56
Water	87.30	90.41	86.45	86.65	86.89	86.78	86.92	87.30

Amount to be Given.—Not only is the character and composition of the food itself of importance, but the amount to be given and the times of giving it demand the physician's careful attention. As Biedert remarks: the infant has no instinct which guards against over-feeding. Even breast-fed children are apt to drink too much, but those artificially fed have a greater tendency to excess, since in general they obtain their food more quickly and with less exertion on their part. The truth should be carefully impressed upon mother and nurse, that a bottle-fed infant thrives best upon the minimum amount of food necessary for good development; excess tends to interfere with digestion, and thus unfavorably affects nutrition.

Dr. Rotch quotes the results of Smitkin's investigations at the Children's Hospital in St. Petersburg, to determine the amount that should be given during the first few weeks of life. He finds that the greater the weight the greater is the gastric capacity, and says that one-one-hundredth of the initial weight of the infant should be taken as the starting figure for each meal, and to this should be added 1 gm. for each day of life.

Illustrations of above rule to serve as guides for especially difficult cases.

Initial weight.	Each feeding.		
	Early days.	At 15 days.	At 30 days.
3,000 gm	30 gm. = (about ℥ i.).	30 + 15 = 45 gm. (about ℥ iss.).	30 + 30 = 60 gm. (about ℥ ij.).
4,500 gm	45 gm. = (about ℥ iss.).	45 + 15 = 60 gm. (about ℥ ij.).	45 + 30 = 75 gm. (about ℥ iiss.).
6,000 gm	60 gm. = (about ℥ ij.).	60 + 15 = 75 gm. (about ℥ iiss.).	60 + 30 = 90 gm. (about ℥ iij.).

The following table (from Rotch) will afford an indication, for an average infant, of the amount to be given at each feeding and the number of feedings which should take place in the twenty-four hours:

GENERAL RULES FOR FEEDING DURING THE FIRST YEAR. (Rotch.)
(The Day feedings are supposed to begin at 6 A.M. and to end at 10 P.M.)

Age.	Intervals in hours.	Number of feedings in in 24 hours.	Number of night feedings.	Amount at each feeding. Ounces.	Total amount in 24 hours. Ounces.
One week	2	10	1	1	10
Two weeks	2	10	1	1½	15
Four weeks	2	9	1	2½	22½
Six weeks	2½	8	1	3	24
Eight weeks	2½	8	1	3¼	26
Three months	2½	7	0	4	28
Four months	2½	7	0	4½	31½
Five months	3	6	0	5½	33
Six months	3	6	0	5¾	34½
Seven months	3	6	0	6¼	37½
Eight months	3	6	0	7	42
Nine months	3	6	0	7	42
Ten months	3	5	0	8½	42½
Eleven months	3	5	0	8¾	43¾
Twelve months	3	5	0	9	45

Very rarely, in the cases of immature and very sickly babies and of infants with cleft palate, the ordinary feeding-bottle is ineffectual, owing to the infants not having power to suck. Feeding by spoon is slow and wearisome to the infant. In these cases Dr. Jacobi recommends the use of Soltmann's *biberon pompe.* In this feeding-bottle simple pressure on the mouthpiece, either by the lips or gums of the infant, or on the expanded portion of the tube outside the bottle by the fingers of the nurse, will cause the food to escape from the bottle. Dr. Jacobi says that in many cases it has done good service. Dr. Rotch recommends the use of a glass cylinder, graduated and capable of holding nine drachms. One end gradually tapers till a small nipple can be fitted on to it; the upper end is covered by a compressible rubber bulb. By gentle compression of this bulb the food may be slowly forced into the infant's throat without any effort on its part.

This method appears to be specially desirable in the case of a weak infant, as it involves no loss of strength.

Gavage.—Some years ago Dr. Tarnier, of Paris, advocated the method of gavage in infants prematurely born or in such as are congenitally weak. The apparatus necessary for the purpose is very simple: a soft-rubber catheter, No. 14 or 15 French, or a piece of gutta-percha tubing with a small glass receptacle, of sufficient size to hold the amount of milk to be administered, attached to the distal end. The child is placed on the knee of the nurse with its head slightly raised. The tube is moistened with milk and introduced at the base of the tongue and then very gently forced down the œsophagus to a distance of 15 cm. The sound is then pinched between the two fingers and the food is introduced into the receptacle. On relaxing the fingers and raising the receptacle the food flows gently into the stomach. Care must be taken to remove the tube gently and quickly; the infant must then be replaced in its warm cradle or couveuse. To the weakest infants 8 gm. of food are given every hour. In spite of this feeding the infant frequently loses weight for the first few days, but soon begins to gain steadily. Dr. Tarnier claims to have achieved marvellous results by this method.

Alexander D. Blackader.

INFARCTION.—(*Infarcio*, to fill in, to stuff into.) The act of plugging up or filling up; also the organ or tissue which is filled with blood, fluid, or other substances. The development of the various meanings of infarction forms a very interesting chapter in the history of medical terminology. Originally used as a designation for the Galenic teaching of the black bile as the cause of melancholia and hypochondria, *infarctus* gradually came to mean a stoppage of the intestinal canal either through hardened fæcal matter or through precipitations from the blood into the intestinal canal. Later, the idea included also obstruction in the blood and lymph vessels and the ducts of glands. The theory of intestinal infarctus as the cause of hypochondria, melancholia, hemorrhoids, and other conditions reached the height of its development in the latter half of the eighteenth century under the influence of the two Kämpfs, father and son. By them the doctrine was reduced to what was considered to be a scientific basis, the infarcts were obtained for examination by means of injections, and were classified according to symptoms, location, and composition. Their treatment by clysters attained an extraordinary degree of popularity. The abuse of this treatment and the advancement of knowledge of the anatomy and physiology of the gastro-intestinal tract brought about the natural death of the doctrine during the early part of the last century. As outgrowths from the early idea of infarctus were such usages as the following: *infarction of humors*, a term formerly applied to ulcers whose base and borders were infiltrated; *infarctus mammæ lacteus*, the collection of coagulated milk in the ducts of the mammary gland; *infarctus lactei extremitatum*, applied to phlegmasia dolens because it was supposed to be caused by metastasis of the milk to the legs; *infarctus uteri*, applied to a variety of diseased conditions of this organ; etc. The term infarction was also formerly used clinically to indicate a sense of fulness or oppression in the chest. The enlarged spleen in chronic malaria was called *infarctus lienis*. The old meaning of intestinal obstruction still survives in the expression *infarcted hernia*.

At present infarction is unfortunately used as a designation for two classes of pathological conditions essentially different in kind: 1. The infiltration of the tubules or tissue spaces of an organ with blood, blood pigment, uric acid or urates, calcium salts, etc. 2. The anæmic necrosis of an organ or tissue due to an obstruction of its nutrient artery by embolism or thrombosis. The different processes are usually distinguished by some modifying term, as uric-acid infarction, anæmic or hemorrhagic infarction, etc.; but when used without such the term is usually narrowed to the second meaning.

1. Uric-acid Infarction.—In the kidneys of the new-born there is almost always present in the medullary pyramids a number of glistening, golden, or orange-red lines converging to the papillæ. These lines are easily scraped away with the knife and form a glistening orange powder on the moist surface of the organ. On microscopical examination the straight tubules are found to be filled with dark semitranslucent masses which dissolve on treatment with acetic acid, leaving behind an albuminous stroma. From the solution uric-acid crystals are formed. The epithelium of the tubules shows little or no change. The condition is known as the uric-acid infarct of the new-born, and was at one time supposed to be of medico-legal value as occurring only in infants who have breathed; but similar infarcts have been found in the kidneys of still-born children and in the fœtus. In one case of ectopic gestation seen by the writer the kidneys presented an extensive degree of this condition. According to Spiegelberg, uric-acid infarct is present in only one-half of the children examined, being most marked after the second or third day after birth. The condition may persist until the seventy-sixth day, but usually disappears early. When persistent, it may give rise to nephritis or cause uræmia by the simple obstruction of the tubules. Neither the origin nor the significance of the condition is known. The change of metabolism following the establishment of pulmonary oxygenation, the slight degree of oxidation processes in the new-born, lack of ability on the part of the urine to dissolve the uric acid, are among the causes adduced in explanation, but no one of these is adequately supported. Uric-acid and sodium-urate infarcts occur also in the adult kidney in cases of gout or the so-called uric-acid diathesis. The appearances are similar to those in the new-born, but the condition is rarely so extensive. More frequently, scattered concretions are formed in dilated tubules.

Calcium Infarcts, Chalk Infarcts.—In senile kidneys, in osteomalacia and other destructive diseases of bone, in cases of poisoning with mercuric chloride, phosphorus, aloin, bismuth, etc., extensive deposits of lime salts, phosphates or carbonates, may occur in the tubules, the deposit taking place either in or upon the necrotic epithelium of the tubules. When visible to the naked eye, such deposits appear as opaque whitish or yellow streaks corresponding to the tubules, or as minute dots representing the glomeruli. Microsopically the deposits give the specific staining reaction with hæmatoxylin. Calcium-oxalate infarction occurs rarely as the result of ingestion of food containing large amounts of oxalic acid or in cases of disturbed metabolism. White streaks occur in the pyramids similar to those of phosphate infarction, but are distinguished from the latter by their insolubility in dilute acids.

Bilirubin Infarct.—In cases of chronic obstructive jaundice the collecting tubules of the kidney usually contain large numbers of bile-pigment casts. In tissue fixed with alcohol these appear as yellow or brown streaks in the cut surface of the medullary pyramids; in mercuric chloride fixation they have a bright green color. Uric-acid infarction is not infrequently combined with this condition, particularly in cases of icterus neonatorum.

Hæmatoidin Infarct.—In cases of hæmoglobinuria, hæmoglobinæmia, and methæmoglobinæmia, due to poisoning, infections, extensive burns, etc., large quantities of blood pigment may be found in the kidney tubules in the form of brownish casts or irregular masses. The pyramids show radiating yellow or reddish-brown striæ. Usually the pigment does not give the iron reaction, and is therefore to be classed with the hæmatoidin group. Very rarely hæmosiderin infarction occurs.

Melanin Infarct.—Very rarely in cases of extensive metastasis of melanotic sarcomata large quantities of melanin are said to be excreted through the kidneys. In such cases melanin casts are found in the tubules. It is doubtful, however, if the brownish casts described as occurring in these cases were composed of melanin; it is more likely that they were formed of blood pigment.

2. Anæmic and Hemorrhagic Infarction.—The occlusion of a terminal artery by embolism or thrombosis leads to an anæmic necrosis of the part supplied by the

obstructed vessel. In the case of end-arteries having very slight collateral anastomosis the dead area remains anæmic (anæmic or white infarct); in situations where the end-arteries possess sufficient anastomosis to admit of the flow of blood into the affected area from the neighboring terminals the dead area becomes hemorrhagic (hemorrhagic or red infarct). The anæmic variety is found in the spleen, kidneys, heart, brain, retina, and rarely in the liver; the hemorrhagic infarct occurs only in the lungs and the area supplied by the superior mesenteric artery, very rarely in the uterus. Hemorrhagic infarction of the suprarenal has recently been reported.

Infarcts are usually found at the periphery of organs where they form cone- or wedge-shaped areas, the base toward the surface of the organ, the apex pointing inward. They may be single or multiple. As the result of the occlusion of a number of neighboring arterioles they are occasionally very irregular in outline. When recent, the anæmic infarct is opaque, yellowish-white, slightly elevated, and somewhat firmer than normal tissue. A peripheral red zone is almost always present. Older infarcts are usually depressed and softer; in the case of those of large size there is usually a central softening. If organization of the dead area has begun the consistence may be firm. On microscopical examination the cells of the infarcted area show a simple or coagulation necrosis. In older infarcts liquefaction necrosis may be present. The red peripheral zone is found to be due to a narrow line of hemorrhage and congestion surrounding the dead area and may be explained as being of the nature of a hemorrhagic infarct in the zone of collateral anastomosis with the neighboring end-arteries. In later stages this zone usually becomes the seat of a leucocyte infiltration and fibroblastic proliferation. The hemorrhagic infarcts are deep red in color, occasionally pale in very anæmic individuals. They are usually much firmer than the anæmic variety. As they become older they grow lighter in color, and softer if liquefaction necrosis occurs. If organization takes place without softening the infarcted area becomes lighter and firmer. The contraction of the newly formed connective tissue leads to depressions on the surface of organs in the case of both anæmic and hemorrhagic infarcts. On microscopical examination the hemorrhagic infarct is found to consist of an area of necrotic tissue, the spaces of which are filled with extravasated blood. It is in fact only an anæmic infarct which has become hemorrhagic. The term hemorrhagic infarction is applied also to the occurrence of simple hemorrhage in tissues; in the case of the kidney to the hemorrhage produced by obstruction of the renal veins. It would be better to drop entirely this confusing use of the term and restrict its application to the true anæmic and hemorrhagic-anæmic necroses produced by arterial obstruction.

Various theories have been offered in explanation of the fact that infarcts in one case are anæmic and in another hemorrhagic. It is held by some that the anæmic infarct is but a later stage of the hemorrhagic, produced by the removal of the blood pigment from the latter. Old hemorrhagic infarcts are not infrequently lighter in color for this reason, but the fact remains that anæmic infarcts are non-hemorrhagic from the beginning except for the small peripheral zone of hemorrhagic infarction surrounding them. The true explanation is probably to be found in the character of the collateral anastomosis of the affected vessels, as well as in local and general conditions of the circulation. Where there is rich anastomosis, as in the lung and mesentery, the obstruction of an end-artery leads to a temporary anæmia which lowers the vitality of the tissue supplied by the obstructed vessel; later, an inflow from the collaterals takes place, but the damaged condition of the vessel walls in the anæmic area leads to extravasation, chiefly by diapedesis, but also by rhexis. The infiltration of the tissue spaces thus produced leads to further damage of the part. Very rarely the local or general conditions of blood pressure may be such in organs in which hemorrhagic infarcts are usually produced that but little blood flows into the anæmic area and the resulting infarct is pale in color. The anæmic infarct occurs in organs whose end-arteries have but little anastomosis, so that no inflow takes place into the anæmic area except just at the periphery, where a narrow zone of hemorrhagic infarct is formed. In cases of extreme local or general congestion this peripheral zone of hemorrhage may be greatly broadened, or in the case of small infarcts the entire area may become hemorrhagic. The inflow of blood is usually under such slight pressure that the integrity of the part cannot be maintained.

Under ordinary conditions the infarcts of the brain are always of the anæmic variety, with more or less peripheral hemorrhage. Liquefaction of the affected area takes place, and if death does not result brain cysts may be formed. Occlusion of the coronary arteries by thrombosis, embolism, or sclerotic changes in the vessel walls produces anæmic infarction of the myocardium, attended by more or less hemorrhage. The infarcts of the kidney and spleen are almost always of the anæmic variety with a narrow zone of hemorrhage. True anæmic infarcts of the liver are very rare. In the normal lung the obstruction of a terminal artery will not produce infarction owing to the rich anastomosis. In conditions in which the pulmonary circulation is already embarrassed, as in the passive congestion of mitral disease, embolism or thrombosis of the pulmonary arteries is quickly followed by infarction. This is practically always of the hemorrhagic variety except in very rare cases, due to extreme weakness of the circulation. The conditions in the superior mesenteric artery are similar to those in the lungs, but inasmuch as the anastomosis is not sufficient to re-establish the circulation after occlusion, obstruction of the terminals of this artery leads more quickly to infarction than in the case of the pulmonary arteries. According to Chiari, bilateral embolism of the hypogastric arteries or bilateral thrombosis of the uterine veins is followed by hemorrhagic infarction of the uterus.

The sequelæ of infarction are: absorption of the necrotic tissues, organization, scar formation, calcification, cyst formation, encapsulation, abscess, or gangrene. In cases of infective embolism suppuration of the infarcted area usually occurs (septic infarct), or the infarct may be secondarily infected by pyogenetic organisms. Infarction of the lungs is frequently followed by moist gangrene, infarction of the intestine almost always. (See *Heart*, *Kidneys*, etc.) *Aldred Scott Warthin.*

INFECTION.—Probably one of the most universally known facts respecting bacteria is that they are related to the development of certain pathological processes; but it should be clearly held in mind that many play a very beneficent part in nature, chiefly by decomposing dead organic material and thus forming other chemical compounds which may be utilized for food by other plants and animals. It has been seen, in the article on *Bacteria*, that micro-organisms are widely distributed in air, soil, and water; and it is among the habitations of man, where the conditions for their growth and multiplication are specially suitable, that they are most numerous. So far as we know, with few exceptions micro-organisms whose natural habitat is in the soil, air, or water are not under usual conditions harmful to man, for they are invariably present in greater or less numbers in the mouth, nose, upper respiratory passage, gastro-intestinal tract, and on the surfaces of the skin, where they are more or less constantly brought by the respired air, by food and drink, and in many other ways. Notwithstanding, however, their occurrence in these situations in great numbers, they do not often gain entrance into the body tissues, so that under normal conditions the blood and viscera are germ-free.*

Although the cutaneous and mucous surfaces of the body are covered with many micro-organisms, these are for the most part harmless, sometimes serving useful functions, as do those in the intestines. Whenever they find their way into the body, conditions are so unsuitable for their existence that they are soon destroyed. Against such incursions the body is guarded in various ways. Among the protective agencies may be mentioned the epithelial investments of the skin and mucous membranes, which so long as they are intact protect the interior from bacterial invasion. Moreover, the germicidal qualities of some of the body fluids and cells also afford important protection. But notwithstanding these protective factors bacteria do sometimes enter, and this may especially occur whenever the skin or mucous membranes are injured, even if ever so slightly so.* Within recent years the entrance of bacteria through the bites of insects has been especially studied.†

---

* For a consideration of the bacterial flora of the body surfaces consult Welch: "Surgical Bacteriology." "System of Surgery by American Authors," edited by Dennis.

Among those gaining entrance into the body, there are some which may under suitable conditions induce phenomena by which disease is characterized. These are the micro-organisms which induce infectious diseases and which we habitually refer to as being pathogenic bacteria. The term pathogenic is, however, a relative one—a fact which should be clearly held in mind for the following reasons: First, an organism quite harmless to one animal may be capable of inducing disease in another; second, an organism which under ordinary conditions is harmless may under special conditions give rise to serious lesions; third, many organisms generally regarded as harmless under special conditions may prove injurious. Thus it is evident from what has been said that infectious disease cannot exist without the presence in the body of living micro-organisms. But, on the other hand, the mere entrance of bacteria into the tissues is not sufficient to constitute infection, for it has been seen that many bacteria are harmless and that the body possesses important safeguards whereby bacteria are destroyed and disposed of. Whether the micro-organism possess pathogenic activity or not will depend largely upon the host and also upon its own variable nature and qualities.

This relationship of host and bacterial excitant has been so admirably stated by Prudden that one can do no better than quote the following:

"In the study of the infectious diseases it is especially important to bear in mind that the abnormal processes through which the disturbances incited by micro-organisms are manifested are processes of the body cells and not processes of the micro-organisms. The micro-organisms do indeed incite the train of phenomena by which the disease is manifested, and the nature or 'species' of the micro-organism may largely influence the character of the phenomena; but the stored-up energy which is released in this manifestation is body-cell energy and not that of microbic metabolism. The microbes are excitants of disease, but the disease is a performance of the body cells. If these obvious considerations be held in view, it will be convenient in considering certain of the infectious diseases to use the familiar and much-abused term 'specific' as indicative of those phases of abnormal body cell performance which are apt to occur in characteristic ways in response to special forms of microbic stimulus. Thus the poisonous substances which the tubercle bacillus build up out of the organic material upon which it feeds are in part such as exert a peculiar influence upon connective-tissue cells, leading to their proliferation and the temporary formation of new tissue—the tubercle. This, together with associated action of the same or other metabolic products of the living bacillus, forms a group of lesions and disturbances which is characteristic of the action of the tubercle bacillus in the body. In this sense tuberculosis is a 'specific' disease. On the other hand, the poisons eliminated by the tubercle bacillus may incite responses on the part of the body cells which are practically identical with those which many other toxic substances, both of bacterial and of other origin, induce—fever, degeneration, etc. These manifestations of the action of the tubercle bacillus upon the living body cells are not 'specific.'"

The Bacterial Excitant.—The reaction of the body cells in infection bears a more or less constant relation to the virulence of the infecting micro-organism and to the number of bacteria gaining entrance into the tissues. The virulence varies considerably under different conditions, and according as these variations are small or great different phenomena will develop within the body. The character of the processes induced will necessarily vary according to the virulence of the infecting bacterium; and this largely depends upon its environment, which may not only modify its morphological characters, but also may change its physiological activities. For example, the Bacillus coli communis as normally found in the intestines is of very low virulence and is not capable of inciting pathological processes, but so soon as its physiological activities are modified by changes in its environment, its virulence is apt to be very much increased. This influence of environment is also well shown by the modifications which may occur in the vital activity of an organism when it finds its habitat in new and unnatural hosts. This point is especially well demonstrated with the mammalian tubercle bacillus, which when transmitted for a long time through another animal host, as birds, will ultimately lose its virulence for the host from which it was originally derived.

As a rule, bacteria lose their virulence with greater or less readiness when cultivated in artificial media. On the other hand, successive passages of a pathogenic organism through susceptible animals exalt its virulence. Thus a streptococcus of attenuated virulence may be exalted a hundredfold by successive inoculations into rabbits.

Differences in the virulence of bacteria often suffice to explain differences in the clinical and morphological types of disease. It is well known that under some conditions an organism of low virulence will incite rather mild reactions of the body cells, whereas under other conditions, when the virulence of the same organism is exalted, the effects are both more marked in severity and in extent of the lesions. Thus I have been able to follow these variations in virulence in the different forms of tuberculosis. For example, in scrofulous lymphadenitis, I have found that the tubercle bacilli which induce this lesion were usually of low virulence, whereas the tubercle bacilli inducing acute miliary tuberculosis are on the other hand of extraordinary pathogenic activity.

The number of micro-organisms which gain entrance into the body is also a factor which modifies the character and extent of the cellular reactions. Within certain limitations the healthy body may dispose without apparent injury of a certain number of given virulence, but when the same organism is introduced in large quantities infection follows. In susceptible animals probably so small a number as one or two anthrax bacilli may incite disease. Usually, however, much larger numbers are necessary for the development of an infection. Further, according to the portal of entry, the number may be increased or diminished. Thus a given dose of bacteria, which when injected into the subcutaneous tissues of an animal may prove quite harmless, will incite, when the same dose is introduced intravenously or into the peritoneal cavity, well-marked disease to follow.

The Host.—This is a factor of the very greatest importance in the consideration of infection in its numerous aspects. It is, of course, well known that certain bacteria will induce infections only in certain species of animals, proving absolutely innocuous for other species. Thus, while the anthrax bacillus usually induces lesions with the greatest readiness in many animals, others, like the white rat, are ordinarily insusceptible to inoculation with these bacilli, unless very large amounts are given or special factors be brought into play. Some diseases are especially peculiar to man, such as typhoid fever, syphilis, leprosy, scarlet fever, measles, etc., these diseases never occurring naturally in other animals. The race and individual peculiarities are also factors which modify the liability to infection. Thus negroes are generally insusceptible to yellow fever, whereas other human beings are quite susceptible to the pathogenic agent of this disease. The influence of age is so well known that investigators commonly make use of this knowledge in their experimental work. It may be stated as a rule that young animals are much more readily infected than older and larger ones. Age as a predisposing factor to infection is well illustrated by the curve of frequency of infectious diseases in man, the maximum point occurring among children. Sex is also sometimes a factor predisposing to infectious disease, although this is not so apparent among animals as it is among human beings. Numerous other conditions affecting the physiological integrity of the body are also predisposing influences for infection. The influence of fatigue, starvation, cold and heat, and loss of blood have been particularly studied from the experimental point of view, the results very conclusively proving that a marked susceptibility to infection is developed.

---

* The view has been recently advanced that with no apparent lesion of the intestinal mucosa, bacteria in large numbers may gain access through this to the liver under what seems to be perfectly normal conditions (Adami: Jour. of the American Medical Association, December 16th and 23d, 1899).

† For a consideration of the rôle of insects in the transmission of disease consult Nuttall: Johns Hopkins Hospital Report, 1900, vol. viii.

Animals which are normally insusceptible to anthrax, such as white rats, may be made vulnerable by fatigue. Thus Charrin and Roger have shown that if white rats be made to work a treadmill until thoroughly fatigued, and be then inoculated with anthrax bacilli, they succumb to the lesions of anthrax infection.

Canalis and Morpurgo have shown that starvation also interferes with the natural resistance of animals to bacterial infection. These observers studied this phase of the subject with pigeons, which are also naturally resistant against anthrax. By starving these animals, either before or just following inoculation, they are made extremely susceptible to the influence of the inoculated organism. These experiments have been repeated time and again with other animals, especially by Pernice and Alessi.

The influence of exposure to heat, cold, and moisture has been similarly investigated by Pasteur, Petruschky, and others. Long ago Pasteur showed that by immersing a hen in cold water it loses its natural immunity to anthrax. Frogs, if kept at a temperature (25°–35° C.) higher than is normal for them, will easily succumb to anthrax infection; and guinea-pigs and white mice, which are resistant to fowl tuberculosis, can be made susceptible by keeping them after inoculation in a warm chamber at 43°–45° C.

Any injury to the body tissues also favors the lodgment and activity of whatever bacteria may reach the affected area. It is a well-known clinical fact that tuberculosis of bones and joints of children often follows different forms of trauma. Rosenbach demonstrated this predisposition of damaged tissues to bacterial invasion by traumatizing one of the heart valves and then injecting cultures of the staphylococcus. Malignant endocarditis almost invariably followed, whereas in the control animals in which the valves had not been injured no lesions of endocarditis were found.

Other factors have also been well investigated, such as the action of chemical substances and unsuitable diet, the latter especially by Hankin, who fed refractory rats on sour milk and bread. Such treatment made the animals extemely susceptible to anthrax infection. Leo administered phloridzin in small doses, and reached the conclusion that it markedly predisposed the animals to bacterial infection. There are still other special influences which may more or less modify the conditions in the development of infection. The removal of certain organs, such as the removal of the pancreas from pigeons for example, will make the body tissues more susceptible than they would otherwise be to the infection. Animals kept in dark and damp places also exhibit marked susceptibility as compared with those living in light and airy localities. Trudeau has conclusively established that rabbits kept in places in which no light penetrates contract tuberculosis more readily than others kept in a more healthful environment.

Portals of Entry of Bacteria.—Bacteria may gain entrance into the body tissues through several different ways, and according to the portal of entry differences not only in the susceptibility of the animals but also in the lesions and symptoms of the disease will be noted. For the most part micro-organisms reach the interior of the body from the skin and mucous surfaces. It is very improbable that bacteria present upon the skin can penetrate this tissue when uninjured. It is true, however, that very often they seem to reach the interior of the body from what seems to be an uninjured skin surface, but in these cases it is probable that the skin injury has been overlooked on account of its smallness. Attention has already been called to the fact that bacterial agents may be communicated through the bites of different insects. Thus it is now a well-established fact that the malarial parasite is transmitted through the bite of the mosquito; and the same is probably true for yellow fever. The mucous membranes of the respiratory and alimentary tracts are frequently portals of entry for micro-organisms which have been carried by the air and water and foods. The mucous membrane of the urogenital tract is less frequently a portal of entry. Other mucous surfaces, such as the conjunctiva, may also under special conditions be points of entry for different pathogenic bacteria. It is only very rarely that bacteria directly gain entrance into the general blood current; they ordinarily reach it through the sources which have been mentioned.

Animal experiments clearly show that the portal of entry and channel of infection bear a more or less direct relation to the severity of the infection which follows. Subcutaneous inoculations in animals are usually much less severe in their results than those made directly into the peritoneal cavity or general vascular system.

Action of Bacteria and Their Products in the Body.—Micro-organisms induce their bad effects in several ways, but chiefly by their presence in the tissues and development of their poisonous products, which either affect the physiological activity of the cell or kill the cell outright. These poisonous products act generally or locally in varying degree, according to the nature and quantity of the product formed. These toxic substances become diffused through the system, and their effects are manifested clinically by the occurrence of fever or disturbances in the functions of the respiratory and nervous systems. In some cases changes are found in the local tissues directly involved. The general effects of bacterial poisons may be so slight as to be regarded of little importance, as in the case of a local inflammation, for example; or they may be very intense, as in tetanus and diphtheria. These results are largely directly attributable to the poisons of the bacteria, rather than to the presence of the organisms themselves. In infectious diseases both factors are prominent features, the toxic side being usually more conspicuous.

In diseases like tetanus and diphtheria it is usually only in the local lesion that the bacilli are found. The profound systemic intoxication is accomplished by absorption of the highly toxic products from the local lesion.

Whenever there is a widespread distribution of pathogenic bacteria in the blood the condition is designated septicæmia; and if associated with multiple foci of pus formation the term pyæmia is applied. The body which is already the seat of infectious disease is much more susceptible to the invasion by other bacteria; thus mixed or concurrent infections are often established, as in tuberculosis of the lungs with cavity formation. In addition to the tubercle bacillus there may usually be found in such lungs pyogenic (pus excitants) bacteria. Individuals the victims of long-standing chronic diseases, such as those of the heart, lungs, kidneys, and liver, often succumb to infectious diseases of one kind or another. The phrase "terminal infection" has been applied by Osler to these infectious diseases.

Communicability of Infectious Disease.—Considered in its practical relations, the subject of the communicability of infectious disease is one of the very highest interest and importance. It has been already pointed out that some infectious diseases, like syphilis, cannot be communicated to animals. On the other hand, some of the infectious diseases of animals are not communicable to man. But certain other infectious diseases, like tuberculosis, are readily transmitted to either man or animals.

The infectious diseases of man may be divided into two great classes: first, those which under usual conditions are communicable; and second, those which under usual conditions are very communicable. Among those of the second class there exist the greatest differences in the liability to transmission. It is well known how readily the excitants of smallpox and scarlatina are given off from the patients under conditions which make their transmission from one person to another an easy matter. In diseases like syphilis and hydrophobia, on the other hand, the excitant is transmitted only by direct inoculation. Between these extremes we have many gradations. It should be clearly borne in mind that a classification based on the communicability of a disease is not fundamental, but is closely dependent upon the sanitary conditions under which these diseases are observed.

Immunity.—Immunity is characterized by resistance to infection or its effects. The absence or loss of this capacity is known as susceptibility. Immunity from an infectious disease may be *hereditary*, or it may be *acquired*, either by an attack of the disease from which the individual has recovered—*natural immunization*—or by the introduction into the body of something which diminishes susceptibility—*artificial immunization*. Acquired immunity may be transmitted from parent to offspring.

Many of the infectious diseases confer greater or lesser immunity to subsequent attacks of the same disease, although there are some exceptions to this. A previous attack of erysipelas makes one more susceptible to subsequent infection with the streptococcus.

From the study of infection it is known that two distinct influences are evidently at play in enabling the body to resist infection. It has been clearly shown that the destruction of bacteria may in part be brought about by the leucocytes and other mesodermal cells, which when thus engaged are called phagocytes. In the body fluids there are also certain albuminous ingredients—alexins or "defensive proteids"—which have well-marked bactericidal properties.

Artificial immunization is generally accomplished by making the body tissues tolerant to the presence of bacteria or their poisons. This may be done by the introduction of attenuated micro-organisms or by the introduction of their poisons. The same result may be obtained by introducing the body fluids from an already immune individual.

This immunizing power is attributable to the development of "antitoxic substances" whose nature is still little understood. They seem to be closely related to the globulins.

It is not possible to determine to what extent the immunization effected is specific. In some cases it seems to be so; whereas in others this is less apparent.

August Jerome Lartigau.

INFILTRATIONS.—The collection of fluid or cells in the tissue spaces, and the deposit in or between the cells of substances abnormal in kind or quantity, are included in the comprehensive class of *pathological infiltrations*. The processes involved are of widely differing nature; each variety of infiltration being usually indicated by some modifying designation, *hemorrhagic, inflammatory, tuberculous, leukæmic, tissue infiltration*, etc. Without such specific designation infiltration is commonly taken to refer to the presence of some pathological substance in or about the cells, and is used as a synonym for pathological deposit. The infiltrated substance itself is also usually spoken of as an infiltration.

Fluid Infiltrations.—Œdema, non-inflammatory in origin, is sometimes spoken of as a hydropic or dropsical infiltration. As a result of injury to the bladder or urethra extravasation of urine into the surrounding tissues, particularly into the perineum, may occur (urinary infiltration). Extravasations of blood, lymph, milk, fæcal material, etc., are also styled infiltrations.

Inflammatory Infiltration.—This may be hemorrhagic, serous, fibrinous, or cellular in character. The collection of serous exudates in tissue spaces is usually spoken of as inflammatory œdema. Fibrinous infiltrations occur in diphtheritic inflammations and other forms of coagulation necrosis. The cellular infiltration of inflammation is for the chief part composed of leucocytes that have migrated from the blood-vessels. Wandering cells arising from proliferating tissue cells may also be found in it. Usually the leucocytes are of the polynuclear variety, but occasionally the infiltration is made up entirely of mononuclear forms. In some cases the cells of the infiltration are chiefly plasma cells; in other cases eosinophile or mast cells may be very numerous. The significance of these phenomena is as yet unknown. A leucocyte infiltration of moderate degree is usually spoken of as a small-celled infiltration; when the leucocytes are in large numbers as a purulent infiltration. (See *Inflammation* and *Exudations.*)

Leukæmic Infiltration.—An increase in the number of the leucocytes in the blood is attended by an increase in the number of the wandering cells in the tissue spaces. This increase is greatest in such organs as the liver and kidneys, and in the submucosa and mucosa of the gastro-intestinal tract. In leukæmia the accumulation of leucocytes in the interstitial tissue throughout the entire body may reach an enormous degree. The liver and kidneys become enlarged, firmer, and lighter in color as the result of such an infiltration. This may be diffuse, or circumscribed grayish-yellow areas of infiltration may occur throughout the organ (leukæmic nodes, lymphoma). The mucosa of the larynx may be infiltrated to such an extent as to give rise to symptoms of œdema of the glottis. In the intestine the swelling of the mucosa may be followed by ulceration. The variety of leucocyte present in the infiltration depends upon the kind of leukæmia, though in some cases of mononuclear leukæmia the proportion of polynuclear forms in the tissues far exceeds that in the blood. Proliferation of the migrated cells occurs, as shown by the occurrence of cell-division figures.

Tumor Infiltration.—The malignant neoplasms, carcinoma and sarcoma, invade adjacent tissues by extension through the tissue spaces in the direction of least resistance, usually through the lymph spaces. This process is styled growth by infiltration. Extension in this manner is always more marked in the case of carcinoma than in that of sarcoma. Around the infiltrating growth there is almost always present a zone of leucocyte infiltration as evidence of the inflammatory reaction produced by the development of the tumor. In many cases it is very difficult or impossible to distinguish between the leucocytes and the young tumor cells.

Tissue Infiltrations.—The term infiltration is very frequently used as a synonym for both pathological degenerations and deposits (albuminoid, hydropic, fatty, glycogenic, cholesterin, mucous, hyaline, amyloid, calcareous, uratic, and pigmentary infiltrations). Inasmuch as in the majority of these conditions the process is of the nature of a deposit in the affected tissue, the designation of pathological deposit seems preferable to that of infiltration. (See *Degeneration* and *Deposits.*)

Tuberculous Infiltration.—The confluence of small miliary tubercles may give rise to a diffuse tuberculous process, or the epithelioid tissue of tubercles may infiltrate into the neighboring tissues after the manner of a new growth. Both of these conditions are included under the head of tuberculous infiltration. The term gelatinous infiltration was used by Laënnec to designate the grayish-red fibrinous exudate filling up the lung alveoli in the neighborhood of tubercles.

Syphilitic Infiltration.—Circumscribed or diffuse gummatous processes affecting bone were formerly designated as gummatous infiltrations.

Parasitic Infiltration.—The presence of large numbers of bacteria in the tissue spaces, the occurrence of the filaria in the lymph spaces and vessels, the invasion of muscle by trichina, etc., are frequently designated as infiltrations.
